Preliminary observations showed that under conditions of favourable population distribution of primary afferent fibres in proximity to the stimulating electrode, the number of primary afferent fibres excited was linearly related with the intensity of the stimulation. Hence, the amplitude of the antidromic spike potential could be taken as a measure of the excitability of their central segments. Rectangular pulses (0·05 msec at 1·5–2/sec) were used at a strength of 1·2–1·8 times the threshold for the antidromic response. Because the ventral roots had been cut, the spike potential so produced in the muscle nerves was due only to impulses propagating antidromically along afferent fibres. Measurements of conduction velocity indicated that group Iα afferent fibres (120–80 m/sec) were involved in the antidromic response. The size of the triphasic spike potential was taken as a measure of the number of group Iα fibres excited by the stimulus.

During relaxed wakefulness, characterized by EEG desynchronization and tonic activity in the neck muscles, the group Iα antidromic response occurred after each stimulus and was rather regular in its amplitude. Slight fluctuations of these responses corresponding to standard deviations of the order of 10–12 per cent of the mean amplitude could be detected. During a spontaneous or induced orienting reaction the Iα antidromic volley changed in an unpredictable way. In most instances, however, a short-lasting increase in the antidromic spike occurred at the beginning of an induced arousal (Fig. 1, *A*, *B*, *C*; Fig. 2, *A*, *B*, *C*).

During transition from quiet waking to drowsiness or to synchronized sleep, there was no significant change in the mean amplitude and standard deviation of the Iα antidromic volley nor was there any significant change in these values found during the EEG spindles and the interspindle lulls.

The main change in excitability of the central terminals of the Iα afferent fibres occurred during desynchronized sleep. In this stage of sleep there was an increase in the mean amplitude of the Iα antidromic spike as compared with synchronized sleep. The mean value, however, never increased above 105–110 per cent of the mean amplitude

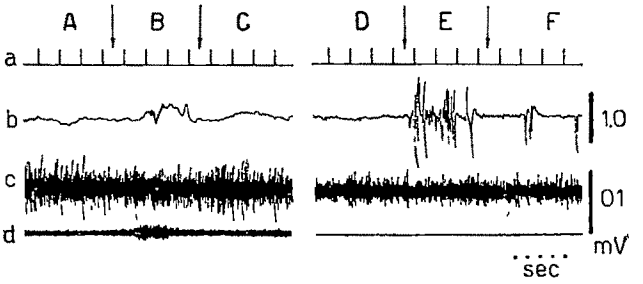

Fig. 1. Unrestrained, unanaesthetized cat Experiment made 2 days after chronic implantation of the electrodes and section of the ventral roots *L5–S2* on the left side. (*a*) Stimulus artefact by stimulating the left ventral horn at the upper level of *S1* with rectangular pulses at one every 1·7 sec, 0·05 msec duration and 1·62 times the threshold for the antidromic Iα volley recorded from left tibial nerve; (*b*) eye movements; (*c*) left parieto-occipital (EEG); (*d*) posterior cervical muscles (EMG). (*B*) Induced orienting reaction during drowsiness. (*E*) Burst of rapid eye movement during desynchronized sleep

observed during synchronized sleep. The increase in mean amplitude was also accompanied by an increase in the standard deviation (15–17 per cent of the mean amplitude). These changes cannot be considered as tonic in character because they were observed only when the episodes of desynchronized sleep were associated with large bursts of rapid eye movement. Abortive episodes of deep sleep, characterized by absence of ocular bursts, or episodes of deep sleep associated with ocular movements isolated or grouped in small bursts were not accompanied by any significant change in the mean amplitude of the antidromic volley. In the last cases only a slight increase in the standard deviation was observed.

An analysis of the relation between excitability changes of the Iα fibres and phasic events occurring during desynchronized sleep indicates that phasic increase of the antidromic volley appeared during the bursts of rapid eye movement (Fig. 1, *D*, *E*, *F*; Fig. 2, *D*, *E*, *F*), particularly when the bursts of ocular movements were rather intense. The phasic increase sometimes outlasted the period of rapid eye movement. The more intense the rapid eye movement burst, the more profound was the enhancement likely to be. The excitabilities of the Iα afferent fibres were then increased up to 110–140 per cent of the mean value observed during synchronized sleep both in tibial and deep peroneal nerves. Not every burst of rapid eye movement was associated with an increase in the antidromic Iα volley, and there were variations in antidromic Iα volley unrelated to the rapid eye movement.

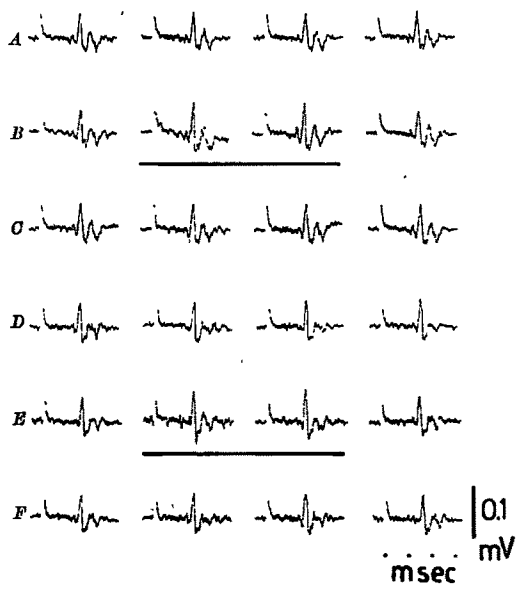

Fig. 2. Same animal as in Fig. 1, same experiment. The records show the antidromic volley of Iα afferent fibres recorded from left tibial nerve on stimulation of their central terminals. *A*, *B* and *C*, Before, during and after an orienting reaction (see *A*, *B* and *C* in Fig. 1). *D*, *E* and *F*, Before, during and after a burst of rapid eye movement (see *D*, *E* and *F* in Fig. 1). The horizontal lines indicate the enhanced responses during induced arousal (*B*) and during the burst of rapid eye movement (*E*)

Once the excitability of Iα muscle afferent fibres had been tested during physiological sleep, the animal was anaesthetized with 'Nembutal', paralysed with 'Flaxedil' and artificially respirated. By using the same stimulating and recording system utilized in the unrestrained cat, the excitability changes produced by maximal group I stimulation of the deep peroneal nerve on Iα fibres of the tibial nerve were measured. Fig. 3 shows the percentage increase in amplitude at the various intervals of the testing Iα antidromic volley in tibial nerve after conditioning by seven deep peroneal volleys, 1·6 msec apart. The time course of the excitability changes produced by the deep peroneal volleys in group Iα afferent fibres of the tibial nerve has a summit at a latency of 20–25 msec and a total duration of 300 msec, which is in agreement with previous observations[7]. The changes in excitability of the group Iα afferent fibres, produced by supraspinal volleys during the bursts of rapid eye movement, can therefore be related to similar effects produced on the same fibres by spinal afferent volleys (presynaptic inhibition)[7].

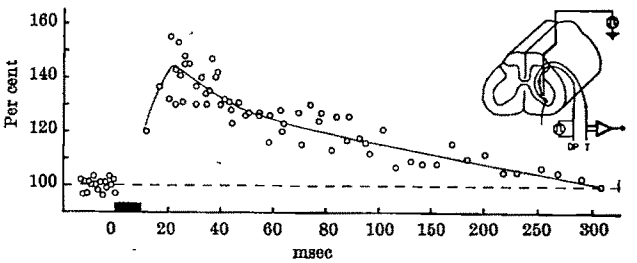

Fig. 3. Time course of excitability changes produced in group Iα afferent fibres. A stainless-steel microelectrode having a resistance of 600,000 Ω was chronically inserted into the motoneurone pool supplying the tibial nerve. After the analysis of the modulation during sleep of the Iα antidromic volley in tibial nerve was made in unrestrained cat, the animal was anaesthetized with 'Nembutal' and paralysed with 'Flaxedil'. The motoneurone pool was stimulated with single negative pulses of 0·05 msec duration, 2·4 times the threshold for the antidromic Iα volley. The testing stimulus was applied at various intervals after seven group I deep peroneal conditioning volleys, 1·6 msec apart. The size of the spike so produced at any test interval is matched against the control series in order to determine the percentage increase in excitability. Percentage increases are plotted as ordinates in the graph, against the conditioning intervals as abscissae. A diagrammatic illustration of the experimental arrangement is shown on the right side

It is postulated that the increase in excitability observed during desynchronized sleep is actually due to supraspinal influences exerting synaptic depolarizing action on terminals of group Iα primary afferents. These influences are phasic in nature and appear to be related with the large bursts of rapid eye movement. This phasic presynaptic inhibition may account for the striking depression of the homonymous monosynaptic reflex that occurs during the bursts of rapid eye movement[4].

Organ Preservation using Ultrabaric Oxygen

ONE of the problems in grafting borrowed organs between human subjects is to obtain an adequate supply of donor material. In some cases a transplant is made on the first sign of clinical death in the donor, a technique which requires considerable organization and great care with timing. A second approach is to obtain the donor organ from the victims of violence, such as motor-car accidents. The latter are probably the most frequent potential sources of donor material but suffer the great disadvantage that the scene of the accident may be remote from the centre at which the transplant is to be made, and the problem of maintaining life in the donor organ is an acute one. One method of maintaining vitality has been

to connect the suitably treated organ to a perfusion apparatus in which it is supplied with oxygenated blood until needed for use. The perfusion and associated cooling apparatus is complicated, expensive and unlikely to be available on any large scale, and for this reason one of us (A. D. B.) suggested that, in view of successful experiments in other fields of surgery with hyperbaric oxygen at a few atm. pressure, it might be worth trying the experiment of seeing whether greater tissue permeation and maintenance of vitality could be produced by the use of 'ultrabaric' oxygen—that is, oxygen at a pressure of some thousands of pounds per in.^{2}. The experiment has now been carried out.

The right and left kidneys were removed from a 19-kgm male dog. Both kidneys were placed within a pressure vessel connected to a source of high-pressure oxygen. The pressure within the vessel was increased to 1,950 lb./in.^{2} in 5 min. During the following 120 min the pressure fell to 1,450 lb./in.^{2} due to a slight leakage. Subsequent tests indicated that under similar conditions the bulk temperature of the kidneys was lowered to 23° C during the period of subjection to the decreasing high pressure. The lowering of the pressure from 1,450 lb./in.^{2} to atmospheric pressure was accomplished in 3 min. The right kidney was immediately preserved in formalin solution. The anastomoses between the recipient's right iliac and the donor's left renal vessels were completed in 29 min, giving a total ischaemia time of 165 min. The animal voided 30 c.c. of urine immediately after recovery from anaesthesia (the donor ureter having been implanted into the bladder). One day after the operation the creatinine level was 2·7 mg/100 c.c. and on the second day the blood urea nitrogen reached 140 mg/100 c.c., both being the maximum values attained. Prior to removal of the kidneys, the measured values of these quantities were 0·9 mg/100 c.c. and 40 mg/100 c.c. respectively. Intake and urinary output daily each varied within the range 400–1,300 c.c. Clinically, the condition of the dog at the time of killing on day 39 after operation was good. The blood urea nitrogen was 47 mg/100 c.c. and the creatinine level 1·6 mg/100 c.c. Microscopically, sections of both kidneys showed no parenchymatous damage apart from superficial patchy subcapsular atrophy and fibrosis in the autotransplanted kidney, which may have been secondary to surgical trauma.

The importance of this experiment lies in the fact that the apparatus needed to preserve the kidney over a period of ischaemia of 165 min consists merely of an oxygen cylinder and a suitable pressure jar in which the organ can be placed. No basic refrigeration equipment is needed, nor any elaborate pump. Pressurized oxygen is available in almost all ambulances at the present time and the pressure vessels can be constructed quite cheaply, especially if they become commonly used.

The really surprising thing about the foregoing experiment is that, because of the rapid lowering of pressure to atmospheric, the kidney effervesced and effectively suffered such explosive decompression that it might be expected to be irreparably damaged. Since this was not the case it would seem clear that the technique is promising. Further experiments to prolong the ischaemia time with improved renal function are in progress and will be reported in due course.

Pyrogens and Monoamine Oxidase Inhibitors

MANY nerve terminals within the hypothalamus contain either noradrenaline or 5-hydroxytryptamine (5-HT) (ref. 1). It has been suggested that these amines may play a part in the thermo-regulatory pathways[2–4].

In the cat, body temperature rises after intracranial injections of 5-hydroxytryptamine in the area of the hypothalamus[3]: in the rabbit, injections of noradrenaline have the same effect[4]. If liberation of these amines plays a part in temperature regulation, monoamine oxidase inhibitors might be expected to cause some abnormality of temperature regulation. For this reason we have examined the febrile response to intravenous injections of leucocyte pyrogen in rabbits pretreated with monoamine oxidase inhibitor (pargyline hydrochloride, Abbott, Ltd.).

Leucocyte pyrogen[5] was prepared and given, in doses of 0·25 ml. and 0·50 ml. intravenously, in two groups each of ten rabbits. The effect of an intravenous dose of 25 mg pargyline was assayed in a group of nine rabbits. The pyrogenic response to the two doses of leucocyte pyrogen was tested in the original groups of rabbits 90 min after they had received 25 mg pargyline intravenously. The responses to leucocyte pyrogen were measured again 3 weeks after the pargyline had been given.

In animals receiving the smaller dose of leucocyte pyrogen, pre-treatment with pargyline resulted in a fever initially similar to that following the control injections, but more prolonged; pargyline given without pyrogen caused a small slow temperature rise, averaging 0·3° C 4 h after injection. The time course of this effect may well account for the apparent prolongation of the fever curve in the animals given leucocyte pyrogen after pargyline.

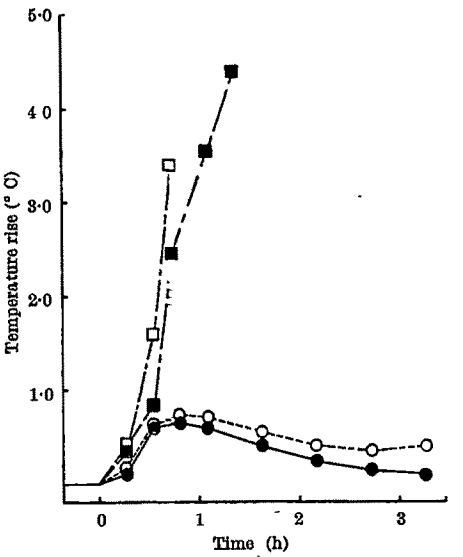

Fig. 1. Temperature responses to leucocyte pyrogen (0·5 ml.) with and without pargyline pretreatment. ● Mean response of ten rabbits receiving leucocyte pyrogen alone; ○, mean response of eight rabbits receiving leucocyte pyrogen after pretreatment with pargyline; ■ and □, responses of two rabbits which died with hyperpyrexia

With the larger dose of leucocyte pyrogen, pargyline caused a similar prolongation of fever in eight of the animals. The average temperature changes in these animals are shown in Fig. 1. In two animals there was a rapidly progressive temperature rise, and both died with rectal temperature above 44° C. This kind of response has not previously been observed by us in more than 200 animals receiving this dose of leucocyte pyrogen.

This hyperpyrexial response seemed to be related to the combined administration of pyrogen with a monoamine oxidase inhibitor, though we do not know why it should only have been manifest in two animals.

Previously the hypothesis that amines may be concerned in temperature regulation has depended on the observations that temperature changes are induced by injection of these substances into the hypothalamus. The observation that an amine oxidase inhibitor can modify a pyrogenic response in some animals is compatible with this hypothesis; though it is clearly unjustifiable to apply these findings directly to man, it seems possible that febrile illnesses might be modified in some patients receiving monoamine oxidase inhibitors.

Lipotropic Effect of Cold on Rat Liver

Sellers and You[1,2] have shown that the total liver lipids were decreased when rats were fed a hypolipotropic diet in a cold environment. Treadwell *et al.*[3] found that a cold environment exhibits a lipotropic effect on liver triglycerides of rats fed a high fat-cholesterol diet. This observation has also been confirmed on rabbits fed an atherogenic diet[4]. The aim of our experiments was to elucidate the mechanism of the lipotropic effect of cold.

White male rats (Wistar stock, weight 180–200 g) were fed *ad libitum* a high fat-cholesterol diet[5] for a period of 7–13 weeks. One group was kept at 22° C; a second group was exposed for 8 h daily to a temperature of 2° ± 1° C. Sodium acetate labelled with carbon-14 (40 μc. per 100 g body-weight) was injected intraperitoneally into the rats 3 h before they were decapitated. After isolation of the total fatty acids of the liver[6] their specific activity was determined. In all animals the concentration of esterified fatty acids[7] and glycogen[8] in the liver and the levels of free fatty acids in the blood serum and epididymal fat tissue were determined[9]. The same analyses were also performed on a group of white rats fed normal Larsen diet which were kept at room temperature. Each group consisted of ten to fifteen animals.

In the rats kept at room temperature, the feeding of high fat-cholesterol diet caused significant increase of the concentration of esterified fatty acids in the liver ($P < 0{\cdot}01$) and a pronounced decrease in liver glycogen ($P < 0{\cdot}001$). This effect of high fat-cholesterol diet was not found in the group kept at 2° C; the concentrations of liver esterified fatty acids and glycogen in this group were nearly the same as in the rats fed control Larsen diet (Table 1). These findings are in agreement with the results of other authors[1–4] and confirm the lipotropic effect of cold environment on the liver. The concentration of free fatty acids in the blood serum and epididymal fat tissue was significantly elevated in the cold acclimatized group (Table 2); this points to an increased mobilization of fatty acids from fat depots. Biosynthesis of fatty acids from acetate-1-^{14}C in the liver was lowered in the group exposed to cold, as can be seen from the low specific activity values of fatty acids ($P < 0{\cdot}01$) in Table 1. In the group of animals exposed to cold increased mobilization of fatty acids from reserve tissues was found and a simultaneous decrease was observed in the concentration of liver fatty acids; this is in agreement with increased ability of liver tissue to oxidize fatty acids, which was observed by some authors[10,11] in animals acclimatized to cold.

Table 1. CONCENTRATION OF ESTERIFIED FATTY ACIDS, GLYCOGEN AND SPECIFIC ACTIVITY OF TOTAL FATTY ACIDS IN LIVER OF WHITE RATS FED NORMAL AND HIGH FAT-CHOLESTEROL DIET, EXPOSED TO TEMPERATURES OF 22° AND 2° C

	Normal diet 22° C	High fat-cholesterol diet 22° C	High fat-cholesterol diet 2° C
Esterified fatty acids m.equiv./100 g	17·1 ± 1·0	21·9 ± 1·1	16·4 ± 0·8
Glycogen g/100 g	2·7 ± 0·2	0·6 ± 0·1	3·2 ± 0 2
Specific activity of fatty acids/c.p.m./ m.equiv.	12·039 ± 2·468	5·442 ± 2·349	1·674 ± 325

Table 2. CONCENTRATION OF FREE FATTY ACIDS IN BLOOD SERUM AND EPIDIDYMAL FAT TISSUE OF WHITE RATS FED NORMAL AND HIGH FAT-CHOLESTEROL DIET, EXPOSED TO TEMPERATURES OF 22° C AND 2° C

	Normal diet 22° C	High fat-cholesterol diet 22° C	High fat-cholesterol diet 2° C
Blood serum m.equiv./1,000 ml.	1·41 ± 0 14	0·86 ± 0·09	1·99 ± 0·16
Epididymal fat tissue m.equiv./100 g	0·47 ± 0·04	0·52 ± 0·04	1·28 ± 0·17

On the basis of these results we assume that the lipotropic effect of cold on the liver of rats fed high fat-cholesterol diet consists in a lowered hepatic biosynthesis of fatty acids and an increased catabolism of fatty acids in the liver tissue of cold acclimatized animals.

A Functional Caudal Photoreceptor in Blind Cavernicolous Crayfish

SEVERAL decapod crustaceans, particularly the crayfish, possess a primitive photoreceptor in their caudal ganglion[1] consisting of only two neurones[2]. An axon courses from each of the cells rostrally along the connectives in Wiersma's[3,4] area 83–84 (ref. 2). Discharge of the receptor is characterized by a relatively long latency which is inversely related to the stimulus intensity, and by a prolonged after-discharge. Stimulation of the receptor in intact animals initiates pereiopod movements and locomotion[5]. A model of the neuronal system which may account for this phenomenon has been suggested[6].

Since the crayfish possess two independent photoreceptor systems, and since some of these animals have undergone a loss of the eyes in cavernicolous environments, experiments were carried out to determine if the blind animals had also lost their central nervous system receptors. There seems to be little doubt that some of the cave crayfish are truly blind. It has been established[7,8] that the lamina ganglionaris and the retinal elements are essentially non-existent in the highly evolved troglobitic species, *Cambarus setosus*. This same blind species, however, has been shown[9] to exhibit a locomotory response on illumination of the head. The response, furthermore, was present even when the eyestalks were removed, indicating a light-sensitive dermal or anterior central nervous system receptor. Interestingly, the locomotory reflex was not produced by illumination of the caudal region of *C. setosus*[9]. The existence of these related data suggested *C. setosus* as the experimental animal.

Specimens of *Cambarus setosus* (Faxon) were obtained from Civil War Cave, Ozark, Missouri[10], and identified[11]. Three males and three females were examined. The response of the receptors of *C. setosus* were compared with those of two epigeal species, *Procambarus clarkii* and *Procambarus simulans*. Several specimens of *P. simulans* from a cave population were also used. The latter animals show sparse pigmentation but retain functional eyes.

Preparations for recording were made by isolation of the abdominal nerve cord from ganglion 1 to 6 inclusive. The cords were allowed to remain in Van Harreveld's[12] perfusion fluid at 5° C for about 8 h to suppress spontaneous discharges. Recordings were made with the 1–2 connective suspended in air on a 0·005-in. platinum electrode. The indifferent lead was a silver wire immersed in the saline. The potentials were passed to a capacity coupled pre-amplifier and into the upper vertical amplifier of a dual beam oscilloscope. The photic stimulator consisted of a 3-V tungsten lamp with a shutter and condensing lens attached. The stimulus indicator was a Texas Instruments *LS*400 light sensor. Permanent records were made on moving film or by recording the frequency of discharge directly[13].

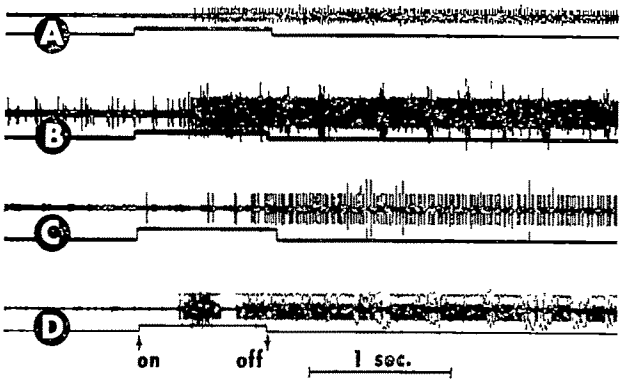

Fig. 1. Responses of sixth abdominal ganglion photoreceptors from (*A*) *Procambarus clarkii*, (*B*) *Cambarus setosus*—blind cave species, (*C*) *Procambarus simulans*, and (*D*) *P. simulans*—cave population. Each preparation received equal intensity 1-sec stimuli. Gain in (*A*) is lower than in the others. The magnitude of the responses more nearly reflects the length of time the cords were isolated than their thresholds

The responses from the caudal photoreceptors of the various species are shown in Fig. 1. Each preparation received a 1-sec flash of equal intensity. Every individual, including *C. setosus*, showed active photoreceptors in its caudal ganglion. Latencies in response to the standard stimulus were approximately equal for the receptors of all three species. This is not apparent from the recordings shown, since each preparation had been isolated for different periods before testing. The after-discharge appears to be more prolonged, however, for the receptors of *P. clarkii*, but approximately equal for *P. simulans* and *C. setosus*.

The light-activated response of the photoreceptor may be modified by appropriate synaptic input[2]. Analysis of this phenomenon led Kennedy to the conclusion that the neurones of *P. clarkii* not only possess properties of primary photoreceptors, but function as interneurones by receiving inputs from the tactile hairs of the telson and uropods. Stimulation of the contralateral roots of the sixth ganglion inhibits light-induced activity, while stimulation of the ipsilateral roots facilitates[2].

The cephalically-blind cavernicolous crayfish rely on tactile and proprioceptive information for locomotion, orientation and position sense. They may, therefore, have retained the important interneurone functions of the caudal receptors for their positive adaptive value, without loss of the photosensitive properties.

PHARMACOLOGY

Testing Chemicals for Mutagenicity in a Mammal

WHILE admitting that mammals would be preferable to diptera for testing newly introduced drugs for possible genetic (that is, mutagenic) effects, Prof. Lüning[1] argues that tests with mice would be expensive and time consuming and therefore advocates the use of *Drosophila* larvae grown on medium containing the drug, which are then tested for chromosome loss and non-disjunction.

The mouse is, however, not so impracticable as test material for mutagenicity as Prof. Lüning implies. The most readily detectable mutation in the mouse is the dominant lethal, which is probably due to chromosome loss. It manifests itself as lethality *in utero* of embryos arising from gametes in which the mutation has arisen.

The most convenient technique is to inject males with the test compound at a dose determined from $L.D._{50}$ tests, which we can assume to have been carried out in any drug of pharmacological interest. The treated males, together with untreated controls, are then mated to untreated females. The females are dissected at mid-term (we have found the most convenient interval to be 12 days after the formation of a mating plug) and the number of implants and their condition recorded. There are two main classes of lethal embryo among the implantations. The first is the deciduoma or 'mole', an outgrowth of the uterus at the site of the implanting blastocyst which itself fails to develop much after implantation. The second type of lethal embryo has developed to a relatively advanced stage before death so that placenta and foetal membranes can be seen. The frequency of this latter kind of lethal is unaffected by mutagens and seems, therefore, to be non-genetic in this test system. The most sensitive test for mutagenicity is the proportion of all implants which are deciduomata. In control matings this runs at about 4 per cent[2], so that the doubling dose, which would yield 8 per cent, is readily detectable.

If the implantation rate (the ratio between number of implants and number of corpora lutea) is much depressed, this may indicate that too high a dose-level is being used, as a low implantation rate can result from a high mutation rate[3,4].

The sensitivity to mutagens varies greatly between the stages of spermatogenesis. To survey all the stages of spermatogenesis from spermatogonia through spermatocytes to mature sperm it would be necessary to make test matings continuously for 8 weeks after treatment. Experience with a wide range of mutagens has demonstrated, however, that dominant lethals are most readily induced in post-meiotic stages which are sampled during the first 3 weeks after treatment. The whole test would then take

about 5 weeks, using, say, thirty males (ten controls and ten at each of two dose-levels) and 360 females (four females per male per week).

Rats may also be used as test animals but, being larger, more accommodation is required to obtain the same information. The vaginal smear has to be used to detect inseminations instead of the convenient mating plug. Moreover, we have found rats unable to mate regularly with more than two females per week; so that more males are needed to produce the same number of pregnancies.

This technique has now been used to study the mutagenic action of X-rays[2], neutrons[5], radioisotopes[6], triethylenemelamine[4] and alkane sulphonic esters[7,8]. Following reports that the radio-opaque medium diodone might be mutagenic we have tested this compound with negative results[9]. Negative results have also been obtained for caffeine[10] by other workers using a similar test.

It is obviously preferable to use a mammal rather than an insect as the test animal for drug assays. The technical simplicity and the few weeks required for the dominant lethal test in mice make it a very suitable system for testing the mutagenicity of any new drug.

Reactivation of Paraoxon-inactivated Cholinesterase in the Rat Cerebral Cortex by Pralidoxime Chloride

IT has been demonstrated by Firemark, Barlow and Roth[1] that the concentration of pralidoxime (PAM) in the rat brain cortex after a single intravenous injection of PAM-^{14}C is significantly higher than in other brain regions. The present communication reports an attempt to see whether such a relatively small dose of PAM as used by these authors (20 mg/kg) is able to reactivate satisfactorily the phosphorylated cholinesterase in the brain cortex of rats poisoned with lethal doses of paraoxon.

Female albino rats weighing 200–250 g were given 10 mg/kg of atropine sulphate followed 20 min later by a subcutaneous injection of paraoxon. Ten minutes after injecting paraoxon, 20 mg/kg of PAM (chloride) was given intravenously. One hour later the animals were killed by decapitation. Brains were quickly removed and immediately chilled in ice. The cerebral cortex (parietal region) was placed on a frosted glass slide and sliced with a razor blade. Cholinesterase activity was measured manometrically at 37° C with the following reaction mixture: 0·15 M sodium bicarbonate, 0·164 M sodium chloride and 0·01 M acetylcholine chloride in a total volume of 2·0 ml.; *p*H 7·4, gas phase nitrogen + carbon dioxide (95 : 5). Enzyme activity was expressed in μl. carbon dioxide liberated per mg of tissue (dry weight) during the first 30 min (Q value). All results were corrected for non-enzymatic hydrolysis.

The results presented in Table 1 show that 1 h after the injection of PAM the mean enzymatic activity in the cerebral cortex of rats poisoned with paraoxon was considerably higher than the activity in the cortex of rats injected with paraoxon only. The differences at each dosage group are statistically significant ($P < 0·05$). With a dose of paraoxon of 0·25 mg/kg the reactivation was on average 54 per cent. With higher doses of paraoxon (0·5 and 1·0 mg/kg) the mean reactivation was 45 per cent and 25 per cent, respectively. In the last group all animals injected only with paraoxon died 10 min after poisoning, and had a cholinesterase activity which was significantly lower than that in PAM-treated animals which survived and were killed 1 h after injection of oxime.

Table 1. CHOLINESTERASE ACTIVITY IN THE BRAIN CORTEX OF RATS INJECTED WITH PARAOXON FOLLOWED BY PAM*

Paraoxon (mg/kg)	Cholinesterase activity Without PAM Q	Without PAM Per cent	With PAM Q	With PAM Per cent	Reactivation per cent
0	12·25 ± 0·17	100	12·54 ± 0·70	100	—
0·25	5·26 ± 1·04	42	9·13† ± 1·32	73	54
0·5	2·51 ± 0·71	20	6·60† ± 1·20	53	45
1·0	3·76‡ ± 0·45	30	5·95† ± 0·30	48	25

* Each value represents the mean and standard error of the activity measured at least in five brains.
† Mean values differ significantly ($P < 0·05$) as determined by the t-test.
‡ Dead 10 min after poisoning.

These data are in contrast to the general belief that PAM, owing to its quaternary structure, does not penetrate the blood–brain barrier in a concentration which is sufficient to reactivate phosphorylated cholinesterase in the brain (reviewed in ref. 2). However, this conclusion is based mainly on results obtained with homogenates of whole brain and makes no allowance for the uneven distribution of PAM in the brain. The use of cortical slices instead of homogenates of whole brain has the advantage that the tissue slices contain most cells in an intact form. This may result in a greater effectiveness of PAM in reactivating the so-called functional cholinesterase on the cell surface than the reserve cholinesterase within the cells. The latter accounts for more than 95 per cent of the enzymatic activity in the isolated frog rectus abdominis muscle[3]. The situation in the brain might be similar and the ability of PAM to reactivate paraoxon-inhibited functional cholinesterase in the rat cerebral cortex would provide an explanation for some of its central actions which have been observed both in animals and human beings poisoned with various organophosphorus anticholinesterase agents[4–6].

This investigation was supported and sponsored by the Commission for Medical Research, Belgrade.

PATHOLOGY

Effect of Environmental Temperature on the Metabolic Response to Injury

THE pattern of the metabolic response by man and the rat to injury (for example, fracture of a long bone) has been under investigation for some time. The reaction is characterized by a marked rise in the urinary excretions of nitrogen, sulphur, phosphorus, potassium and creatine, which reach a peak in the rat at the third day after the injury and then slowly decline[1–3]. It was early noted that in man once shock had subsided there was also a rise in

the 'basal' consumption of oxygen and a slight rise in body temperature paralleling the increase in the catabolites[1]. It was suggested that following injury there is an increased demand for energy from endogenous sources[2,4,5]. At that time it seemed reasonable to assume that in some way by releasing energy from endogenous sources metabolism is raised following moderate to severe injury and this facilitates the healing process.

Using a direct gradient-layer calorimeter constructed by one of our colleagues, Dr. J. D. Pullar, it was shown that the average total metabolism of rats maintained on a moderately high protein diet also rises to a maximum on the third day following such injury which is also the time of the maximum excretion of nitrogen[6]. The rise was essentially due to a rise in the minimum metabolic rate which was found to be increased by 7 per cent by the third day. This could be explained in terms of a greater restlessness during the hours when the metabolic rate is normally low. From the metabolic data it was also inferred that both in man and the rat the increased heat output must arise mainly from oxidation of protein. Earlier observations had indicated that when rats were fed a diet deficient in total protein they did not respond to trauma by increasing their protein catabolism[7], for no increase in metabolic rate nor in urinary excretion of nitrogen appeared[6]. Wilkinson[8] believed that these disturbances of bodily composition in the normally nourished organism might be held to assist the patient in recovery from a major operation.

It is therefore interesting to note that Caldwell[9] recently showed in the rat that at the higher environmental temperature of 30° C the normal metabolic response to injury (burning) no longer occurred if the animal's intake of food was fixed at the pre-burn level, while animals with similar wounds but maintained at 20° C, also with their diets fixed at the pre-burn level, lost weight, had a high mortality and exhibited a negative nitrogen balance. When both environmental groups were allowed free access to food in the post-burn period these striking differences between the groups were not seen and the apparent adverse effect of restriction at the lower temperature disappeared. The rate of wound healing was found to be significantly faster at an ambient temperature of 30° C than at 20° C with both groups having free access to food. Mortality was then low in both groups and the differences not statistically significant. Caldwell's hypothesis is that when rats with burn wounds are kept at an environmental temperature below that of the surface temperature of the wound they must then compensate for the heat they lose as heat of vaporization from extra-renal water loss which occurs through the wound. This hypothesis seemed to us to demand an investigation on wounds such as fracture of the femur where surface phenomena would not be involved—or not to such an extent. According to Caldwell's theory, an obligatory heat loss requires a corresponding increase in total heat production to maintain body temperature.

In our preliminary experiments, 3-month-old male hooded Lister rats of the Rowett Institute strain were used and the animals were kept in individual cages and fed the Institute's stock diet No. 86 once daily at 9 a.m., the food being left with them. The average intake for each rat for the 3 days, that is, −5, −4, −3 days, prior to the beginning of the urinary collections was the basis of the food fed throughout the experiments. Body-weight, food intake and urinary nitrogen were measured in a direct gradient-layer calorimeter by the technique previously described[6]. All operations were performed under ether anaesthesia. The basal urinary nitrogen was the average for the 3 days (that is, −3, −2, −1 days) selected before treatment and was expressed as mg nitrogen/100 g body-weight above or below basal level (the average of the 3 days prior to treatment being taken as zero).

In the first experiment, twenty-four rats were kept in an ambient temperature of 30° C: twelve rats were fractured and twelve littermates received the same manipulation but without fracture and were termed the incision group. The food intake for the fracture group was 19·4 g/day for the pre-injury period and 18·6 g/day for the 10-day post-injury period. For the incision-only group the value remained at 19·9 g/day throughout and probably accounts for the higher urinary nitrogen excretion. The fractured animals gained 17 g in weight over the post-operation days as against 22 g gained by the incised group.

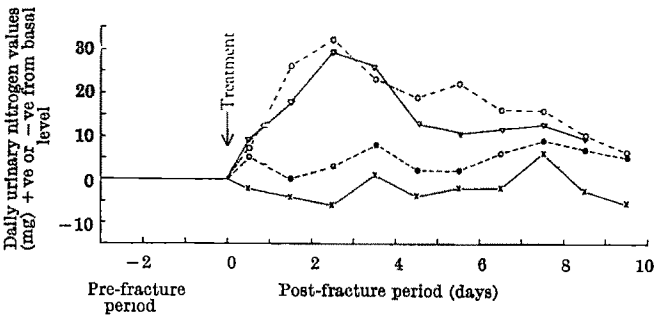

Fig. 1. Variation of daily urinary nitrogen values from basal level in mg nitrogen/100 g body-weight. ×——×, Fracture, 30° C (average of 12 rats in each group), ●- - -●, incision, 30° C (average of 12 rats in each group); O—·—·—O, fracture, 22° C (see ref. 3); ▽———▽, fracture, *c.* 20° C (see ref. 2)

The fractured group did not show the characteristic protein catabolic effect seen in similar apparently well-nourished animals held under normal environmental temperature conditions (compare with Cuthbertson *et al.*[2] and Campbell *et al.*[3]); indeed, 22 mg less nitrogen (that is, negative from base-line) was excreted in the urine/100 g body-weight over the 10-day post-operative period. The rats were apparently in positive nitrogen balance (see Fig. 1). In the incised group, 47 mg nitrogen in excess over the base-line were excreted/100 g body-weight over the 10-day period. In one of the earlier fracture experiments[3] conducted under normal laboratory temperature conditions, the urinary nitrogen excreted over the 10-day period was 177 mg/100 g body-weight in excess over the base-line; in a still earlier experiment[2] it was 146 mg in 9 days.

The disappearance of the characteristic increase in urinary nitrogen excretion following injury at 30° C was rather unexpected, but agreed with the findings of Caldwell[9]. The question arose whether the increase in heat production following injury would likewise disappear.

Our second experiment, using the gradient-layer calorimeter, was designed to answer this question. Nine male rats were placed in individual cages in the calorimeter at 30° C. After stabilization they were fractured and held in the chamber. They maintained their body-weight throughout the experimental period, but the food intake fell by 1·7 g/day/rat during the 10 days of the post-injury period (that is, from 16·0 g pre-injury to 14·3 g post-injury). There was no evidence of the increased heat output previously found to be a characteristic response to injury induced in animals at normal room temperature. A pair-fed fractured group also at 30° C, but maintained outside the calorimeter in metabolism cages, also showed a decreased urinary nitrogen excretion throughout the 10-day post-injury period, as was noted in Exp. 1—the figure being 63 mg (negative from base-line) over the 10 days, again tending towards a positive balance.

Further experiments are now in progress involving injury on animals on *ad libitum* feeding in ambient temperatures at 30° C and 20° C and the rates of healing of skin wounds are also being followed, but in view of present interest in this problem we report the present stage of our experiments for Caldwell's hypothesis would not seem to cover these observations on the disappearance of the normal protein catabolic response to fracture when the animals are held at a high environmental temperature.

We thank Dr. J. D. Pullar for his assistance with the calorimetry.

Complete Inhibition of Mouse Leukaemia *L*1210 by 5(or 4)-[3,3-*bis*(2-Chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (*NSC*-82196)

IT has been shown that 5(or 4)-(3,3-dimethyl-1-triazeno)-imidazole-4(or 5)-carboxamide (*NSC*-45388) and related triazenoimidazoles inhibit the growth of experimental neoplasma[1]. The triazenoimidazoles were prepared by reaction of various amines with 5-diazoimidazole-4-carboxamide[2,3]. This investigation has been extended to embrace a variety of substituted triazene derivatives. We now report the synthesis of one of these, 5(or 4)-[3,3-*bis*(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (*NSC*-82196), and its inhibitory action in preventing the development of mouse leukaemia *L*1210.

NSC-45388: $R = CH_3$
NSC-82196: $R = CH_2CH_2Cl$

NSC-82196 was prepared by treating 5-diazoimidazole-4-carboxamide with *bis*(2-chloroethyl)amine free base in a mixture of methanol and ethyl acetate. The atomic analysis was found to be carbon, 34·54 per cent; hydrogen, 4·27 per cent; nitrogen, 30·25 per cent; chlorine, 25·5 per cent. The atomic analysis calculated for $C_8H_{12}N_6OCl_2$ was: carbon, 34·42 per cent; hydrogen, 4·32 per cent; nitrogen, 30·10 per cent; chlorine, 25·4 per cent. *NSC*-82196 is sparingly soluble in water and in methanol, but stirring a suspension of the compound in either solvent transforms it into a water-soluble ionic compound having the same composition. Analysis gave the result: carbon, 34·35 per cent; hydrogen, 4·18 per cent; nitrogen, 29·85 per cent; total chlorine, 25·2 per cent; ionic chlorine, 12·7 per cent. Calculated values for $[C_8H_{12}N_6OCl]^+Cl^-$ were: carbon, 34·42 per cent; hydrogen, 4·32 per cent; nitrogen, 30·10 per cent; total chlorine, 25·4 per cent; ionic chlorine, 12·7 per cent. Infra-red absorption bands in the spectrum of *NSC*-82196 at 3,390, 1,655 and 740 cm^{-1} are replaced by bands at 3,460, 1,685 and 770 cm^{-1} in the spectrum of the ionic transformation product; but the appearance of a strong band at 1,515 cm^{-1} in the spectrum of the ionic transformation product and the absence of this band in the spectrum of *NSC*-82196 is of greater diagnostic value. The infra-red spectrum of a specimen of *NSC*-82196 stored at −15° C was unchanged after 7·5 months; on the other hand, an earlier specimen that had been kept during most, but not all, of a corresponding length of time at approximately 5° C was partially transformed into the ionic product. The structure of the ionic transformation product has not been established; it may be an aziridinium, a *v*-triazolinium, or a piperazinium salt. Owing to the sparing solubility of *NSC*-82196 in water, specimens containing small quantities of the ionic transformation product may be rendered essentially free of this impurity by rapid washing with water and rapid drying.

Because of the instability of *NSC*-82196, it was injected into test animals as a suspension in carboxymethylcellulose solution within 5 min of the preparation of the suspension. Results of daily treatment of leukaemic mice beginning 2 days after intraperitoneal inoculation of the animals with 10^5 *L*1210 cells and continuing to death or to day 30 are shown in Table 1. In two tests at 75 mg/kg/day the average life-span of the treated mice was more than three times that of the control groups. In initial tests, *NSC*-82196 has also demonstrated activity against sarcoma 180 and adenocarcinoma 755 in mice and against Walker carcinoma 256 in rats. The ionic transformation product was inactive at doses of 50 and 75 mg/kg/day in initial trials against *L*1210.

† Survivors beyond 30 days maintained on oxytetracycline therapy to minimize the danger of bacterial infection.
‡ Still alive at this writing.
§ One death after 162 days; four alive after 165 days.
‖ Experiment terminated after 120 days.

Skipper, Schabel and Wilcox[4] have demonstrated the necessity for complete eradication of leukaemic cells *in vivo* and the possibility of achieving this goal through massive, single-dose treatment with active compounds. As shown in Table 2, some of the leukaemic animals treated in this way with *NSC*-82196 have survived for periods of 5·5 and 8 months. At 500 mg/kg/day, for example, all the treated animals in one experiment have survived for 8 months, and four of six survived until a second experiment was terminated after 4 months.

In summary, *NSC*-82196 administered daily exerts a strong inhibitory action against mouse leukaemia *L*1210 and also shows inhibitory activity against certain other tumours. The massive, single-dose therapy of Skipper *et al.*[4] has brought about complete inhibition of *L*1210 in a high proportion of the treated mice. *NSC*-82196 is rather easily transformed into an ionic compound that was inactive in preliminary trials.

We thank Dr. J. A. Montgomery for encouragement; members of the Cancer Chemotherapy Screening Section for tumour testing performed under the supervision of Mrs. Mary Trader, Dr. W. R. Laster, jun., and Dr. F. M. Schabel, jun ; and members of the Analytical Section for

elemental analyses and infra-red spectra determined under the supervision of Drs. W. C. Coburn, jun., P. D. Sternglanz and W. J. Barrett. ANATOMY

Role of the Lens in the Morphogenesis of the Iris and Cornea

WITH the view of analysing the part played by the lens during the morphogenesis of the eye, the following experiment was performed: lens primordia of chicken embryos between stages 16 and 22 of Hamburger and Hamilton[1] were implanted into the optic cup of host embryos at the same stage of development. The lens primordium was placed through a section in the wall of the optic cup (at the level of the posterior chamber) by means of a rounded glass needle. The pupil of the host embryo thus came to possess two lenses—its own and an implanted one.

The host embryos were killed with a 10 per cent formalin solution, between stages 17 and 32. After embedding them in paraffin–'Celoidin', 8μ serial sections were made and stained with haematoxylin–eosin. In five of the twenty-five embryos that we investigated, plastic reconstructions were prepared according to Born's method but with slight modifications. The left eyes of the host embryos were considered as controls.

The most pronounced effect of implanting the new lens was that it evoked very intensive structural changes at the wall of the optic cup and in the cephalic mesoderm at the level of the pupil. At the latter, a new pupillary border was reconstituted and the pupillary became greatly increased in size. In front of this newly-formed pupillary area, the cephalic mesoderm was re-organized in such a way that an anterior chamber and a corneal membrane was formed.

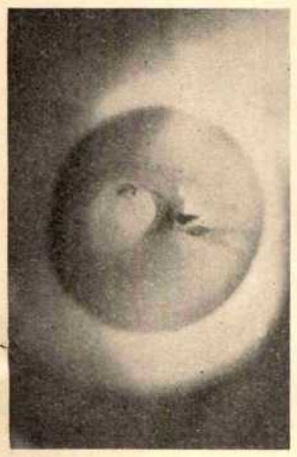

Fig. 1

Fig. 2

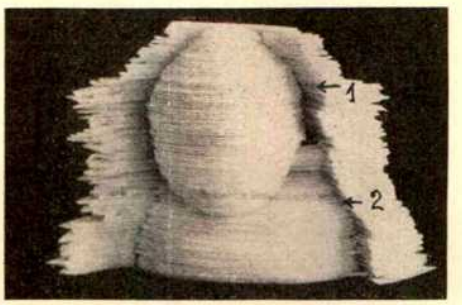

Fig. 3

Fig. 4

Fig. 5

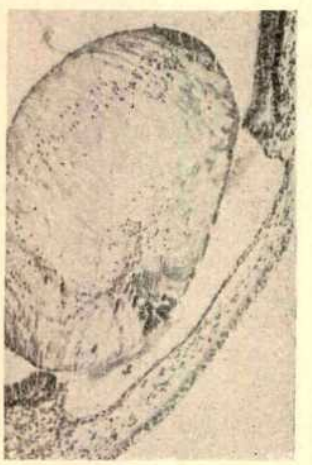

Fig. 6

Compared with the controls, the pupil of those eyes receiving implanted lens were noticeably larger: in front of the latter some pigmented material was present from the primitive iridian border (Figs. 1 and 2).

The plastic reconstructions have enabled us to demonstrate the general aspect of the pupil with the two lenses. In embryo 1252 the cranial equator of the host's crystalline demonstrated the adherence of the implanted lens (Fig. 3). A partial aspect of the same reconstruction (Fig. 4) shows the very clear and definite limits of the anterior chamber and cornea.

Fig. 5 corresponds to a histological section taken through the region marked by arrow 2 in Fig. 3. Both the lens of the host and the implanted lens are sectioned, but only a small section of the latter can be seen. The pupillary border, anterior chamber and cornea all show the same structure as that observed in the control eyes.

Fig. 6 represents a more cranial section through the region marked by arrow 1 in Fig. 3, and a section of the implanted lens can be seen. Although some structural differences exist when a comparison is made with the

control eyes, a pupil is present and the mesenchyme is organized to form an anterior chamber and a cornea.

Our results confirm the suggestion that the lens plays an important part in corneal morphogenesis[3–5]. At the same time they agree with the views put forward by Giroud[6] and Stroeva[7], who emphasize a strong organogenetic connexion between the iris and the lens.

RADIOBIOLOGY

Manganese Free Radicals in Cobalt-60 Gamma-irradiated Strawberries

THE formation of free radicals in biological systems exposed to ionizing radiation is well established[1–7]. Some of the induced radicals, as well as some of those occurring naturally[8], have long lives[9–11]. The surprising stability of the induced radicals may have far-reaching biological implications. As an example of stability, cystine, on irradiation *in vacuo* at room temperature, gave electron paramagnetic resonance signals even after 35 days[12]. Numerous investigations in connexion with irradiation damage of proteins and amino-acids confirm the stability of these radicals[13–18]. This stability must be considered carefully in assessing the wholesomeness of foods preserved by ionizing radiation. Such assessment involves the concepts of stored chemical energy and consequent radiomimetic hazard[19–20]. Chromosomal aberrations have been shown to occur in germinating barley and onion seeds following treatment with orange or apple juice, which had been irradiated with 200 Krad of γ-rays[21]. Although the radiomimetic precursors generated by irradiation of fruit juices have not been ascertained, preliminary studies indicate that peroxides may be implicated.

From research in our laboratory, strawberries appear to be one of the most promising fruits for application of irradiation to extend shelf life[22]. This communication reports on an investigation to determine whether long-lived organic free radicals were present in irradiated fruits. Greenhouse-grown 'Shasta' strawberries were irradiated at 200 Krad at 0° C, and maintained at this temperature for 64 h. Samples taken at regular intervals, starting immediately after irradiation, were held in evacuated quartz tubes submersed in liquid nitrogen, until electron paramagnetic resonance measurements. The spectra were determined with a Varian electron paramagnetic resonance spectrometer having a 9-in. magnet system, over the temperature range of $-196°$–0° C. The scan was varied from 500 to 1,000 G at roughly g 2. The samples were evacuated continuously during the measurements.

We found no organic free radicals and were only able to detect Mn^{2+} in the samples. Similar results were recorded from commercially available fruit irradiated over a dose range of 200–600 Krad. Atomic absorption spectroscopy showed 19 p.p.m. Mn^{2+} (dry weight basis) in the greenhouse strawberries.

Preservation of foods by radiation, as a novel concept, led to extensive investigations concerning the wholesomeness of irradiated foods. Among the various general principles used to evaluate the biological safety of such foods, sub-threshold toxicity and delayed response are particularly significant when considering wholesomeness in relation to long-lived free radicals.

Due to the absence of any long-lived organic free radicals, the foregoing concept is of no significance in irradiated strawberries. Comprehensive feeding trials of the irradiated foods have shown no adverse effects in test animals. Likewise, in trials conducted by the United States Army Quartermaster Corps, troops fed sterilized rations showed no ill effects. Manganese resonance also has been detected in various non-irradiated plant materials, such as fallen oak leaves and pine needles and naturally dried ivy stems.

On the basis of the evidence available, it is logical to assume that wholesomeness of irradiated strawberries is not affected by the presence of Mn^{2+} free radicals. We have been unable to locate any references in the literature as to the fate of ingested transition metal free radicals. More definitive evidence regarding the biological safety of Mn^{2+} free radicals will come from such an investigation.

Strontium-90 Content of First Bicuspids

THE tooth crown, once formed, is a stable calcified structure removed from direct equilibrium with body fluids and therefore undergoes minimal remodelling, exchange or turnover of mineral elements. During development and calcification, the mineral elements of the crown are in equilibrium with body fluids and, indirectly, with the diet. The concentration of strontium-90 in the tooth crown is, therefore, a measure of the equilibrium between the tooth and dietary strontium-90, and the tooth crown represents a permanent record of the equilibrium existing at the time of tooth formation.

We have recently reported[1,2] that the accumulation of fall-out strontium-90 in deciduous teeth of children is adequately described by a linear equation of the form $C_T = K\,C_D$, where C_T and C_D are the strontium-90 concentrations expressed as pc. strontium-90/g calcium in the tooth crown (C_T) and the diet (C_D). The slope, K, was

derived from considerations of the percentage of the tooth crown formed *in utero* and *post partum*, known discrimination factors between the foetus and its mother, and discrimination factors between the baby and its diet. The slope, K, varies with the type of tooth and time of formation and has been found to be 0·59, 0·76, 0·69 and 0·77 for healthy incisors, healthy cuspids, carious first molars and carious second molars, respectively. The strontium-90 content of the deciduous teeth represents a function of the dietary strontium-90 content some 5–8 years before natural exfoliation.

For permanent teeth that are formed after birth and are predominantly formed after breast feeding is discontinued, the factors of placental discrimination and the influence of the maternal nutrition are effectively absent. Thus, the slope (K) of the equation is simplified and is primarily equivalent to the discrimination factor between permanent tooth crown strontium-90 and the dietary strontium-90. The slope (K) must be experimentally determined. Sound first bicuspids, often extracted for orthodontic purposes, are readily available for estimation of strontium-90 content[3]. Furthermore, the rate of growth of the first bicuspid crown is well characterized[4], and data concerning the age of the patient, geographical area of and later development and other pertinent informa- may be readily obtained.

This report describes the strontium-90 content of the crowns of first bicuspids and the relationship to dietary strontium-90 from fall-out.

Healthy first bicuspids, extracted between July 1, 1964, and May 1965, from children born within a 150-mile radius of St. Louis, Missouri, and ranging in age from 9 years to 17 years were analysed for strontium-90 by methods previously described[1,2,5]. The crowns and roots were separated at the crown-enamel junction and the crowns were pooled to make a sample containing four crowns and weighing 2–4 g. Of forty-six samples analysed, twenty-four samples (52 per cent) contained four crowns from one child, eighteen samples (40 per cent) were pooled from two or three children, and four samples (8 per cent) were pools of teeth from four children. When crowns were pooled, care was taken to check that they came from children born within 6 months of each other. Because strontium-90 analysis of milk in the St. Louis area was not carried out before 1959, milk strontium-90 values were estimated as previously described[1]. For American children of this age group, previous estimates have shown that the daily dietary strontium-90 intake is equal to the milk strontium-90/g calcium multiplied by 1·20 (ref. 6).

The first bicuspid forms between the ages of 1·5 years and 6 years[4], and an average value of 4 years after birth was taken as the mid-point for time of development.

As shown in Fig. 1, the strontium-90 concentration in the crowns of permanent first bicuspids increases with time for children born between 1948 and 1955, corresponding to a tooth development time between 1952 and 1959, a period associated with increasing fall-out. When the strontium-90 content of the tooth crown is plotted against the strontium-90 content of the diet (Fig. 2), the data are adequately described by a linear equation, $C_T = K\,C_D$ (calculated by the method of average points), with a high correlation coefficient of 0·98. The slope of the line (K), equivalent to the discrimination factor between tooth crown and diet, is calculated from the data to be 0·31.

Discrimination against strontium relative to that of calcium is assumed to be absent in new-born infants[7] and a factor of 0·25 has been accepted for calcified tissues of adult subjects between 20 years and old age[8]. These and other known discrimination factors have been plotted (Fig. 3) to indicate the rapid decrease of the discrimination factor from the time of birth until about 4 years of age, thereafter decreasing slowly to adult values. We estimate, therefore, that the discrimination factor approaches the adult value at about 10–12 years of age.

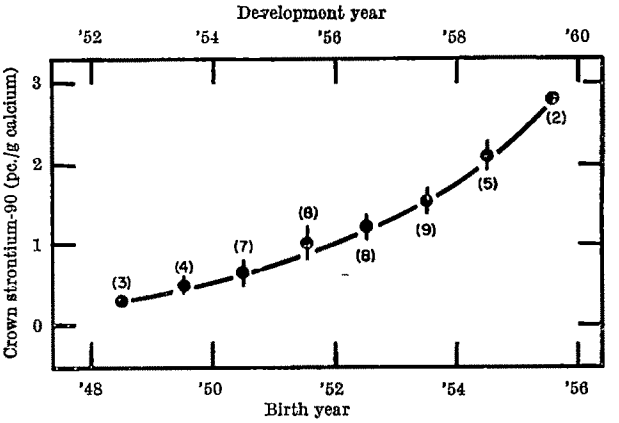

Fig. 1. Strontium-90 content of first bicuspid crown versus year of birth and year of average development. Vertical lines are standard error of the mean for the number of samples in parenthesis

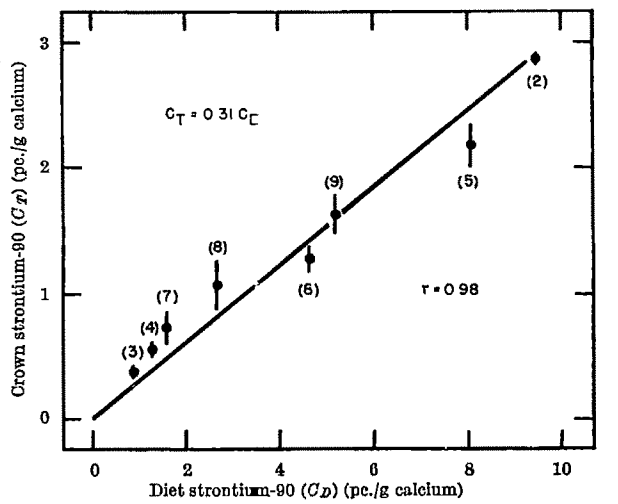

Fig. 2. Strontium-90 content of first bicuspid crown (C_T) versus diet strontium-90 (C_D). Vertical lines are standard error of the mean for the number of samples in parenthesis

The data described in the present report for first bicuspids and our previous reports for deciduous teeth[1,2,5] indicate the usefulness of the teeth as a permanent record of strontium-90 deposition at the time of tooth formation. Furthermore, the stability of the formed crown with respect to minimal turnover time, exchange and remodelling and the known time for tooth development[4] makes it possible to estimate the changing discrimination factors in the growing child—estimates that are difficult to determine by other means.

We recognize the influence of the time lag of about 4 years for development of the bicuspid crown and the

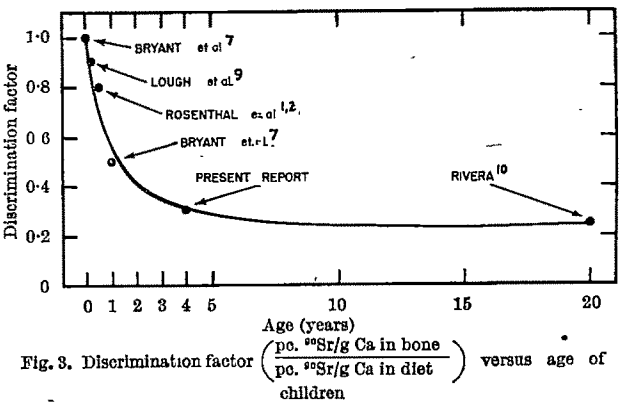

Fig. 3. Discrimination factor $\left(\frac{\text{pc. } ^{90}\text{Sr/g Ca in bone}}{\text{pc. } ^{90}\text{Sr/g Ca in diet}}\right)$ versus age of children

fact that the crown consists of enamel and dentine that calcify at different times. These and other factors need to be clarified, but they would not seem to influence seriously the results and are presumed to be much smaller than the analytical error of strontium-90 analysis. Although Starkey, Bryant and Henderson[3] have criticized the usefulness of deciduous teeth and have preferred to analyse permanent first bicuspid and third molars, we believe that the tooth crown reflects the equilibrium between calcified tissues and diet strontium-90 concentrations at the time of tooth formation.

Deciduous teeth are useful because they are readily available in large numbers by natural exfoliation, reflecting the strontium-90 incorporation during a short calcification period of less than 1 year. The various factors influencing the strontium-90 content of deciduous teeth such as discrimination by the placental barrier during *in utero* development, or discrimination between the baby and its diet, have already been evaluated[1]. Permanent teeth, although not so readily available as deciduous teeth, are larger, require fewer teeth for adequate sampling and represent the strontium-90 equilibrium with the diet in the absence of minimal maternal influence. The longer development time of permanent teeth represents an average incorporation of strontium-90 during the period of calcification, thus obviating the influence of sharp and rapid changes in dietary strontium-90 levels.

It appears, therefore, that all kinds of teeth may be useful as an index of dietary strontium-90 when due consideration is given to the many factors involved in tooth and bone formation and metabolism.

Unexpected Dose-rate Effect in the Killing of Mice by Radiation

IT has been well established for many years that the effectiveness of ionizing radiation may be correlated with dose-rate[1–4]. The relative ineffectiveness of radiation at low dose-rates is generally regarded as resulting from the operation of intracellular repair or recovery mechanisms, which may act between successive damaging events, when an accumulation of these is required to give the effect under investigation. In most radiobiological investigations on mammals, or with mammalian cells, experimenters have used dose-rates of up to a few hundred rads per min, so that the duration of 'acute' doses is usually to be measured in minutes or tens of minutes.

In mammalian work, only Lindop and Rotblat[5], so far as we know, have examined the relative effectiveness of a series of dose-rates greater than 1,000 rads/min, their measurements being concerned with the mean dose required to kill mice within 30 days ($L.D.$ 50/30), and with the life-shortening effect of radiation. They used an electron beam to deliver dose-rates varying between 80 and 160,000 rads/min, and found very little change in the $L.D._{50/30}$ in this range. Ainsworth *et al.*[6] likewise found no difference in the $L.D._{50/30}$ for mice with γ-ray dose-rates of 100 and 10^6 rads/min. These results justify the assumption implicit in much mammalian cell-survival work that it is a matter of indifference whether dose-rates of, say, 100 rads/min or 1,000 rads/min are used.

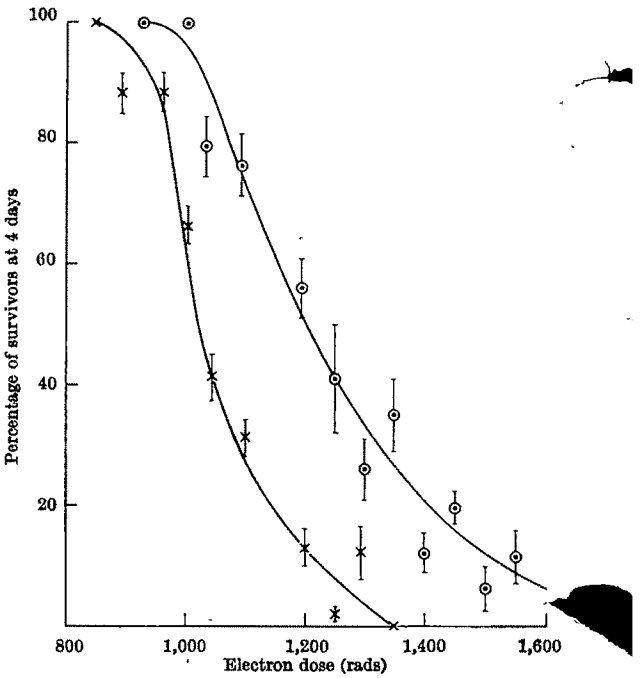

Fig. 1. 4-day survival curves for mice, strain *TO*, exposed to electron beams at 6,000 rads/min (×) and 100 rads/min (⊙)

It was therefore unexpected to find that the mean dose required to kill mice within four days ($L.D._{50/4}$) was strongly dependent on dose-rate for rates up to 6,000 rads/min. This mode of death is attributable to depletion of the stem cells in the crypts of Lieberkühn, which give rise to the epithelial cells covering the villi in the small intestine[7]. Fig. 1 shows survival curves for female mice 6–8 weeks old, strain *TO*, breathing oxygen during exposure to an electron beam (energy about 8 MeV) at dose-rates of 100 and 6,000 rads/min. (Exposure time about 10 min and 10 sec.) The data have been collected from several experiments, in some of which the mice were anaesthetized with 'Nembutal' before irradiation. The results for these and for unanaesthetized animals were the same, provided the mice were breathing oxygen.

We have determined the $L.D._{50/4}$ for electron beams or 250 kV X-rays at dose-rates between 20 and 50,000 rads/min, with results shown in Fig. 2. We do not think that this strong dependence of $L.D._{50/4}$ on dose-rate, observable up to about 6,000 rads/min, can be due to experimental artefact. Dosimetry for the electron beam was based on measurements with a Baldwin/Farmer substandard ionization chamber, used at a low dose-rate; these measurements were used to calibrate the monitor present in the electron beam[8]. The monitor chamber is not fully saturated at dose-rates greater than 2,000 rads/min, but the correction factors we apply have been verified by dosimetry with lithium fluoride[9]. At 6,000 rads/min, the dose-rate at which many of the observations were made, the correction factor was only 1·1 per cent. An additional internal check was provided by using dose-rates of 100, 250 and 6,000 rads/min for determining

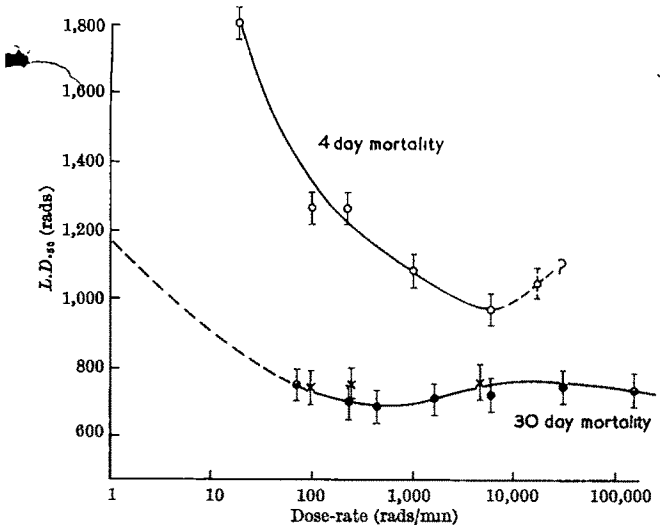

Fig. 2. (○), 4-day mortality with *TO* strain mice; (×), 30 day mortality with *TO* strain mice; (●), 30-day mortality results taken from Lindop and Rotblat (ref. 5)

values of the $L.D._{50}$ at 30 days. These were the same at the three dose-rates, and agreed with the results of Lindop and Rotblat[5] (Fig. 2). The dose-rate effect we have observed is not peculiar to the strain of mice (*TO*) used for most of these experiments. We have carried out preliminary experiments on *C3H* mice inbred in these laboratories. These are not yet available in numbers sufficient to obtain full survival curves; but experiments have been carried out with small homogeneous groups. When a group irradiated at 100 rads/min was given a dose 200 rads more than a similar group irradiated at 6,000 rads/min, the patterns of death up to 9 days were closely similar.

The 10–15 min exposure time required for delivery of lethal doses at 100 rads/min might be long enough to permit of some "recovery from sub-lethal damage", in the sense used by Elkind[10]. We tested this possible explanation for the dose-rate effect by giving a series of doses at 6,000 rads/min, each split into two fractions separated by 10 min. As shown in Table 1, this procedure resulted in survivals equal to those seen after low dose-rate irradiation, when the total doses were 1,050 rads or less. With the higher doses, however, the doses given at 100 rads/min were less effective than doses given at a higher dose-rate but split by 10-min intervals. This may perhaps be accounted for by the relatively small amount of recovery which can occur during the few seconds' irradiation time required for delivery of the second fraction, at the higher dose-rate. No increased sparing effect was observed when the interval was extended to make the overall time always equal to the time required for the delivery of the same doses at 100 rads/min; for example, when a total dose of 1,300 rads was split into two fractions separated by 13 min.

Since data dealing with dose-rate effects at greater than 100 rads/min are sparse, it is not possible to know whether gut-death in mice is exceptional in demonstrating dependence on dose-rate up to 6,000 rads/min. In these laboratories Miss B. Cullen has found no difference in the effectiveness of the electron beam in killing mouse ascites tumour cells (Landschütz strain) for dose-rates varying from 100 to 12,000 rads/min. Thus there is one *in vitro* system, at least, for which the results are like those for haemopoietic death in mice, in that maximum effectiveness is reached at a dose-rate less than 100 rads/min.

Table 1. COMPARISON BETWEEN EFFECTS OF DOSES GIVEN AT 100 RADS/MIN AND AT 6,000 RADS/MIN IN TWO FRACTIONS 10–14 MIN APART

Dose (rads)	Survival at 4 days							
	6,000 rads/min						100 rads/min	
	Single shot		Two fractions				Single shot	
			Interval 10 min		Interval shown in brackets			
	%	S.E.	%	S.E.	%	S.E.	%	S.E.
1,000	66	± 3	96	± 7			100	
1,040	42	± 3	81	± 4			80	± 5
1,000	31	± 3	46	± 5			77	± 5
1,200	18	± 3	22	± 4	8	± 6 (12′)	56	± 5
1,250	2	± 1			23	± 9 (12·5′)	41	± 9
1,300	12	± 4	21	± 5	4	± 4 (13′)	35	± 6
1,400	0		8	± 6	8	± 6 (14′)	13	± 3

From two reviews on dose-rate effects in mammals and mammalian cells[11,12] the impression might be gained that the effectiveness of radiation increases indefinitely with dose-rate, perhaps because data on dose-rates above 100 rads/min were not available when those reviews were written. The three sets of data discussed here show that effectiveness approaches a maximum level, and indeed the results of Lindop and Rotblat[5], on life-shortening in mice, show that effectiveness decreases with increasing dose-rate, above 500 rads/min. In any event, it could be expected that at very high dose-rates local oxygen depletion would start to play a part in reducing the effectiveness of radiation.

In the range of dose-rates we have used, namely 20–50,000 rads/min, our results do not fit the conclusion reached by Bateman *et al.*[11] that the effectiveness of radiation varies with the cube root of the dose-rate. The relationship between dose-rate and effectiveness must clearly depend on the kinetics of intra-cellular repair mechanisms, and, for the epithelial cells of the small intestine, a particularly rapid form of repair would seem to operate.

Use of Multiple Biopsies for the Study of the Cell Cycle of the Mouse Hair Follicle

IN investigating the cell proliferation of normal tissue in rodents individual animals have to be used for each experimental time interval and thus the problem of inter-animal variation is always present. This presents a particular problem when the cell cycle is investigated by the method in which the fraction of mitoses labelled is plotted against time[1].

This communication describes the use of multiple biopsies for the study of the cell cycle of the hair follicle in mice. It also describes a method of obtaining sections of skin for investigation prepared from autoradiographs using a cold microtome technique.

Adult Carworth Farms No. 1 female mice of the Argonne strain, about 90 days old, had their hair plucked from their back in order to induce the anagen phase of the hair cycle. Experiments were carried out 5 days and 10 days after this plucking. Although there is no diurnal cycle in the hair follicle[2], intraperitoneal injections of 20 μc. of tritiated thymidine were made at 10 p.m. in all animals.

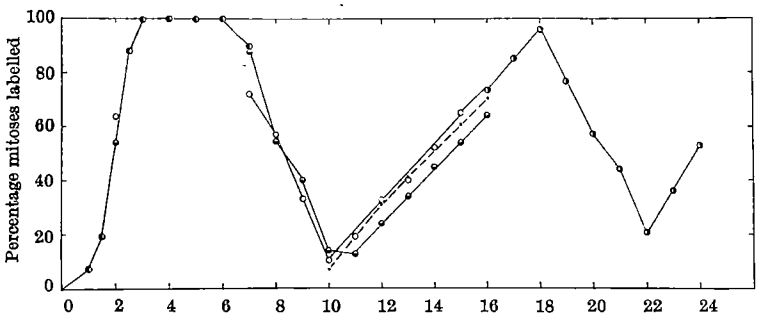

Fig. 1. Percentage of mitoses labelled as a function of time interval between injection of label and biopsy. O - - - O, Data taken from a mouse 5 days after plucking; O——O, data taken from several mice 10 days after plucking. The following symbols are used for individual mice. O, ◒, ◐, ◑

Because of the size of the mouse the largest number of biopsies carried out on one mouse was eleven. (In the rat it is possible to obtain thirty or more biopsies of the skin. Additional experiments on rats are in progress.) Ten days after plucking, one mouse was biopsied at 1, 1·5, 2, 2·5 and hourly intervals between 3 and 7 h after injection. Two mice were biopsied at 2 h and at hourly intervals between 7 and 16 h. Two mice were biopsied hourly between 16 and 24 h. One animal was biopsied from 10 to 16 h after injection of tritiated thymidine and 5 days after plucking.

The 4-mm punch biopsies were dipped in mounting fluid, frozen with a carbon dioxide quick freeze unit and sectioned on a cold microtome at −30° C. Sections 4μ thick were made, fixed in 4 : 1 methyl alcohol–acetic acid fixative and then taken through graded solutions of ethyl alcohol to water. The slides were dipped in Kodak *NTB* 3 liquid emulsion, dried and stored for 1 or 2 weeks in light-tight boxes, developed in *D*-19 developer for 1·5 min at 20° C, washed, fixed, and then stained with Mayer's haematoxylin and eosin. Labelled mitoses were counted in the region of the matrix in sections cut perpendicular to the skin, and longitudinal to the hair shaft. Proliferative cells in the dermal papilla and external root sheath were not counted.

Following the punch biopsy the skin healed well without appreciable scarring. The cold microtome sections proved to be an advantage from the point of view of convenience and speed of preparation, and yielded undistorted sections of the skin and subcutaneous structures with good nuclear detail. The autoradiographs were exposed for 1 and 2 weeks in order to establish whether there were false negative results following 1 week of exposure to the label. No difference was observed.

Fig. 1 is a composite curve constructed from the data obtained from the several animals biopsied at various time intervals after injection of tritiated thymidine. The presence or absence of label was scored for between 100 and 300 metaphases observed in the follicles available in each sample. In some follicles it was noted that there were clusters of cells which appeared to be in the same phase of the cell cycle. The composite curve so obtained showed that the percentage of mitotic figures labelled reached 100 per cent at 3 h and remained at this level for 3 h. Following this there was a rapid decrease in the percentage of mitoses labelled to a minimum between 10 and 11 h. Afterwards the curve of the percentage of mitoses labelled rises to a second maximum of 96 per cent at 18 h. A third minimum point of 20 per cent is reached at 22 h. From this curve an estimate of the *S* phase can be made from the time elapsed between the 50 per cent points (at 2 h and at 8 h) resulting in an *S* period of 6 h. A similar estimate of *S* is obtained between the 50 per cent points on the second cycle (at 14 and 20 h). If the duration of $G2 + M$ phase is considered to be the time from 0 h to the 50 per cent point, a figure of 2 h is obtained from these data. The duration of the cell cycle may be obtained as the time elapsed between homologous points on the curve; for example, between successive 50 per cent levels. The time elapsed between the 50 per cent point on the first ascending limb to the 50 per cent point on the second ascending limb gives a cell cycle of about 12·5 h. If the time elapsed from the origin of the first ascending limb to the beginning of the second ascending limb is taken, a cell cycle of about 9·5 h is obtained. If the duration from the second minimum at 10·5 h to the third minimum at 22 h is measured, this yields a cell cycle of 11·5 h.

It is of interest that there is a gross correlation between the data from various animals so that similar results were obtained at the same time-interval irrespective of the number of biopsies that had previously been carried out. The percentage of mitoses labelled at intervals between 10 and 16 h was similar for the anagen hair follicle at both 5 and 10 days after plucking. This suggests that there is little or no change in the cell cycle during this period of anagen.

The data obtained at 5 days and 10 days differ from previously published data in that there is a plateau on the first curve and there is less clear-cut dampening of the curve in the first 24 h than was previously reported by Cattaneo[3].

From these results it would seem that there is little inter-animal variation; however, it remains to be seen whether this will be so under other conditions. This method is being extended to study the whole period from 0 to 30 h in the hair follicle of rats. This technique may be useful in investigations in which comparisons are made of the curve of the percentage of mitoses labelled under various conditions such as radiation, changes in temperature, and the like.

This investigation was supported in part by the U.S. Public Health Service and in part by the U.S. Atomic Energy Commission.

Malonaldehyde from the Autoxidation of Methyl Linolenate

THE pink colour obtained when 2-thiobarbituric acid (TBA) reagent is heated with foods or tissues has often been used as an index of lipid oxidation. It has been assumed that malonaldehyde (MA) is responsible because the colour obtained with oxidized food or fat has the same absorption spectra as that from MA[1,2]. Recently, however, Saslaw *et al.*[3] and Saslaw and Waravdekar[4] irradiated fatty acids in air, separated by thin-layer chromatography several different substances which reacted positively with TBA, and suggested that none of these was MA, thus casting some doubt on the previous assumption. The present experiments show that the principal TBA-reactive substance produced during the air oxidation of methyl linolenate is indeed MA.

A column (2 cm × 75 cm) was prepared from 'Sephadex *G*-10' with 0·05 M *tris*-HCl buffer containing 0·1 M sodium chloride, *p*H 7·4. 1 ml. of 2×10^{-4} M MA[5] in buffer was added to the column and 250 fractions (1 ml.) were collected at a flow rate of 1 ml./1·5 min (Spinco 'Accu-flo' pump). 1 ml. of aqueous 0·02 M TBA had been added to every other test-tube in the fraction collector. The void volume (*Vo*) of the column was determined with blue dextran 2000. The fractions with TBA reagent were maintained at room temperature for 22 h in order to develop the colour, and then the absorbance was measured at 532 mμ. Fractions which had not had TBA reagent added were examined for their ultra-violet absorption spectra: the results are shown in Fig. 1. The elution volume (*Ve*) of MA was 148 ml. with *Vo*, 80 ml. The ratio $A_{532\ m\mu}/A_{267\ m\mu}$ was 2·4 (ref. 5) for the MA peak.

5 g of methyl linolenate (Mann Research Laboratories) in a 10 ml. beaker were stirred continuously in air at 40° for 16 h. 2 ml. of distilled water were added to the rancid ester and the whole was mixed for 5 min. The water extract ($A_{532\ m\mu} = 52$) was separated by centrifugation and subjected to fractionation as already outlined. Three TBA-positive peaks were detected as shown in Fig. 2. Peak No. 1 was not further characterized. Peak No. 2 was identified as MA by the following criteria: (1) The elution volume ($Ve = 148$ ml.) was the same as that of authentic MA. (2) The ratio $A_{532\ m\mu}/A_{267\ m\mu}$ was 2·4. (3) On acidification to *p*H 3, the absorption maximum was shifted from 267 to 245 mμ; the ratio ($A_{267\ m\mu}/A_{245\ m\mu}$) was 2·3. A similar change occurs with MA, and this can be attributed to the transformation of enolate anion to the *s-cis* chelated form[5]. Although MA accounted for about 90 per cent of the total TBA-reactive substances in this experiment, the concentration in the peak fraction was too low to give a positive ferric chloride test[4]. Saslaw *et al.*[3] had used this criterion as one argument against the presence of MA in their extracts. Peak No. 3, which represented about 8 per cent of the total TBA-reactive substances, had an absorption spectrum with maximum at 230 mμ independent of *p*H. The material in the three peaks gave identical visible absorption spectra with TBA.

Saslaw and Waravdekar[4] demonstrated the presence of two TBA-reactive substances in fatty acids that had been irradiated with ultra-violet light, but only one from substrates irradiated with cobalt-60. Fränz and Cole[6] isolated four TBA-reactive substance peaks on gas chromatograms of methyl linolenate that had been irradiated with ultra-violet light; however, they were unable to identify the substances concerned. According to Thiele and Huff[7], TBA-reactive substances may result from both enzymatic and non-enzymatic oxidations of liver fractions.

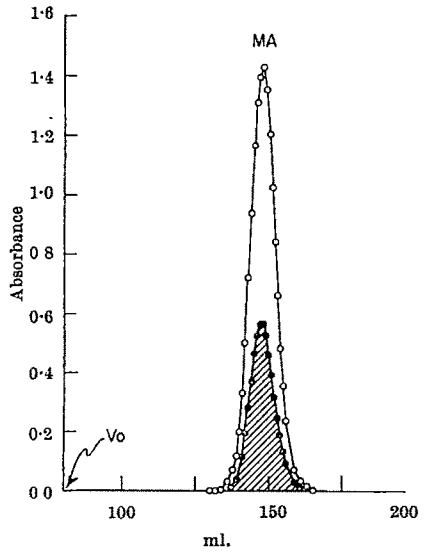

Fig. 1. Elution of malonaldehyde (MA) (1 ml. of 2×10^{-4} M) from 'Sephadex *G*-10' column (2 × 75 cm) with 0·05 M *tris*-HCl buffer containing 0·1 M sodium chloride, *p*H 7·4. ○——○, 532 mμ; ●——●, 267 mμ

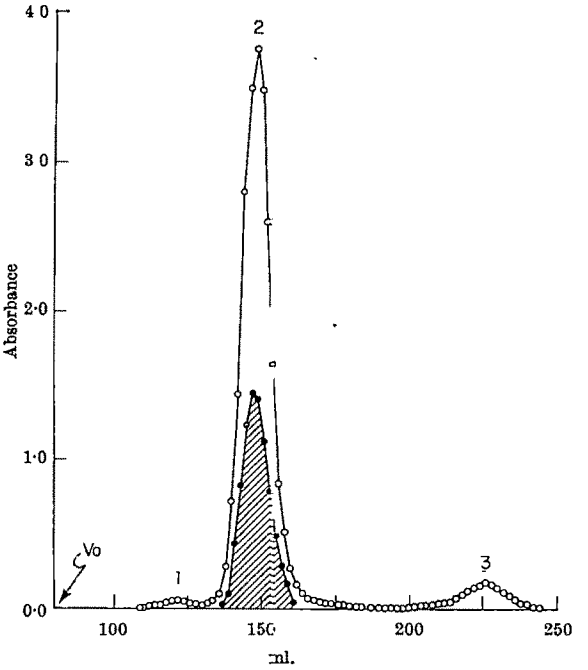

Fig. 2. Elution of water extract of oxidized methyl linolenate from 'Sephadex *G*-10' column. ○——○, 532 mμ; ●——●, 267 mμ

Saslaw *et al.*[3] reported that MA, obtained by distillation from the bisulphate addition product, migrated only slightly and with tailing in thin-layer chromatography. The solvent used was *n*-butanol–dichloromethane–water, 20:4:1. These results were confirmed in this experiment.

However, when MA which had been prepared by acid hydrolysis[5] of malonaldehyde *bis*(-diethyl acetal) was used two TBA-positive spots could be separated by the same thin-layer chromatography technique with silica-gel *G* (E. Merck *AG*, Darmstadt, Germany). The main spot (R_F, 0·77) clearly separated from the other which migrated slowly (R_F, 0·16) with tailing. When the MA solution (10^{-3} M) was heated at 90° for 15 min the original principal spot disappeared and the pink colour of the second spot became more intense. These observations suggest that either polymerization or some other as yet unidentified change may occur during the application of MA to the thin-layer chromatography plate even at room temperature or during heating of MA solution, or during distillation of the bisulphite addition product.

In any event, MA seems to be the single most important TBA-reactive substance of air-oxidized methyl linolenate, The identity of the other TBA-reactive substances is under investigation.

BIOLOGY

Deviant Index : a New Tool for Numerical Taxonomy

A MEASURE of the extent to which an individual differs from the norm of a population, taking many attributes into account, would often be useful in numerical taxonomy. With metrical attributes, the distance in an attribute space between the point representing the individual and the centroid of the population would serve such a purpose[1]. Similar measures have been proposed for binary attributes, but no fully appropriate way of combining binary and metrical attributes has been proposed, and no suggestion has been made for the inclusion of ordered non-metrical attributes except by allotting arbitrary metrical equivalents to the class values. Significance tests for these distance measures have proved elusive except in the multivariate normal case; but a significance test is often required as a guide to taxonomic action. The index proposed here not only combines information from all types of attributes, but also provides a direct test of significance.

When dealing with a metrical attribute, the natural choice for the norm is the arithmetic mean (unless the distribution is very skew, in which case one might, for example, prefer the geometric mean), and the deviant index for a particular value of such an attribute (as we will call the proposed index of deviation from the norm) is simply the proportion of the population further from the mean than the individual in question.

For ordered but non-metrical attributes, the appropriate choice for a norm seems to be the median value. Here, distance from the median has no meaning, but one may fit classes above and below the median together in accordance with the proportion of the population they contain. Thus, a class is considered to be further removed from the norm than a class on the other side of the median if, together with the tail of the distribution beyond it, it contains a smaller proportion of the population than the class in question with its tail. If the proportions in the successive classes are p_i $(1 \leqslant i \leqslant n)$, with m as the median class, the deviant index for this attribute for an individual with a value x $(< m)$ is thus:

$$D_x = \sum_{i=1}^{x} p_i + \sum_{i=y}^{n} p_i$$

where y is defined by:

$$\sum_{i=y}^{n} p_i \leqslant \sum_{i=1}^{x} p_i < \sum_{i=y-1}^{n} p_i$$

For a purely qualitative attribute, the only possible choice of norm seems to be the most frequent value. No natural ordering of classes around this norm suggests itself, but, as in the similarity index already proposed[4], it seems reasonable to use the proportion of the population in the class for this purpose, the rarer class values being considered to represent wider deviations from the norm than the commoner values. Thus, in this case:

$$D_x = \sum_{i \in S} p_i$$

where:

$$S = \{i : (p_i \leqslant p_x) \wedge (1 \leqslant i \leqslant n)\}$$

When all the D_x for all m attributes have been calculated, they need to be combined to give an overall value $\mathfrak{D}_x$ for the deviation of individual x from the population norm. This can be done by Fisher's[2] method:

$$\chi^2_{2m} = -2 \sum_{i=1}^{m} \ln D_i$$

or the modification with a correction for continuity introduced by Lancaster[3]. $\mathfrak{D}_x$ is then defined as the probability of the χ^2 value obtained, or a greater one.

The analogy between this deviant index and the similarity index described earlier[4] is clear. The latter is the complement of the probability that a pair of individuals with a random selection of attributes would differ as greatly as the pair in question. This amounts to the complement of a deviant index calculated not as above for a single individual but for the deviations from the norm common to a pair. Generalization of this concept to larger sub-sets can be envisaged.

The deviant index proposed here could clearly be used for deciding whether, at a given significance level, a certain individual should or should not be included in a proposed taxon, or for a decision between two possible taxa to which an individual could be ascribed.

Programmes for computing $\mathfrak{D}_i$ for all individuals in a set have been written in *Fortran II* for the IBM 1620_3 computer, and are available on request.

I thank Mr. D. W. G. Moore for facilities in the Computing Centre of the University of Western Australia.

Note. While this communication was under editorial consideration, Hall's note[5] about a proposed 'peculiarity index' was published. He, too, was concerned to express the extent to which different individuals deviated from the norm of a set, and the purposes of the two proposed indices are very similar. The peculiarity index, however, covers binary attributes only, and is unstandardized, so that its magnitude depends on the number of individual (taxa) in the set under consideration. It may be defined as:

$$P = \frac{Nm}{2} - N \sum_{i=1}^{m} q_i$$

where N is the number of individuals (taxa), m the number of attributes. and:

$$q_i = \min \{\tfrac{1}{2}, p_i\}$$

p_i being the proportional frequency of the observed value of the ith attribute.

Present Status of Known Populations of the Vendace, *Coregonus vandesius* Richardson, in Great Britain

AT least thirteen different populations of *Coregonus* have been recorded in Great Britain and Ireland; four of these were of the Vendace, *Coregonus vandesius* Richardson. The status of these four populations was discussed by Regan[1], who divided them into two sub-species: the Lochmaben Vendace, *C. vandesius vandesius*, from two lochs near Lochmaben in Dumfriesshire; and the Cumberland Vendace, *C. vandesius gracilior*, from two lakes in Cumberland. The most recent revisions of the genus in Europe[2-4] agree that *C. vandesius* in Great Britain is equivalent to *C. albula* (L.) in Europe, though little evidence is brought forward to prove this. Practically nothing original has been published on the species in Great Britain since 1908 (ref. 1), and, in fact. other than very occasional specimens found accidentally at the water's edge, the species has not been taken in any numbers since the beginning of the century. Because of this, and the fact that several unsuccessful attempts have been made in recent years to capture specimens, many workers have assumed that this fish is extinct in Great Britain, or almost

so. Thus it was stated in 1958 of the Lochmaben vendace, "Cette forme doit être considérée comme éteinte"[4].

There has been no recent revision including all the populations of *Coregonus* in this country, and in 1963 I started making collections of material for this purpose. In April 1964, netting was carried out in the Castle Loch and in the Mill Loch near Lochmaben, from both of which *C. vandesius* had been previously recorded[5]. No fish was caught on that occasion. A second attempt, however, was made in August 1965, and this time thirty-nine specimens were taken in the Mill Loch. None was taken in the Castle Loch, which is now extremely eutrophic owing to the discharge into it of the Lochmaben sewage effluent; it may well be that the species is extinct there now. (The possibility of specimens occurring in it cannot be ruled out, however, because the outflow from the Mill Loch eventually runs into the Castle Loch, and an occasional fish may pass down by this route.) In September 1965 similar netting was carried out in the recorded localities for the species in Cumberland, at Bassenthwaite and Derwentwater. Both of these lakes were found to have thriving populations of *C. vandesius*, 225 specimens being taken in Bassenthwaite and eighty-four in Derwentwater. Unfortunately many of the latter fish were badly damaged in the nets by eels *Anguilla anguilla* (L.).

This material is being retained for future study and comparison with other British and Irish *Coregonus*. It is of great interest, however, to note immediately that the species is still present in at least three localities in Britain, and in two of them at least in considerable numbers—sufficient to enable a very useful and exciting study of their ecology to be made there. The fact that thriving populations such as these can remain undetected over long periods in bodies of water where they are known to have occurred makes it seem quite feasible that there may well be unknown populations of this and other forms of *Coregonus* in some other British lakes. It is hoped that several of the most likely of these may be investigated in the next few years.

I am grateful to Mr. J. F. Flannagan and to my wife, Kathleen, for help with netting in Dumfriesshire, and also to Mr. H. C. Gilson and his staff at the Windermere Laboratory of the Freshwater Biological Association for assistance in Cumberland.

Photoperiodism and Fecundity in *Plutella maculipennis* (Curt.)

INVESTIGATIONS on the population dynamics of the diamondback moth, *Plutella maculipennis* (Curt.), at Ottawa[1,2] revealed that its numbers were regulated by factors affecting the adult stage. One of the more important of these was fecundity of the insect, which declined during the season. More recent findings, communicated here, indicate that fecundity is influenced by photoperiod.

The diamondback moth is a cosmopolitan species, occurring almost everywhere where cruciferous crops are grown. In temperate climates it has two to seven generations per year and overwinters most often in the adult stage[3,4]; in the warmer parts of the world it breeds without interruption[5,6]. There is neither true nor facultative diapause, and in the northern parts of its range the moth succumbs to the frost annually. At Ottawa, infestations arise each year from adults that overwinter in the central and southern United States and migrate north in the spring as the weather moderates[7]. There are usually four generations per year but sometimes as many as six.

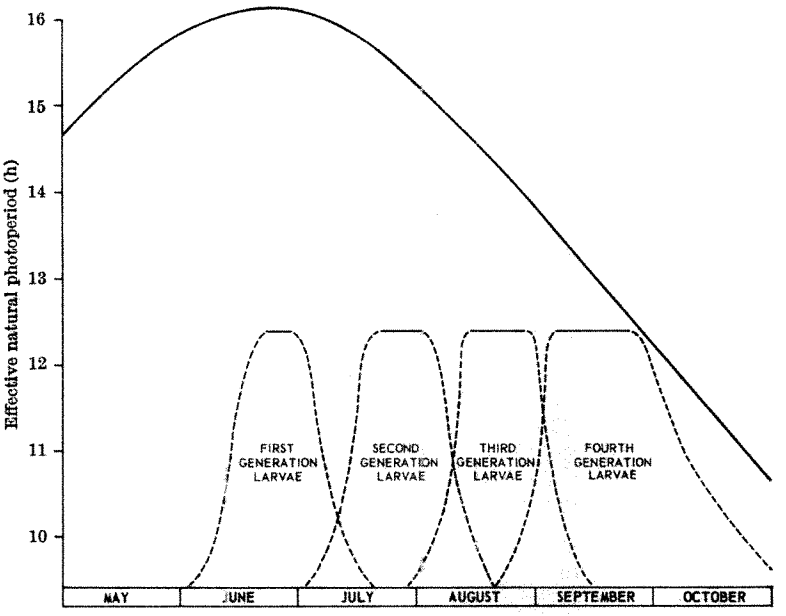

Fig. 1. Effective natural photoperiod at Ottawa (latitude, 45° 34′) in relation to seasonal activity of *P. maculipennis*, 1960–64

In the population studies, life tables have been compiled for thirty-two generations since 1958, and fecundity in each generation has been measured since 1960. Table 1 shows that the reproductive rate declined gradually in successive generations each year. To shed light on this phenomenon, we plotted photoperiod in relation to seasonal activity of the insect at Ottawa for the past 5 years. Fig. 1 shows that larvae in each generation were exposed to different lengths of day, the effective natural photoperiod (length of day as measured from sunrise to end of civil twilight—solar elevation, −6·00°) diminishing gradually from 16·1 to 13·0 h or less. These data suggest a causal relationship between photoperiod and fecundity of the insect. To test this hypothesis, progeny of generation 5, 1964 (photoperiod 11 h, fecundity 32), were reared on cabbage leaves in the laboratory at 20° C. Batches of larvae were placed in a divided rearing chamber designed to provide both a 12-h and 16-h period of light. Sixteen adults (eight males, eight females) from each light regime were liberated in 2 × 2 × 2 ft. screened oviposition cages containing young cabbage plants. The moths were fed on a solution of sugar-water, given a 16-h photoperiod, and held at a temperature of 25° C, relative humidity 70 per cent. The test was replicated twice. Differences in egg production (Table 2) provide experimental evidence of a photoperiodic effect.

Table 1. NUMBERS OF EGGS LAID PER FEMALE IN SUCCESSIVE GENERATIONS OF *P. maculipennis*, OTTAWA, ONTARIO, 1960–64

Year	Generation 1	2	3	4	5
1960	187	119	97	14	—
1961	192	108	129	20	—
1962	189	198	151	80	—
1963	144	115	98	60	30
1964	164	164	125	59	32
Mean	175	141	120	47	31

Table 2. NUMBERS OF EGGS LAID BY *P. maculipennis* AFTER LARVAL EXPOSURE TO PHOTOPERIODS OF 12 AND 16 H

Photoperiod	Replicate *A*	Replicate *B*	Mean per female
12 hours	260	331	37
16 hours	544	639	74

The relationship between photoperiod and fecundity in *P. maculipennis* appears to be analogous to that between photoperiod and diapause in other insects, and the decline in its fecundity may, in fact, represent incipient reproductive diapause. Short photoperiods frequently promote development of the insect fat body instead of the ovaries[8,9]. This process is accompanied by other body changes that result in cold-hardiness. Thus, decreasing day length may enable the moth to survive moderate frosts such as occur at the northern limits of its overwintering distribution.

Experiments are now in progress to determine the seat of photoperiodic induction and possible temperature-photoperiod interactions.

Migration of Epithelio-muscular Cells in *Hydra*

RECENT reports have directed attention to the part played by connective tissue in the histogenesis and morphogenesis of epithelial tissue[1]. In *Hydra* the possibility that the acellular mesoglea influenced the differentiation of cells almost suggests itself. It is widely held that epithelio-muscular cells in the epidermis and digestive cells in the gastrodermis undergo a net movement down the body[2] and change in certain cytological and physiological details as a function of the region in which they temporarily reside[3].

Among the possible ways connective tissue could be influencing adjoining tissues are two that appear to be mutually exclusive, if defined in a strict sense: (1) connective tissue could act as a substratum for cell migration or (2) as an adhesive, a 'cement', holding the cells in one place. The object of our experiment was simply to determine whether the epithelial cells were capable of disassociating themselves from given positions on the mesoglea and migrating to other positions.

Hydra viridis of both green and white (bleached) varieties were used. The experiment consisted of placing a ring of both cell layers and mesoglea, cut from a normal white animal, over the isolated gastrodermis and accompanying mesoglea, taken from a green animal stripped of its epidermis. The green colour derives from the presence of an algal symbiont found exclusively in the gastrodermal piece. Such algae allowed us to distinguish between the two sorts of gastrodermal cells in histological sections. The composite animals were fixed about 2 h after grafting. Our object was, ultimately, to determine if epithelio-muscular cells could be found overlying gastrodermal cells containing the algal symbiont. Such epidermal cells would have to have broken whatever contacts they originally had with the mesoglea in the ring and migrated to their new positions.

A mildly acidic solution[4] (*p*H 2·5) was used to loosen the attachment of the epidermis to the mesoglea in order to obtain the green gastrodermal piece. Animals were placed in the solution for about 1 min during which the tentacle ring and adhesive foot were cut off. The gastrodermis, surrounded by the mesoglea, thereupon stretched into a cigar-shaped piece while the epidermis contracted into a thick annulus. The two cell layers could then be separated with the aid of forceps. The gastrodermis was placed in a small petri dish containing a solution known to support the life of isolated gastrodermal cells[5].

The petri dish had been prepared with a slant of paraffin over half the bottom and a piece of filter paper over the other half. A normal animal of the white variety was placed into the dish and a ring cut from its mid-gastric region. This ring was stretched over a pair of forceps until it could accommodate the isolated gastrodermal piece. The former was slipped over the latter and set into place at about its midpoint. The paraffin slant provided a working surface; the isolated gastrodermal pieces adhered to the paraffin sufficiently well not to slide around while the rings were slipped over them. The mesogleas were, however, damaged by prolonged contact with the paraffin. The composites were therefore transferred to the half of the bottom of the dish covered by filter paper; the paper proved to be a more suitable substratum on which the composites could rest since the gastrodermal pieces did not adhere to it. Neither glass nor agar was as suitable as either paraffin or paper in their respective roles.

Following grafting, the rings seemed to expand and encompass the isolated gastrodermal pieces. The grafted animals were then fixed in Bouin's fluid, and later dehydrated in alcohol and embedded in paraffin. Sections were cut at 6μ and stained with the periodic acid-Schiff technique followed by toluidine blue, or by aqueous light green and carmine[6].

In all, eighteen grafts were made and gave unambiguous results; a continuous epidermis could be seen overlying both algae-less gastrodermal cells and algae-rich gastrodermal cells. Such a free edge of migrating epidermis (*E*) is seen in Fig. 1. Interstitial cells accompanied the migrating epithelio-muscular cells. Mitotic figures were rarely seen in the epidermis or in any other part of these preparations.

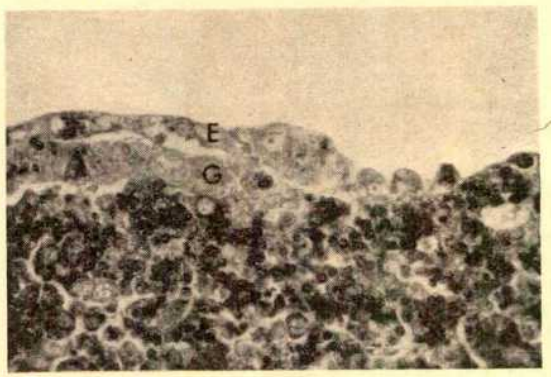

Fig. 1. Longitudinal section through part of grafted white ring and host green gastrodermis. The algal symbionts in the latter stain intensely with periodic acid-Schiff and are seen here as black granules. The gastrodermal cells derived from the ring (*G*) lack these granules. The epidermis derived from the ring (*E*), likewise lacking these granules, covers both the gastrodermal cells of the ring and some of those of the isolated gastrodermis. (×300)

Often, extracellular spaces were seen between the epidermal cells and the mesoglea in the original ring. These spaces can be seen in Fig. 1, and suggest that the cells are undergoing a sort of mobilization for migration. In addition, the epidermis, particularly near the edge of the ring, seems to be thinner than normal, suggesting that the cells are stretched.

It is not possible, in most of our sections, to identify the mesoglea originally accompanying the isolated gastrodermal piece even though the mesoglea brought along with the ring was often conspicuously stained.

However, the latter never extended beyond the edge of the gastrodermis of the ring. Possibly the difficulty was due to our having dissolved a carbohydrate moiety of the mesoglea in either the solutions used for isolating or maintaining the gastrodermal piece, or in that used for fixation. The outer surface of the gastrodermal piece remained smooth throughout the experiment, suggesting that the mesoglea, or at least its structural component, was still present. Moreover, what appeared to be a mesoglea could be dissected away from completely isolated gastrodermal pieces even 12 h after removing the epidermis.

Clearly, the question of whether the epithelio-muscular cells can migrate has been answered positively. These cells, originally adjacent to digestive cells lacking algae, evidently migrated and came to overlie other digestive cells containing algae. At least under the experimental conditions described here the mesoglea of *Hydra* permits cells to migrate over it, and does not act as a 'cement' prohibiting cell migration.

This investigation was supported by grants from the National Science Foundation and the U.S. Public Health Service, and while the senior author was a post-doctoral fellow of the National Institutes of Health in the laboratory of Dr. A. L. Burnett.

New Method for studying Mammalian Melanocytes *in vivo*

MOST reports on the morphological changes of mammalian melanocytes associated with alterations in melanogenesis have been based on observations made either with a split skin preparation or by the use of tissue culture. The former method involves the use of trypsin[1,2] or other chemical agents[3] or the use of a freezing microtome[4] to bring about separation of the epidermis from the dermis. Tissue culture of melanocytes using the technique described by Cruickshank[5] requires that the epidermis be broken down into individual cell units in the early stages, and this results in a dissolution of the melanocyte keratinocyte relationship. Furthermore, the continued growth of the culture is dependent on the presence of an artificial medium[6]. The method which is described here allows the observer to study for hours, days, months or even years the activity of a single melanocyte or groups of melanocytes in their natural undisturbed environment. The method is simple and is particularly suited to time-lapse photography.

Black *C57* mice, 3–4 weeks old, are commonly used. The animals are anaesthetized with 'Nembutal' given by the intraperitoneal route (80 mg/kg body-weight). The hair of the pinna of the ear is removed with a commercial depilating agent ('Neet'). The cream is applied for about 5 min and the hairs are washed off. If the cream is allowed to act for too long it will produce an inflammatory reaction. The ear is then moistened with glycerine which is gently massaged into the epidermis. The glycerine improves the optical properties of the epidermis so that the melanocytes can be more clearly seen. The pinna is placed dorsal surface downwards on to a glass slide and the pinna edges are glued in position with rubber cement. (Rubber cement has the advantage that the ear can be separated from the slide at the end of the period of study without damage to the epidermis.) The rest of the animal is then loosely tied down to the microscope stage leaving the proximal end of the pinna slack. The latter precaution is important since it reduces the possibility of the respiratory movements and heart beat being conducted to the slide holding the pinna. The microscope objectives (× 10, × 25 and × 40) can then be lowered on to the pinna and further glycerine is added to immerse the lens. Having selected a particular field this may now be observed continuously for a number of hours. Continuous anaesthesia is facilitated by leaving the 'Nembutal' syringe needle in the peritoneal cavity. This allows the drug to be administered as required without disturbing the animal. We have found that open ether plus 'Nembutal' is a satisfactory combination when the melanocytes are to be observed for a long period of time. If repeated studies of the same melanocyte are to be made at long intervals, then either the ear skin must be marked at the site or the general topography of the blood vessels and hair follicles in that region carefully noted.

This method is at present being used by one of us (R. S. S.) in the study of the influence of hormones and other agents on the morphology of mammalian melanocytes. It is also being used to observe the circulatory and follicular changes which accompany the hair cycle (A. F. S. and H. B. C.)[7,8]. The wing and interfemoral membrane

of the bat can similarly be used for the direct observation of melanocytes by transmitted light[9].

MICROBIOLOGY

Transduction in *Proteus morganii*

PHAGES capable of generalized transduction among strains of *Proteus mirabilis* have been described[1–3]. *Proteus morganii* differs in many respects from *P. mirabilis*[4] including a growth requirement for pantothenate and *l*-cystine in addition to the nicotinic acid requirement of the latter organism[5]. Several gene loci of these two species are being investigated in this laboratory. With *P. mirabilis* biochemical work is complemented with genetic (transductional) studies. In order to do the same with *P. morganii* it was decided to search for transducing phages active on this species.

The seventeen temperate *P. morganii* phages previously isolated[4] from an equal number of *P. morganii* strains[6] were investigated. The screening test used was the ability of phage to transduce a one-step marker (*str-r*) controlling resistance to 1 mg streptomycin/ml. from a mutant to the wild-type host. The materials and methods used for this part of the investigation were those previously used[1]. The minimal medium used was that of Porter and Meyers[5] solidified when necessary by the addition of 1·5 per cent agar. Under these conditions the growth factors *l*-cystine, calcium pantothenate and nicotinic acid were added to the agar at 47° C just before the plates were poured. Auxotrophic mutants of *P. morganii* strain N.C.T.C. 2815 were selected by the penicillin method after ultra-violet irradiation of washed suspensions of the organism to about 1 per cent survival. With transductions of prototrophy to auxotrophic mutants 0·05 ml. of the adsorption mixture (constituted as for streptomycin transductions) was plated on minimal medium 15 min after mixing. Colonies were scored after 4 days at 37° C.

One of the seventeen phages was capable of intra-strain transduction of the *str-r* marker. This phage (named *M*) was derived from *P. morganii* strain N.C.T.C. 10041 by ultra-violet induction of an overnight broth culture. Phage *M* is strictly inducible. No phage was detected in supernatants of an unirradiated broth culture tested at intervals for 10 days. The host of the phage is *P. morganii* strain N.C.T.C. 2815 on which it forms markedly turbid plaques. The transduction rate of the *str-r* marker from mutant 2815 *str-r* to wild-type 2815 is 6–9 × 10^{-6}/phage particle adsorbed. The transducing ability of phage *M* is completely abolished by prior addition of 0·1 ml. pure phage antiserum which reduces the phage titre from 7 × 10^{9} plaque forming units/ml. to 8 × 10^{4} P.F.U./ml., but it is unaffected by treatment of the lysate with deoxyribonuclease. A large number of strains of all the genera of the family Enterobacteriaceae were tested for susceptibility to the phage with negative results. The infectivity of phage *M* is Ca^{++} independent and undergoes 90 per cent inactivation at 60° C for 15 min and 99·9 per cent at 70° C for the same period of time. The structure of the phage was examined[7] before its transducing potential was recognized. It resembles the *Salmonella* transducing phage *P22* (ref. 8), but its overall dimensions are slightly smaller and it has a collar around the short neck.

Mutants of strain N.C.T.C. 2815 with individual growth requirements for histidine, tryptophan, isoleucine plus valine, ornithine and adenine were isolated. Phage lysates of the wild-strain transduced all the foregoing auxotrophs to prototrophy at rates similar to the *str-r* transductions. Phage *M* is thus capable of generalized transduction. Particular attention was given to the detection of abortive transductants, but none of the systems yielded any[2]. All prototrophic transductant clones examined so far are lysogenic and yield no *str-r* transductants when used as recipients for phage prepared on 2815 *str-r*.

Thermophilic Micro-organisms from Rotting Maize

TEMPERATURES of up to 58° C were observed within a 20-ton stack of maize which accidentally became wet in Ado-Ekiti, Western Nigeria.

Samples collected deep in the stack were plated out on Difco corn meal agar (for fungi) and on glucose-yeast extract agar[1] (for bacteria) and incubated at 55° C.

Three fungi, *Thermomyces lanuginosus* Tsiklinsky (I.M.I. 110803), *Mucor pussilus* Lindt (I.M.I. 110805) and a possibly new species of *Rhizomucor* (I.M.I. 110804), were regularly isolated. The last-mentioned isolate is at present being studied.

Three strains of spore-forming bacteria and one of an actinomycete were also obtained. The morphological and physiological properties of the bacteria (N.C.I.B. 9667–9669) suggest that they are strains of *Bacillus licheniformis* (Weighman) Chester *emend. Gibson*, while the actinomycete (N.C.I.B. 9670) belongs to the genus *Thermoactinomyces* and is probably *T. thermophilus* Krassilnikov.

Table 1 illustrates the temperature requirements of the isolates on the aforementioned media.

Table 1

	Minimum (° C)	Optimum (° C)	Maximum (° C)
Thermomyces lanuginosus	28–32	45–50	58–60
Mucor pussilus	21–23	40–45	50–53
Rhizomucor sp.	25–30	45–53	60–61
Bacillus licheniformis	27–30	38–45	58–59
Thermoactinomyces sp.	30–35	45–47	59–61

All the isolates hydrolysed starch; none 'cleared' chitin or cellulose agar[1]. The bacteria and the actinomycete visibly dissolved finely ground particles of maize incorporated with mineral salts into agar; the fungi did not.

These isolates have been recorded in other parts of the world in various habitats, and especially in decomposing vegetable matter[2,3]. A new species of *Thermomyces* was recently isolated from self-heating oil-palm produce in Nigeria[4].

'Polyspheroids' from American Soils

A RECENT electron microscopic examination of a soil sample from Texas revealed the presence of unusual forms of micro-organisms. As a result, a more extensive survey of North American soils was undertaken, to find whether the so-called 'polyspheroids' were more widely distributed, or restricted to limited areas.

Soil samples from New Jersey, Louisiana, Florida and New York yielded, on inoculation into selective culture media, mixed microbial cultures that were examined by electron microscopy. Among several unusual forms observed, some closely resembled the 'helicoidal polyspheroids' described by Nemec and Bystricky[1,2] and Bystricky and Nemec[3] and seemed to be identical to those encountered from Texas. These unusual forms (Fig. 1) were of the general size of bacteria, about 0·5μ by 0·6μ–1·5μ. Electron micrographs revealed several strongly contoured, longitudinal rows of roughly spherical sub-units, with diameters of about 0·1μ, in a maize cob-like arrangement (Fig. 2). The sub-units were not detected by light microscopy. A helicoidal arrangement of the sub-units was suggested in some instances, but was less pronounced than in the forms described from Europe[1–3].

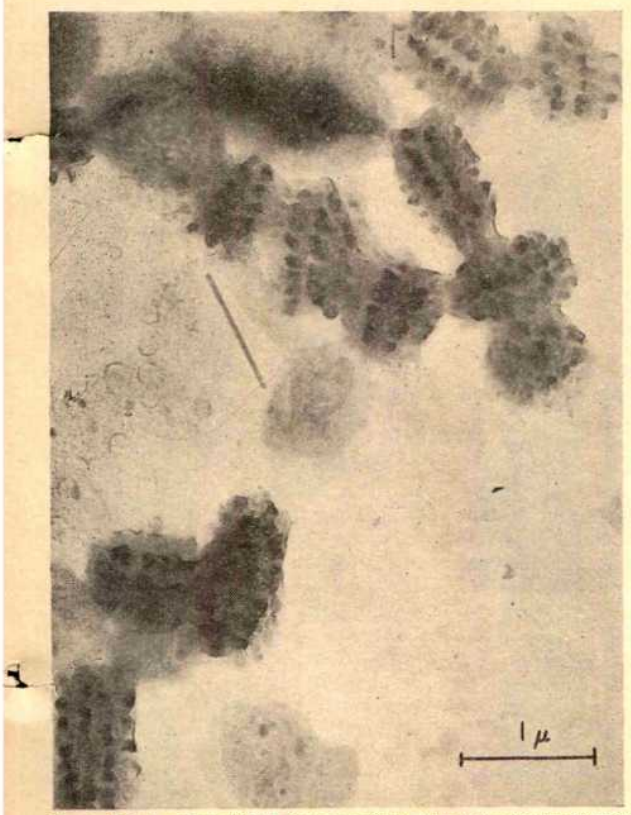

Fig. 1. Mixed culture of soil micro-organisms, with several polyspheroids

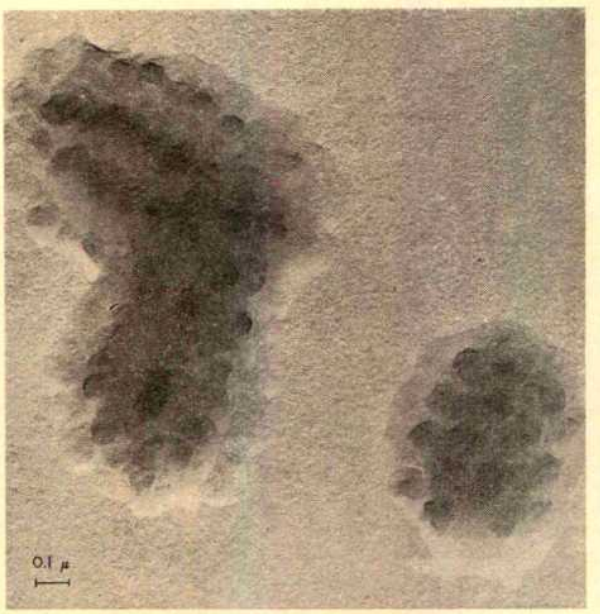

Fig. 2. Polyspheroids, at higher magnification

As to the nature of the observed forms, the following interpretations are suggested: (*a*) they might represent a stage in the normal or abnormal life cycle of a bacterium, or of some other soil micro-organism; (*b*) they could be a hitherto undescribed soil bacterium, of unusual morphology; (*c*) they might belong to a new, hitherto undescribed group of micro-organisms. The latter interpretation is the most challenging, and seems very likely at present.

Attempts are at present being made to obtain enriched mixed cultures with a higher percentage of these forms, and it is hoped eventually to gain pure cultures of the micro-organisms. Their tentative designation as polyspheroids will be maintained.

This investigation was sponsored in part by a grant from the U.S. National Science Foundation and by a U.S. Public Health Service grant from the Institute of Allergy and Infectious Diseases, Bethesda, Maryland.

GENETICS

Genetic Control of Lipid Metabolism in *Tribolium*

GENE blockages of protein synthesis in micro-organisms are now classical to the study of gene action. While a few metabolic defects are well known to be under genetic control in higher organisms, including man, experimental evidence of genetic control of lipid metabolism is not known. Therefore, discovery of a gene in *Tribolium* which apparently influences the metabolism of fatty acids may be of general interest.

The mutant gene arose in a quantitative genetic study of selection response of 13-day larval weight in *Tribolium*

castaneum when cultured under two levels of nutrition[1]. Initially, the base population's 13-day larval weight on the 'good' diet (percentage composition: vitamin premix 10, soybean meal 17, corn (maize) meal 58, dried brewers' yeast 10, and corn oil 5) was about twice that on the 'poor' diet (percentage composition: vitamin premix 3, soybean meal 11, and corn meal 86). However, after twelve generations of selection for small 13-day larval weight on the 'good' diet, the average weight in one experimental population (GS_2) was considerably greater on the 'poor' diet than on the 'good' diet. Typical growth of the GS_2 population on the two diets in comparison with the base population is illustrated in Table 1. It should be noted here that the quantitative trait 13-day larval weight has been studied using biometrical techniques and has also been investigated with the intention of specifically identifying the genetic basis of selection. The importance of the latter approach has been emphasized by Thoday[2].

An analysis of the influence of the components of the 'good' diet on larval growth revealed corn oil to be the inhibiting factor for the GS_2 population. The population grown in the absence of corn oil showed normal growth. Inheritance investigations revealed the observed sensitivity to corn oil to be inherited as a single autosomal recessive gene and is referred to as *cos* for corn *oil sensitive*.

The action of *cos* suggests that the system (or systems) of corn oil metabolism is altered in homozygous *cos*/*cos* individuals. To investigate experimentally the possibility of differential utilization of fatty acids in the sensitive (*cos*/*cos*) and normal (+/+) genotypes, larvae of these two types were grown on 'good' and 'standard' (95 per cent wheat flour, 5 per cent yeast) media for 13 days, then washed free of media and analysed by gas-liquid chromatography. The relative percentages of C_{16}—C_{18} fatty acids in a representative analysis are reported in Table 2. Fatty acids with less than 16 or greater than 18 carbons occurred only in trace amounts and no trend as to diet or genotypes was apparent.

Table 1. GROWTH OF THE GS_2 AND BASE POPULATIONS OF *Tribolium* ON 'GOOD' AND 'POOR' DIETS AS MEASURED BY 13-DAY LARVAL WEIGHT

	Mean ± standard error of 13-day larval wt. (μg)	
Population	'Good' diet	'Poor' diet
Base	2,303 ± 25	1,215 ± 37
GS_2	350 ± 15	906 ± 36

Number of larvae weighed in each treatment group = 100.

Table 2. RELATIVE PERCENTAGES OF THE FATTY ACIDS OF THE SENSITIVE AND NORMAL GENOTYPES REARED ON 'GOOD' AND 'STANDARD' DIETS

Medium	Genotype	Palmitic	Palmitoleic	Stearic	Oleic	Linoleic
'Standard'	*cos*/*cos*	32·0	2·8	10·2	37·4	17·6
,,	+/+	31·0	3·5	12·7	34·6	18·2
'Good'	*cos*/*cos*	18·5	2·1	7·4	31·8	40·2
,,	+/+	26·0	2·1	12·1	33·9	25·9

Dietary corn oil produced an increase in the linoleic acid content of the tissues in both the corn oil sensitive and normal genotypes. However, the marked difference in the distribution of fatty acids in +/+ and *cos*/*cos* genotypes on the 'good' diet suggests an alteration in lipid metabolism in the corn oil sensitive population.

Evidence for a fatty acid oxidizing system in insects has been reported[3]. The present investigations suggest a genetic block in the oxidation of linoleic acid which results in a build-up of this fatty acid. It appears reasonable that the accumulation of linoleate may interfere with other systems (for example, membrane permeability) and thus account for the observed growth reduction. Whether or not the genetic block is specific for linoleate, or represents a general block in the oxidation of all fatty acids, is not known as, in either case, an accumulation of linoleate would represent the predominant change resulting from dietary corn oil because of the high concentration of linoleate in corn oil (58 per cent). Further biochemical analyses of the *cos* gene are now being undertaken.

This work was supported by a grant from the National Science Foundation.

VETERINARY SCIENCE

Effect of Plane of Nutrition on Changes in the Rate of Wool Growth in Sheep induced by Hexoestrol

TREATMENT with exogenous oestrogen is known to influence growth in ruminants, for example the retention of nitrogen, the rate of weight gain and ossification of bone are increased. The effect is considered to occur by way of the anterior pituitary gland, oestrogens facilitating the synthesis of growth hormone[1]. It has been claimed, however, that, while causing a general increase in somatic growth, treatment with oestrogens decreases the rate of wool synthesis in sheep, possibly by means of a lowered thyroid activity or a pituitary or adrenal effect[2]. In view of this apparent anomaly, and the fact that most of the evidence to support it was obtained using gross methods of measurement such as fleece weight, the following work was undertaken.

The experiment was designed to use an absolute method of assessing the rate of wool growth in order to determine more accurately how this is influenced by hormone implantation. An autoradiographic technique involving incorporation of sulphur-35 cystine into wool which enables growth in single fibres to be accurately measured has been described by Downes and Lyne[3] and this was adopted without modification.

The experiments were carried out using four cross-bred wethers maintained in metabolism cages in a controlled temperature room (65° F) under a controlled light régime equivalent to that of the time of year at the commencement of the experiments (11 h daylight). They were acclimatized to a standard ration before taking measurements of wool growth. At the beginning of the experimental period wool was removed by shaving areas 4-in. square on each sheep, one on each shoulder, flank and rump. After 10 days, sulphur-35 cystine was injected intravenously twice with a 3-day interval between injections. One week later, the squares were reshaved and the rate of wool growth for each sheep was measured on a number of fibres selected at random from the six patches. After the determination of wool growth each animal was implanted with a 15-mg pellet of hexoestrol subcutaneously in the ear. After a further 2 weeks the animals were reinjected with sulphur-35 cystine, the squares reshaved as before and the rate of wool growth again measured. Investigations of nitrogen retention were undertaken throughout the experiment in order to establish that the hormone implant was having the expected effect. All animals showed a significant increase in nitrogen retention following hormone treatment (3·748 g nitrogen/day for the control period; 6·066 g nitrogen/day after treatment ($S.E. = 0{\cdot}477$; $P < 0{\cdot}01$)).

In order to determine nitrogen retention accurately it was necessary to control the weight of food consumed by each animal. Observations were made on the appetite of each animal during a preliminary period and, after examining the data, each sheep was given a maximum of 5,675 g of food per week and uneaten food was weighed back. Weekly food consumption is given in Table 1.

Table 1. FOOD CONSUMPTION OF EXPERIMENTAL SHEEP
Food consumption per sheep (g./week) (Max. given = 5,675 g)*

Week	A	B	C	D
1	5,664	4,342	4,196	5,675
2	5,675	5,269	3,958	5,217
3	5,675	5,568	3,690	5,512
4	5,675	5,675	4,047	5,675
		Implantation		
5	5,668	5,675	4,391	5,600
6	5,675	5,675	5,078	5,579
7	5,675	5,675	5,606	5,675
8	5,675	5,675	5,643	5,675
9	10,050	10,125	5,650	9,985

* The results for week 9 are for the sheep fed *ad libitum*.

Table 2. EFFECTS OF HEXOESTROL IMPLANTATION ON THE RATE OF WOOL GROWTH OF SHEEP UNDER CONTROLLED FEEDING

C (b)†	1·444 (45)		(over b)		
D	1·297 (34)	1·622 (25)	Increase	< 0 001	± 0·2324

* Numbers of observations in parentheses.
† b, Result after first treatment.

The results of observations on the rate of wool growth are shown in Table 2.

Three sheep, namely *A*, *B* and *D*, showed decreases in wool growth rate although only *A* was significant ($P < 0{\cdot}001$). Sheep *C* showed a significant increase in the rate of wool growth ($P < 0{\cdot}001$). This difference in response appeared to be related to the level of feed intake of the sheep. Sheep *A*, *B* and *D* consumed virtually all the food offered at the commencement of the experiment whereas sheep *C* did not. After implantation its appetite increased, but on no occasion did the animal consume all the food offered. The appetites of sheep *A*, *B* and *D* were re-established at the end of the experiment by feeding the animals *ad libitum* for a further week (week 9, Table 2). This demonstrated that sheep *A*, *B* and *D* were capable of consuming considerably more than they were actually being fed and in consequence possessed a potential to retain more nitrogen which was not satisfied by food intake. It was possible that, in order to satisfy this potential, the animals utilized nitrogen from sources which, under normal conditions would have been available for wool synthesis, leading to the observed effect of a decrease in the rate of wool growth. Sheep *C*, however, was fed to appetite throughout and therefore the increasing potential to retain nitrogen could be satisfied without recourse to nitrogen utilized for wool synthesis.

To test this theory, all four animals were fed *ad libitum* for 6 weeks, re-implanted, and the experiment was repeated. The results are shown in Table 3.

There was an increased rate of wool growth in sheep *A*, *B* and *D* when compared with the original control values (non-significant for sheep *A*). The rate of wool growth in sheep *C* also increased, due possibly to variations in the rate of release of hexoestrol. The amount of nitrogen retained daily was also increased in all sheep.

The results show that the mechanism of action of oestrogens on the rate of wool growth must be more complex than was previously realized, and that the nutritional status of the animal has a direct effect on the changes in wool growth induced by hexoestrol.

It has been established that there is an order of priority of tissue growth which becomes more apparent under restricted dietary régimes[1]. These experiments indicate indirectly that, in the sheep, wool follicles have a low priority, since the rate of wool growth was depressed in animals which were not fed *ad libitum*. Thus, under conditions of restricted feeding, hexoestrol treatment, which increases the demands for nutrients for systems which have a high priority, would be expected to decrease the growth rate of wool. It is possible that the availability of amino-acids might be the factor limiting wool growth under these conditions. On the other hand, hexoestrol treatment coupled with *ad libitum* feeding would result in an increase of nitrogen retention with no restriction in the use of this nitrogen for wool growth. This would be expected to give the result observed in the second experiment, that is, an increase in the rate of wool growth. The foregoing results emphasize the need for careful definition of the conditions used in work of this nature.

Prenatal Loss of Foetuses and Abortion in Guinea-pigs

DURING experiments designed to determine the effects of stresses on pregnancy in guinea-pigs, it was noted that a large proportion of sows aborted within 4–7 days when their diet was restricted. The effect of a hot environment on foetal resorption and abortion in pregnant rats has already been reported[1], but only one brief reference[2] has been found describing prenatal losses caused by dietary restriction in guinea-pigs. This communication describes two experiments illustrating the effects of severe sudden dietary restriction during pregnancy.

In the first experiment, eighteen multiparous guinea-pigs were arranged in pairs of similar weights and allotted at random into one of two groups. From the 30th to 39th day of gestation they were caged individually and offered 5 g lucerne hay and 400 g freshly picked clover and ryegrass daily. From 40 days' gestation, the control group continued on this diet and 25 mg ascorbic acid (Parke, Davis and Co.) daily in tablet form *per os*. The daily intake of the second group was restricted to 5 g lucerne hay, 20 g fresh clover and grass and 25 mg ascorbic acid. All animals were weighed daily and observed twice daily until abortion or normal parturition occurred.

The results are summarized in Table 1.

Table 1

	n	Mean weight at mating (g) ± S.D.	Litter size Living: Mean	Litter size Living	Litter size Dead	Litter size Total	Mean gestation length (days)
Restricted diet	9	747·7 ± 100·0	2 9 ± 0 82	0	26	26	48·1 ± 5·57
Unrestricted diet	9	780 0 ± 95·7	2·8 ± 0·65	22	3	25	67·1 ± 1·67

There was a highly significant difference between the restricted and unrestricted groups in foetal survival ($\chi^2 = 37{\cdot}7$, $P < 0{\cdot}001$) and gestation length ($t = 9{\cdot}8$, $P < 0{\cdot}001$). Six of the nine animals the diet of which was restricted aborted fresh foetuses between 44 and 46 days' gestation. The others aborted degenerating foetuses after 12 days (two sows) or mummified foetuses after 20 days (one sow).

In the second experiment, thirteen multiparous sows were allotted into one of two groups as before, were caged at 42 days of gestation, and to 51 days' gestation were fed a diet of 45 g freshly picked clover, 10 g lucerne hay leaf and proprietary guinea-pig pellets *ad lib*. From the 52nd to the 62nd day the control group received 90 g,

and the restricted diet group received 8 g, of lucerne leaf hay daily. All experimental animals received 50 mg ascorbic acid in tablet form daily *per os* during this period. After the 62nd day they were offered fresh clover, hay and pellets as before 52 days.

The results are presented in Table 2.

Table 2

	n	Mean weight at mating (g) ± *S.D.*	Litter size Mean	Living	Dead	Total	Mean gestation length (days)
Restricted diet	7	773·6 ± 84·6	3 3 ± 0·74	1	22	23	61·3 ± 2·21
Unrestricted diet	6	763·2 ± 74 6	3 2 ± 0·73	19	0	19	68·3 ± 2 89

There was a highly significant difference between the restricted and unrestricted groups in foetal survival ($\chi^2 = 34{\cdot}4$, $P < 0{\cdot}001$) and maintenance of gestation after the onset of treatment ($t = 6{\cdot}26$, $P < 0{\cdot}001$).

Two sows in the restricted diet group developed a condition resembling pregnancy toxaemia at the 56th and 58th days of gestation and were destroyed. In each, the foetuses were dry and had been dead for some time as estimated by opacity and wrinkling of the cornea and haemoglobin staining of subcutaneous tissues. The placentae contained brown or grey necrotic areas and fell away from the endometrium with very light traction. One sow was destroyed on the 65th day of gestation following opening of the vaginal membrane on the 63rd day, and passage of a profuse vaginal discharge for 2 days. The four foetuses were degenerating and emphysematous. It may be assumed that normal pregnancy was interrupted in each of these three instances, but they might not have been able to pass the foetuses through the narrow unrelaxed pelvis. They have not been included in the data referring to gestation length and maintenance of gestation.

The litters of the other four female guinea-pigs were aborted from the 58th to the 63rd day and included three mummified, two degenerating, six freshly dead, and one living foetus. One litter, delivered at 63 days, consisted of a mummified foetus, a degenerating foetus, a freshly dead foetus and a small living foetus. Bacteriological examination of eighteen uterine swabs and foetal stomach contents failed to reveal the presence of any significant pathogens.

The severe sudden stress imposed in these experiments usually resulted in the loss of the whole litter. This was commonly accompanied by the abortion of fresh foetuses, and less frequently by retention, resorption and delayed delivery of foetuses. Mummification occurred if foetuses were retained for a sufficient period, and when this happened the foetal fluids and products resulting from embryonic degeneration appeared to be largely absorbed by the uterus, as the vaginal membrane may remain intact until delivery is imminent. Brambell[3] found no evidence that products of embryonic disintegration were absorbed by the maternal tissues although the possibility had not been excluded.

The factors which determined whether abortion or foetal degeneration and mummification would occur have not been elucidated, but did not appear to be related to size of dam at mating or at the beginning of dietary restriction, or to the amount or the rate of weight loss during restriction. The loss in weight between the beginning of dietary restriction and abortion ranged in a linear fashion between 13 per cent when abortion occurred on the 4th day, and 30 per cent when abortion occurred on the 20th day.

It has been suggested by Csapo *et al.*[4] that foetal death *in utero* results in a reduction of both uterine volume (v) and placental progesterone (p) and, if the rate of decrease is such that the ratio v/p stabilizes as in normal gestation, pregnancy is maintained. This could account for the retention of litters resulting in their mummification. The prompt delivery of freshly dead, or occasionally of living premature foetuses, might have been the result of sudden placental damage with diminished production of progesterone.

I thank Prof. D. McFarlane for advice and Mr. K. L. Hughes for help with the bacteriological examinations.

ANTHROPOLOGY

Cusp Number, Occlusal Groove Pattern and Human Taxonomy

EVER since Gregory and Hellman, the number of cusps on the molar teeth and the pattern of the occlusal grooves have been used as taxonomic criteria in the assessment of hominid and hominoid remains[1,2]. Both number of cusps (4, 5 or 6) and the groove pattern (+ or *Y*) have been used in the comparison of many recent human populations[3–11]. The addition of the *X* groove pattern by Jørgensen in 1955 (ref. 8) completed the series of polymorphisms, giving three groove patterns (+, *Y* and *X*) and three or more cusp numbers (4, 5 and 6), or at least nine possible combinations in all. However, it has not been known for certain whether cusp number and groove pattern represent a single pleomorphism or two independent dental polymorphisms[8].

In our studies on 258 White subjects with unworn dentition, we have found side-to-side concordance to exceed 96 per cent both for cusp number and groove pattern. Further, extreme discordances have not been found; individuals did not differ by more than one cusp or by one step in the (+, *Y*, *X*) groove series. However, the two polymorphisms on M_1 proved to be essentially unrelated. For males taken separately, for females taken separately, and for both sexes considered together, the association between groove pattern and cusp number was not significant ($\chi^2 = 1{\cdot}99$).

Despite the independence of these two dental polymorphisms within individuals, they do appear to be correlated among recent human populations. Ranking twenty different groups, sixteen taken from the literature[3–11], with due attention to problems of grouping cusp numbers in excess of five, and groove patterns other than *Y*, there was a clear-cut relationship between the percentage of individuals exhibiting the *Y* pattern and the percentage of individuals with five or more cusps on the

mandibular first molar (Table 1). Although sampling effects, inter-observer differences in techniques of morphological assessment, and the failure of earlier workers to recognize the *X* pattern may be expected to minimize such association, the rank order correlation (ρ) was 0·54 on a population basis.

Since our data show high monozygotic twin concordance with respect to both cusp number and groove pattern, and excellent bilateral symmetry for both sets of dental traits, they appear to be genetic polymorphisms of considerable potential value in the analysis of recent human populations. Because cusp number and groove morphology are unrelated within individuals, it would seem expedient to separate the two, describing a particular subject as "*Y* and 5", or "*Y* and 4", rather than as *Y*5 or *Y*4 as has been the custom. Finally, the degree of association within recent populations suggests that common selective factors have brought about a simultaneous reduction in cusp number and deviation from the *Y* pattern, even though the two are independent dental polymorphisms.

We thank Dr. K. Tomita for the systematic morphological assessments made on plaster casts of our Ohio White subjects. The work was supported in part by a National Institute of Dental Research, Bethesda, Maryland.

PSYCHOLOGY

Attentional Factor in Delayed Response

THE loss of an animal's ability to perform delay tasks following bilateral prefrontal lobe ablations is well established and has been attributed to diverse causes, notable among which is the factor of attention. Equally established are techniques which, by altering the animal's physiological state or the problem situation, are effective in restoring the animal's task performance to the preoperative level. Typically, the techniques reduce the animal's distractability or emphasize the cueing procedure thereby presumably enhancing the animal's ability to attend[1,2]. While this evidence implicates attention as an important factor in delayed response, it does so indirectly, and thus far attention has eluded direct study as a dependent variable.

Delayed response deficits comparable with those seen in ablated animals have been reported in the essentially intact animal as the result of electrical stimulation of certain brain foci through chronically implanted electrodes[3,4]. The technique of electrical excitation has also been used to elicit alerting or 'attentional' responses. This behavioural 'attention' is characterized by: (i) arrest of the on-going behaviour of the animal; (ii) arousal, that is, the animal seems to be more alert and often undergoes a change in facial expression and attitude; (iii) orientation, the animal looks about usually toward the side contralateral to the stimulation. On the basis of these behavioural observations and electroencephalographic evidence, it has been concluded that the frontal lobes have their own attentional system unrelated to any known sensory system[5,6].

The purpose of this investigation was to examine more directly the part that attention may play in delayed response performance. After mastering a 5-sec *L–R* delayed response task by the direct method, five macaque monkeys were implanted with stainless steel electrodes insulated except for the cross-sectional area at the tip. Two weeks after surgery each brain point was stimulated to see if an 'attentional' response could be elicited. A 60 c/s sine wave pulse of 1–2 sec duration was delivered monopolarly in these determinations; current values ranged from 50 to 400 μamp. The animals were seated in restraining chairs modified to include components of the Wisconsin general test apparatus. A brain point was judged to be 'attentional' in nature if on stimulation the animal manifested alerting behaviour according to the stipulated criteria. In so far as attention may be a critical element in the performance of the delay task, one would expect a high degree of overlap between brain points eliciting 'attention' and those causing delayed response deficits on stimulation.

The effect of electrical excitation on delayed response was then investigated. Each brain point was stimulated monopolarly during the associative and retentive phases of the delay task. A current intensity below the threshold for eliciting the attentional response was used during this phase of the investigation to preclude direct interference with behavioural performance. The electrical stimulation lasting for 5 sec, 0·5 sec on and 0·5 sec off during each phase. Details of this aspect of the study have been reported elsewhere[4].

Table 1 summarizes the results. Twenty-nine of the 55 brain points were judged to elicit an alerting response while 34 of the 55 resulted in a statistically significant deficit in the delayed response score when stimulated. A χ^2 test revealed no significant relationship between the two classes of points, indicating that the delay deficits seen were not due to disruption of processes in neural tissue judged to be part of an attentional system.

Table 1. EFFECTS OF ELECTRICAL STIMULATION ON DELAYED RESPONSE PERFORMANCE AND 'ATTENTION'

		'Attention' Yes	No	Total
Delay deficit	Yes	18	16	34
	No	11	10	21
	Total	29	26	55

Table 2. RELATIONSHIP BETWEEN 'ATTENTION' AND PHASE OF DELAY PROBLEM WHERE DEFICIT WAS SEEN

	Phase related delayed response effect: Assoc. +	−	Retent. +	−	Both +	−	No effect +	−	Total +	−
Cortex and basal ganglia	3	5	3	1	0	0	7	8	13	13
Limbic and deep extrapyramidal	0	3	2	0	6	6	0	0	8	7
Thalamic and brain stem	1	3	1	1	2	0	4	2	8	6
Total	4 (12)	8	6 (8)	2	8 (14)	6	11 (21)	10	29 (55)	26

\+ Symbolizes an 'attentional' point.
− Symbolizes a 'non-attentional' point.

Table 2 shows the problem phase during which the stimulation-caused deficit was seen, its relationship to attention and the gross neuroanatomical locus of the electrode. With regard to attention, the locus does not appear to be important since attentional and non-attentional points are distributed about equally within the three classes of tissue. While the number of points in each cell is too small for meaningful statistical analysis, it would appear that the deficits seen were neither specific to the animal's ability to attend, that is, form an associa-

tion, nor to retain, that is, be distracted from an already formed association. This suggests that the delay deficits seen were more likely due to interference with associative and retentive processes directly rather than due to interference with an attentional mechanism. While this investigation demonstrates that attention is not the critical factor in accounting for delayed response deficits it does not suggest that the task can be performed without attending. Indeed, the validity of results in delayed response experiments is contingent on the experimenter's judgment that the animal attended to the cueing procedure on each and every trial. Thus it seems more likely that the delay deficits are not due to an inability to attend, but rather may be due to an inability to process the information.

I thank Prof. J. Olds, University of Michigan, for providing facilities for this work.

Effects of Loudness and Presentation-rate on Auditory Short-term Memory

MACKWORTH[1] has presented evidence suggesting that if lists of, for example, letters or digits are presented auditorially for immediate recall, fast presentation is more advantageous than slow. The converse has generally been found true for visual presentation[2–4]. It has been hypothesized by Mackworth that subjects might use a short-lasting auditory memory after-image for recall purposes, this image probably persisting for longer than the visual memory after-image. It might then be that fast presentation-rates of auditory material facilitate recall because more of the list is still available in image-form after a fast presentation than after a slow presentation.

At the same time we[5] have found that when seen lists were voiced aloud by the subject at presentation, such vocalization also gave relatively more advantage for recall after fast than after slow presentation-rates. If it be argued that, when voicing, the subject is presenting himself with an auditory message (the sound of his own voice) in addition to the visual message, then our results would be consistent with Mackworth's hypothesis. In other investigations, however, we have found only slight, insignificant advantage for loud-voiced lists over soft-voiced lists for immediate recall. The question is therefore raised whether loud presentation in itself will give rise to a 'stronger', more persistent after-image which ought to aid immediate recall of loud material: we might also ask whether, if lists are presented rapidly, less of the image will have disappeared when the list comes to be recalled. To examine this, immediate recall has been obtained for lists of eight letters presented either quickly (120 letters/min) or slowly (60 letters/min), the lists also being presented at three intensities.

Thirty-six subjects, mainly from introductory psychology courses at Queen's University, came in groups of six to the University Language Laboratory. In this laboratory, each subject had a private booth and a set of earphones through which messages from a central tape-deck could be relayed. After initial practice on six lists, they heard a total of twenty-four lists of eight consonants each (for example, LVMKTNCS), having four lists at each of the six combinations of rate and loudness. Variations in rate were obtained by recording the sequences of lists in either fast or slow versions, using a metronome; loudness was varied by adjusting a dial on the central tape-deck. With each booth having been previously set to be equal in general sound-output to the other booths, the three levels of loudness as measured at the earphone were: 50 db (soft), 80 db (medium), and 90 db (loud). At these levels, each list was clearly audible, but the differences between the soft, medium and loud levels were plainly discernible to subjects. The design was balanced so that each group of subjects worked through the six presentation-conditions in a different order; and subjects were always warned of the rate and loudness to expect for each list. As soon as each list ended, subjects wrote down their recall on prepared answer-sheets: they were told they could omit or guess if they could not recall a letter, and were allowed to write down their recall in any order provided they put each letter into its correct original position. The main index of recall was the number of letters in their correct positions.

The percentages of letters correct out of the total possible are shown in Table 1.

Table 1. PERCENTAGE OF LETTERS CORRECT AS A FUNCTION OF LOUDNESS AND PRESENTATION-RATE

	Soft	Medium	Loud
Slow (60/min)	59·11	64·32	63·37
Fast (120/min)	60·24	57·03	55·96

Analysis of variance showed that the effects of loudness and rate were not significant; there was a significant subject-variance ($F = 7{\cdot}707$, $P < 0{\cdot}005$); and there was a significant interaction between loudness and rate ($F = 5{\cdot}08$, $P < 0{\cdot}01$). Other interactions were not significant. Increasing the loudness appeared to improve recall of slow lists except at the loudest level, but to depress the recall of fast lists.

From these results it would seem that we shall have to qualify our original suggestions. Rather than aid recall of fast lists, increasing loudness seems to hinder it. We suggest that the results might most simply be explained if we assume that loud lists did leave stronger after-images but that these images themselves interfered with the rapid intra-presentation rehearsal required on fast lists. Furthermore the images probably interfered with simple grouping of letters, a strategy which Mackworth[6] has found to facilitate the recall of fast lists in particular. Posner[7] has also found that if recall is forced (that is, if the results must be given in the order in which they are presented) the advantage of fast lists increases. This type of recall, also used by Mackworth[1], was not used in the present situation.

It can therefore be concluded that it is not appropriate to generalize that fast auditory lists will necessarily be better recalled than slow auditory lists. Apart from grouping and recall-strategies, we have found that increasing the loudness of fast lists is detrimental to their recall, probably because of a greater difficulty of rehearsal due to interference. With regard to our own work on vocalization, these findings suggest that what advantage might have accrued to the recall of loud-voiced lists by virtue of a more persistent after-image was probably diminished due to various kinds of interference being simultaneously produced by loud voicing.

This work was done under an operating grant from the National Research Council of Canada. I thank P. S. Day of the Queen's University French Department for his generous assistance in the Language Laboratory, and E. Bauman for research assistance.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Tuesday, April 12

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Overseas League, Park Place, London, S.W.1), at 6.30 p.m.—Annual General Meeting.

Wednesday, April 13

SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, 26 Portland Place, London, W.1), at 3.30 p.m.—Symposium on "Automation in Coal Mining".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—NUTRITION PANEL (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Annual General Meeting, followed by Dr. R. J. L. Allen: Chairman's Address.

INSTITUTE OF INFORMATION SCIENTISTS (at the Whitehall Hotel, Bloomsbury Square, London, W.C.1), at 6.15 p.m.—Mr. H. Schur: "The Sheffield University Postgraduate School's Course on Scientific and Industrial Librarianship and Information Work".

CROYDON NATURAL HISTORY AND SCIENTIFIC SOCIETY (in the Maple Room, Fairfield Halls, Croydon), at 7.30 p.m.—Dr. K. Fea: "Some Aspects of Lunar Geology".

Thursday, April 14

INSTITUTION OF CIVIL ENGINEERS, ENGINEERING MANAGEMENT GROUP (at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Difficulties of Communication in Management", introduced by Mr. R. F. Heynes.

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "Non-Optical Transmissions".

Friday, April 15

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 5.30 p.m.—Colonel J. Kelsey and Mr. D. N. Bisgood: "Land Navigation".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. A. H. Reeves, O.B.E.: "Equilibrium Coding for Pulse Code Modulation".

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Mr. W. Silvie: "Domestic Video Recording".

Monday, April 18

OPERATIONAL RESEARCH SOCIETY (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 4.30 p.m.—Forum on "O.R. and Accountancy".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. C. Claydon: "Electricity for Grain Drying".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.E.–I.E.R.E. COMPUTER GROUPS (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Computer Bulk Storage".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Annual General Meeting followed by Ordinary Meeting—The Chairman's Address.

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"The Days of Whiskey Gap" and "City of Gold" (films).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (with experience in general experimental psychology and an interest in laboratory teaching) IN PSYCHOLOGY—The Secretary, The Queen's University, Belfast, Northern Ireland (April 13).

LECTURER and an ASSISTANT LECTURER (with special interests in North America and/or economic geography) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Leicester (April 15).

LECTURER IN INORGANIC CHEMISTRY in St. Salvator's College—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife, Scotland (April 16).

LECTURER (preferably with a medical qualification) IN MEDICAL VIROLOGY—The Registrar, University Senate House, Tyndall Avenue, Bristol, 2 (April 16).

LECTURER (with appropriate academic qualifications, good teaching experience with recent developments concerning education in chemistry) IN EDUCATION—The Deputy Secretary, The University, Southampton (April [illegible]).

READER or SENIOR LECTURER IN APPLIED MECHANICS, and a LECTURER or ASSISTANT LECTURER IN MECHANICAL ENGINEERING IN THE SCHOOL OF APPLIED SCIENCES—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (April 16).

CHAIR OF ELECTRONICS—The Registrar and Secretary, The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex, marking envelope "Confidential" (April 17).

LECTURER (man or woman graduate with experience of research in education and an interest in philosophy) IN THE SCHOOL OF EDUCATION—The Registrar, The University, Liverpool, quoting Ref CV/3 (April 18).

ASSISTANT LECTURER or LECTURER (with a medical qualification and preferably an additional dental qualification) IN ORAL PATHOLOGY—The Registrar, The University, Sheffield (April 23).

LECTURER IN HYDRODYNAMICS—The Registrar, The University, Manchester 13, quoting Ref. 73/66 (April 23).

LECTURER IN MEDICINE—The Registrar, The University, Sheffield (April 23).

LECTURER (with a good honours degree in mechanical engineering together with industrial and/or research experience and a special interest in applied thermodynamics) IN THE DEPARTMENT OF ENGINEERING—The Secretary, The University, Aberdeen (April 25).

UNIVERSITY RADIATION PROTECTION OFFICER (with experience in the use of nuclear radiations)—The Assistant Registrar (Science and Engineering), University of Birmingham, Birmingham, 15, quoting Ref. PO/N (April 23).

ASSISTANT LECTURER IN STATISTICS, preferably in mathematical statistics or probability theory—The Registrar, The University, Hull (April 25).

DEMONSTRATOR (graduate) IN INORGANIC CHEMISTRY; and a DEMONSTRATOR (graduate) IN ORGANIC CHEMISTRY—The Secretary, Trinity College (University of Dublin), Dublin 2, Republic of Ireland (April 25).

RESEARCH ASSISTANT (preferably with a higher degree and research experience in biological productivity and/or methods of plant and soil analysis) IN ECOLOGY IN THE DEPARTMENT OF BOTANY for work on the role of bryophytes in the productivity and mineral cycle of woodland ecosystems—Prof. P. W. Richards, Department of Botany, University College of North Wales, Bangor, North Wales (April 25).

VETERINARY OFFICERS (men or women aged at least 23, M.R.C.V.S. and at least one year's appropriate postgraduate experience) WITH THE MINISTRY OF AGRICULTURE, FISHERIES AND FOOD—Civil Service Commission, Savile Row, London, W.1, quoting Ref. 30/66/1 (April 26).

JUNIOR LECTURERS (2) (with an honours degree in physiology with zoology, chemistry or physics, or a medical qualification, and preferably some postgraduate experience in teaching and research) IN PHYSIOLOGY—The Registrar, King's College (University of London), Strand, London, W.C.2 (April 29).

LECTURER IN MATHEMATICS at Makerere University College, University of East Africa, Uganda—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 29).

ASSISTANT LECTURER IN GEOGRAPHY—The Registrar, The University, Manchester, 13, quoting Ref. 76/66 (April 30).

ASSISTANT LECTURER or LECTURER IN CHEMISTRY—The Registrar, The University, Sheffield (April 30).

ASSISTANT LECTURER (with an honours degree in physiology or prepared to attend an honours course, and preferably with a veterinary qualification) IN THE DEPARTMENT OF VETERINARY PHYSIOLOGY—The Secretary, The University, Edinburgh (April 30).

ASSISTANT LECTURER (with research interests in comparative physiology, preferably neurophysiology) IN ZOOLOGY—The Registrar, The University, Sheffield (April 30).

DEMONSTRATOR (graduate or about to graduate) IN BIOLOGY—The Registrar, The University, Keele, Staffs (April 30).

KEEPER (with a good university degree and relevant experience in an academic or scientific library, and preferably professional qualifications and experience or interest in the field of scientific librarianship) OF SCIENCE BOOKS—The Librarian, University Library, Palace Green, Durham (April 30).

LECTURER or ASSISTANT LECTURER IN BIOLOGICAL CHEMISTRY—The Registrar, The University, Manchester, 13, quoting Ref. 71/66/Na (April 30).

LECTURER or ASSISTANT LECTURER IN MATHEMATICS at the University of the West Indies, St. Augustine, Trinidad—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 30).

SENIOR LECTURER (Grade I) or LECTURER (Grade II) IN APPLIED MATHEMATICS—The Registrar, University Senate House, Tyndall Avenue, Bristol, 2 (April 30).

THIRD CHAIR OF CHEMISTRY—The Registrar, The University, Hull (April 30).

TUTOR (with a good honours degree in either social anthropology or sociology) IN THE DEPARTMENT OF SOCIAL ANTHROPOLOGY—The Secretary, The University, Edinburgh (April 30).

LECTURER or ASSISTANT LECTURER (with special qualifications in organic chemistry) IN ORGANIC CHEMISTRY—The Secretary, The University, Edinburgh (May 2).

CHAIR OF BACTERIOLOGY—The Secretary, The University, Edinburgh (May 3).

LECTURER IN THE DEPARTMENT OF PSYCHOLOGY—The Secretary, The University, Edinburgh (May 4).

AGRICULTURAL SCIENCE or SCIENCE GRADUATE (with an honours degree in agriculture or science (majoring in botany) or equivalent, and suitable postgraduate research experience) for research on the manuring, ecology and related management aspects of grassland—The Director, An Foras Taluntais (The Agricultural Institute), 33 Merrion Road, Dublin 4, Republic of Ireland (May 6).

LECTURER or ASSISTANT LECTURER IN PHILOSOPHY—The Registrar, The University, Sheffield (May 7).

LECTURERS or ASSISTANT LECTURERS (for one post preference will be given to candidates with a special interest or experience in X-ray crystallography) IN THE DEPARTMENT OF INORGANIC AND STRUCTURAL CHEMISTRY—The Registrar, The University, Leeds, 2 (May 7).

TEACHING FELLOWS (with a Ph.D. degree) IN THE DEPARTMENT OF INORGANIC AND STRUCTURAL CHEMISTRY, to give laboratory and tutorial instruction and to engage in research—The Registrar, The University, Leeds, 2 (May 7).

LECTURER (with research interests and industrial experience in the fields of automatic control, power systems analysis or electronic circuit design) IN ELECTRICAL ENGINEERING—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (May 13).

POSTDOCTORAL RESEARCH ASSISTANT IN THE DEPARTMENT OF PHYSICAL CHEMISTRY, for the investigation of ion molecule reactions, using a differentially pumped mass spectrometer—Dr. M. J. Henchman, Department of Physical Chemistry, The University, Leeds, 2 (May 31).

LECTURER (with a postgraduate degree and preferably some experience of teaching biochemistry at University level) IN BIOCHEMISTRY, at Lincoln College, University of Canterbury, New Zealand—The Association of Commonwealth Universities, Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, June 30).

GRADUATE MICROBIOLOGIST or BACTERIOLOGIST (male, between 20 and 30, and industrial experience of research or quality control, preferably in the

food industry) to work on problems associated with the microbiological spoilage of baked products and the introduction of new methods of prevention—The Secretary, British Baking Industries Research Association, Chorleywood, Rickmansworth, Hertfordshire.

LECTURER IN STATISTICS to teach statistics and some mathematics to the standard of the B.Sc. General Degree of the University of London—Clerk to the Governing Body, Northern Polytechnic, Holloway, London, N.7.

LECTURER or SENIOR LECTURER (with a first- or second-class honours degree or equivalent in civil or mechanical engineering) IN THE MATERIALS BRANCH OF THE DEPARTMENT OF CIVIL ENGINEERING, primarily to lecture on the properties of materials and stress analysis at degree level and to supervise the relevant laboratory work—The Registrar, Royal Military College of Science, Shrivenham, Swindon, Wiltshire.

LECTURER (with a good honours degree in psychology) IN PSYCHOLOGY (Experimental Psychology/General Psychology) for work mainly with honours and general degree courses—The Registrar, Goldsmith's College (University of London), London, S.E.14.

LECTURERS or ASSISTANT LECTURERS (or exceptionally Senior Lecturers) IN MATHEMATICS—The Assistant Registrar (Establishment), University of Sussex, Stanmer House, Stanmer, Brighton, Sussex

MASTER TO TEACH MATHEMATICS (this is largely a Sixth Form appointment)—The Headmaster, St. Albans School, Abbey Gateway, St. Albans, Herts.

PHYSIOLOGIST to join a small team of scientists studying the human environment—D. C. Page, Head of Personnel Services, The Electricity Council Research Centre, Capenhurst, Cheshire, quoting Ref. N/19.

POSTDOCTORAL FELLOW IN ORGANIC CHEMISTRY to join a team working on a major synthetic project—The Registrar, The University, Manchester, 13.

PRINCIPAL LECTURER IN MATHEMATICS; a PRINCIPAL LECTURER IN CHEMICAL ENGINEERING; a LECTURER IN BIOCHEMISTRY; a LECTURER IN MICROBIOLOGY; a LECTURER IN PRODUCTION PROCESSES (Machine Tools or Metal Forming); an ASSISTANT LECTURER IN PRODUCTION ENGINEERING, an ASSISTANT LECTURER IN ELECTRICAL ENGINEERING; and RESEARCH ASSISTANTS IN ELECTRICAL AND IN MECHANICAL ENGINEERING—Clerk to the Governing Body, Borough Polytechnic, Borough Road, London, S.E.1.

SENIOR LECTURER (with a good honours degree and preferably with a further degree or research experience in animal physiology or genetics/cytology) IN ZOOLOGY; and a LECTURER (with a good honours degree and preferably a special interest in plant physiology) IN BOTANY—The Registrar, Regional College of Technology, Leicester.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Transactions of the Royal Society of Edinburgh. Vol. LXVI, No. 6 (1963–64): On the Cupule Structure of *Eurystoma angulare*. By Albert G. Long Pp. 111–128+1 plate. 8*s*. 6*d*. Vol. LXVI, No. 7 (1964–65): Nuclear Phenomena in *Marasmius androsaceis* (L. ex Fr.) Fr. and M. *Rotula* (Scop. ex Fr.) Fr. By E. Julian Duncan and J. A. Macdonald. Pp. 129–141+4 plates. 10*s*. 6*d*. Vol. LXVI, No. 8 (1964–65): Raised Shorelines Associated with the Perth Readvance in the Forth Valley and their Relation to Glacial Isostasy. By J. B. Sissons and D. E. Smith. Pp. 143–168. 10*s*. 6*d*. (Edinburgh: The Royal Society of Edinburgh, 1965.) [281

Institute of Personnel Management. The Labour Market. By John Corina. (Part 1 of Incomes Policy—Problems and Prospects.) Pp. 35. 7*s*. 6*d*. The Development of Incomes Policy. By John Corina. DEAD HEAT ON THE MOON

IT is beginning to look as if the race to the Moon could be decided by what happens in 1966. The United States has already carried out a successful rehearsal of an encounter between two rockets in orbit about the Earth, and the first flight of a version of the *Apollo* spacecraft is imminent. The U.S.S.R. has landed instruments on the Moon in working order, and has now put *Luna* 10 into an orbit about the Moon. These are all steps in the process of sending a man to the Moon, and of bringing him back as well. It is only a matter of time before they are integrated into sequence. In a few months, those who are so inclined will be able to guess with some show of plausibility which of the two competitors is likely to win. Bookmakers, no doubt, will start taking bets.

Deciding what the race has accomplished and will accomplish is unfortunately more difficult. The undoubted benefits and the undoubted penalties are incommensurable. Whether to cheer or to hang the head in gloom is therefore a question for subjective judgment, not mere logic.

The benefits are easier to catalogue. Exploration of the Moon and of its geology will be extremely valuable, but a good start should have been made with automatic devices long before the first men arrive. So close is the development, indeed, that a lot of fun has already gone out of the Earth-bound controversy about the nature of the surface of the Moon; only a few more months, and this will be known once and for all. Beyond the Moon itself lies its potential usefulness as a site for telescopes and other instruments, but not even the most vigorous supporters of the competition for the Moon would claim that the technical benefits of victory can justify more than a tiny fraction of the cost.

The disparity between the cost of sending a man to the Moon and the costs of the most ambitious projects on which Earth-bound scientists set their hearts is by itself sufficient proof that space travelling is not mere science. The cost of the large reflecting telescope in the southern hemisphere, the lack of which has been a painful frustration in the past decade, is perhaps a thousandth of the cost of Project *Apollo* in the United States. The same programme of space development might alternatively provide the cost of a hundred proton synchrotrons to succeed the machines at Brookhaven and Geneva. It would also support scientific research in British universities for the best part of a century or provide every university in the world with a really up-to-date computing installation. Obviously such a distribution of the efforts of skilled people would not have been settled in the light of strictly scientific considerations. Even the most ardent space-travellers would have sought a more balanced effort.

"But we only send the rocket to the Moon—not the money spent on developing it." This is the crypto-Keynesian justification. It is in this spirit that officials in the United States have from time to time extolled the virtues of what is called 'spin-off', and it is true, at least in the United States, that a large space programme does introduce industry to new techniques. The trouble is that many of the new techniques have no application outside rocketry. The educational consequences of the space programme—again in the United States—have been mixed. Plentiful funds have provided the United States Government with a convenient means of channelling supporting scientific research into universities and other institutions. Inevitably, however, the result has been lop-sided. Already there are some who claim that much greater benefits would have been forthcoming, in industry and in education, if a part of the money spent on rocketry had been spent, instead, on the development of fast surface transport (on the Earth) or on the advancement of computer techniques. The defect in this analogy with Keynes's argument that a nation with a slump on its hands can usefully employ men to dig holes in the ground and then to fill them in again is plain. Any research and development is better than none, but for advanced nations such as the United States and the U.S.S.R., where research and development are limited by skilled manpower and not by money, it is meaningful and certainly prudent to seek an optimum strategy for the effective deployment of resources. To aim to get to the Moon by such and such a date introduces a needless constraint on this operation.

But must we not go to the Moon because it is there? President Kennedy made good use of the analogy of the Moon and Everest. There are also on record the unforgettable words of the distinguished American who told Congress that going to the Moon is unavoidable "because that's the kind of person Man is". And, of course, it is exciting. Which of us will not wish, at least in part, for a place in an early expedition? Next best, we shall sit glued to our television sets—not every day is there a chance to see a kind of Colombus go about his business.

But why the hurry? Nothing vital would be lost if the first landing were delayed a decade. Even a few years of grace would help to lend moderation to the present course of events. The ideal would be some kind of co-ordination of the programmes of the United States and the U.S.S.R., tacit or otherwise, for there is an urgent need to see that the race to the Moon does not become an empty but symbolic trial of strength between two great nations.

The dangers are already great. Both nations can probably afford the cost. They can also afford some substantial departure from the ideal pattern of research and development. But because so much prestige has now been attached to reaching the Moon, neither nation can afford to lose. Unfortunately, however, success will not be an accurate yardstick of prowess, technological or otherwise. Luck will matter. So will the somewhat arbitrary decision the two nations have already made about the commitment of resources to this project. The best man may not be the winner—and the loser will be bound to save face by nominating some more distant celestial body than the Moon as the next finishing post.

The reputations of nations are chiefly at stake, but the reputation of science and technology is also involved. Even if—again in the United States—scientists have been able to establish that the cost of going to the Moon should not be thought of as a charge against scientific research, popular and not-so-popular opinion still holds

that the competition for the Moon is a comparative assessment of science and technology in the two nations. In reality, it would be as sensible to assess the merits of two chess-players by pitting them one against the other at *Karate*. It will do no good, and much harm, if the competition for the Moon should lead to another spate of invidious and pointless comparisons of the conditions of science in the U.S.S.R. and the United States. It will be damaging if science and technology are found to have lent themselves, without protest but even with a sneaking sense of delight, to a hollow competition. Obviously it is too late now to stop the race but, in the circumstances, it may be best to hope for a draw.

BRITISH GAS

THE discovery of natural gas in substantial quantities under the North Sea will still further sharpen the need that the British Government should have a consistent policy on fuel. A quarter of a century ago the British industrial economy was virtually dependent on a single fuel—coal. Since then, and particularly in the past decade, there has come almost bewildering diversity. First came a rapid growth of the import of petroleum. The prospect of nuclear power competitive in price with electricity from coal has finally become reality. Now there is natural gas—or the promise of it—and nobody will blame the British Government for hoping that the exploration of the North Sea will do for the British industry what the natural gas at Laq did for French industry a decade ago, and what the more recent finds of gas in Holland have done for the Dutch. There will even be some who will point to the way in which cheap coal sustained the Industrial Revolution in Britain.

Unfortunately, however, exploiting natural gas from the North Sea will not simply be a matter of laying pipes and turning on the taps. It will also somehow be necessary for the British Government to arrange for this new fuel to fit easily into the existing fuel economy. Negotiating prices will be relatively easy, although there is likely to be hard bargaining between the nationalized gas industry and the oil companies which have found the gas. The real difficulty will be to cushion the changes which there are bound to be elsewhere in the British economy. How, for example, is the coal industry to be persuaded to contract even faster than at present? And how are the communities thus robbed of livelihood to be recompensed? Hitherto, successive British Governments have vacillated between the opposing beliefs that social considerations should determine—and limit—the pace of change, and that prices should be settled in the market and that supply and demand should then determine the balance with the fuel industries. If the natural gas finds in the North Sea turn out to be as plentiful as everybody hopes, the pressure on the Government to find a consistent compromise may even be great enough to prompt a satisfactory solution. Briefly, it needs to be recognized that marked changes in the pattern of the fuel economy have been and will be inevitable, and that the full costs of these are met by the prices charged for fuels of different kinds. Only in such a way can the most economic pattern be evolved with the greatest speed, but without grave social injustice to those with a vested interest in the preservation of an existing pattern—communities of coal-miners in Britain, for example.

NATIONALIZATION AND POLITICS

Politics and the Airlines

By Prof. David Corbett. Pp. 350. (London: George Allen and Unwin, Ltd., 1965.) 35*s*. net.

ONE of the most surprising things about Prof. Corbett's study of the policies and the politics governing airlines in Australia, Britain and Canada—to which the first six chapters of *Politics and the Airlines* are devoted—and, to a lesser extent, in the United States and India, is that in so technical a matter he never discusses the question of the technical or scientific adviser and his position in the formation of policy. Not that he is unaware of the problem. He remarks, for example, that studies of public enterprise tend to be sterile when they ignore the technology and the social environment of the industry they purport to analyse. He recognizes that the vital managerial decision for an airline is the choice of aircraft and that such choice must lie with the technical staff of the airline. Further, he maintains that airline managements make sound decisions when they can stand up to their Ministers. Airlines need strong boards and strong managements if they are to continue their tradition of excellence, and Prof. Corbett's study endorses the verdict of Prof. W. A. Robson in *Nationalized Industry and Public Ownership* as to the importance of resisting Ministerial pressure.

Again, he is well aware of the difficulties which, in Britain at least, arise out of the relations between civil aviation and the aircraft manufacturing industry. The interests of the two industries inevitably conflict at some points, and the Ministry tends to resolve differences at the expense of the airlines. For this reason, *Politics and the Airlines*, particularly the chapter in which Prof. Corbett discusses the means of Government control, is of some interest in connexion with the report of the Plowden Committee of Inquiry into the Aircraft Industry (see *Nature*, 209, 1053; 1966). He does not, however, pursue the implications of the view expressed by the Chairman of British Overseas Airways Corporation that the expense attendant on introducing an aircraft into service is part of its development and should be regarded as a proper charge against research and development funds, which are at the disposal of the Government. He is, in fact, concerned with the issue of public enterprise in general, and it is as a contribution to the discussion on the future of nationalization and a comparison of experience in different countries that his book derives its main value.

As such it is an admirably objective study though, as already indicated, of less interest to the scientist and technologist because scientific and technical issues are so largely ignored. Prof. Corbett first describes civil aviation before nationalization, and in his next four chapters examines the issue of public ownership, the great debate on nationalization, public versus private airlines and the issue of the public corporation. The chapter on Government control, already noted, is followed by two chapters on competition and regulation of airlines and on the International Airline of India—an example of enterprising bureaucracy; the conclusions of the study are set forth in a final chapter. These chapters reiterate the need for strong boards of directors in publicly owned airlines and the inherent inconsistency of placing related industries, such as aircraft manufacture and air transport, under the regulatory power of a single department. The tensions and political pressures thus generated can prevent either activity from being performed well. Prof. Corbett's own leaning is towards a mixed economy of private and public ownership, but he suggests that the system may have its own virtues and requires deliberate creation rather than that even the theory of such a system already exists. When regarded from an economic point of view, private and public ownership differ only marginally, and Prof. Corbett insists that party politics are increasingly irrelevant to the questi[illegible] though the rise and fall of

public enterprises depends as much on the political mood of the times and on the country in which they operate as on the formal relations linking them to the executive and legislative branches of Government. Although the book has copious references, a bibliography would have increased its usefulness; there appear to be important omissions among the British works cited.

R. BRIGHTMAN

ARCHAEOLOGICAL IDENTIFICATION

The Inorganic Raw Materials of Antiquity

By Dr. Andrée Rosenfeld. Pp. xiii+245+26 plates. (London: Weidenfeld and Nicolson, 1965.) 45*s*. net.

THE intention of Dr. Rosenfeld in writing *The Inorganic Raw Materials of Antiquity* was to provide the archaeologist with an introduction to the principles of mineral and rock identification, emphasis being given particularly to those materials most commonly used in antiquity. The need for such a book could only be doubted by those who have never had to cope with objects directly from archaeological excavations, for the identification of the materials from which antiquities were made can often only be described as frightening. Not only may wrong identifications find their way into final excavation reports, but also a failure at the time to appreciate the nature of the materials excavated may even result in inadequate excavation.

Allowing that most archaeologists have scant scientific training, in preparing this book Dr. Rosenfeld was clearly faced with one of two possible approaches. On the one hand, she could have provided a kind of 'cookery-book' for the identification of materials; on the other, she could begin by explaining the structure and composition of minerals, and go on from there. Wisely she chose the latter and, from the point of view of a writer, more difficult course. Molecular structure and crystal systems may seem remote when all the archaeologist wants to do is to ascertain whether a neolithic battle-axe was made of granite or syenite, but it is difficult to see how a really reliable method of mineral identification could be presented without these basic ideas. As it is, Dr. Rosenfeld has compacted the essence of mineral classification into a mere twenty pages of text; and this alone is no mean feat.

The contents of this book fall into two main sections. The first four chapters deal with the properties and identification of minerals and rocks. These chapters are of necessity brief, and the author has clearly taken pains to eliminate from the text all but the really vital materials. So far the book could have been written as an introduction to the subject for students of petrology, and one has little doubt that many such students will find it useful.

In the second half of the book are discussed the ores and metals used in antiquity; the manufacture of implements and ornaments; building materials; and the dating—by physical means—of rocks and minerals. Finally, a four-page appendix suggests how the archaeologist should set about identifying the materials that confront him. These final chapters are particularly valuable for their discussion of the merits and shortcomings of the various materials used by early man for tool-making and construction.

The book is clearly written and well illustrated, although many of the line drawings would have been better reproduced at a greater reduction. It is to be hoped that all archaeologists—professional and amateur alike—will not only read this book, but also continue to use it as a work of reference. It will be a pleasure indeed to open one of those neatly docketed little bags and to find that the description bears some resemblance to the contents: that the 'corroded bronze object' really is what it says, rather than a fragment of chlorite schist.

H. W. M. HODGES

NIGGLI METHODS FOR THE MANIPULATION OF GEOCHEMICAL DATA

Petrochemical Calculations

By Conrad Burri. Translated from the German by A. Katz. Pp. viii+303. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 108*s*.

A BASIC problem in geochemistry is the relation between the bulk chemical composition of the rock and the individual compositions of the component minerals. Prof. Niggli was interested in this problem throughout his life, and gradually evolved a series of procedures of which no connected account appeared during his lifetime. *Petrochemical Calculations* is a translation of a work which had been contemplated as a joint publication but which, in the event, was compiled by Prof. Burri after the death of Prof. Niggli in 1953.

An introductory section on some general problems of rock chemistry and on graphical methods of displaying analytical data leads to an exposition of the calculation, and application, of 'Niggli values'. These values are obtained by recalculation from the weight-percentage data of a chemical analysis, and their relation to other representative data such as cation percentages and molecular equivalent percentages is discussed. Their utility in geochemical calculations is fully demonstrated in the main section of the book, on the 'equivalent norm'. In contrast with the earlier CIPW norm, the equivalent norm permits rapid recalculation to different heteromorphic assemblages, and enables one to use the actual chemical compositions of modal minerals as easily as the standardized normative compositions. Thus the methods of calculation are equally applicable to metamorphic rocks, as the author demonstrates by examples of the determination of standard katanorms and epinorms and some modal variants. Brief reference is made to more recent proposals by T. F. W. Barth and P. Eskola concerning calculations in terms of anions and of a 'standard cell' based on 160 (O + OH).

The appendix provides an alphabetical index, with name, formula unit and equivalent weight, of the symbols of all the equivalent normative components used; a compilation of equations showing important reaction relations; and tables of equivalent numbers allowing for interpolation of 0·01 wt. per cent. A short section on "The Concept of a Magma-type" is followed by the tabulation, first published in 1945, of more than 180 supposed magma-types. The reappearance of this long list of recalculated rock-analyses under this head is regrettable, although it is stated in partial justification "in the context used here . . . a magma-type is defined merely as an abbreviated designation for the characterization of the rock's chemism". Many of the types listed are represented by rocks, such as manifest accumulates, for which the existence of a magma of the same composition is out of the question or has never been demonstrated.

The translation is adequate for a work of this kind, though phrases such as "the modus is not unequivocally determined by the chemism" or "the CO_2 evolved during the assimilation of the calc" do jar on the reader. The CIPW norm is misprinted as 'CPIW' in many places, including the index. The nonsensical term 'mesocratic' should read 'mesotype'.

The German edition, first published in 1959, referred to the "completely new development in rock analysis" which was beginning to take shape, in the form of rapid methods, at the hands of Shapiro and Brannock and other analysts. Because a much greater number of determinations could be carried out in a given time, it was becoming feasible to apply statistical methods to their interpretation. The intervening period has seen further developments which make this statement still more applicable to-day;

the advent of X-ray fluorescence procedures has so increased the rate of output of analytical data that the 'small calculating machine' recommended by the author must now give place to the computer. The large number of fully worked examples is a specially valuable feature of the book, the same three selected igneous rock-types being used wherever appropriate. Now that this first comprehensive account of the calculations is available to English readers it is likely that there will be greatly increased interest in, and use of, the elegant Niggli methods.

F. C. PHILLIPS

THEORY AND PRACTICE OF ELECTRON OPTICS

Electron Optics

By Prof. P. Grivet. Revised by A. Septier. Translated by P. W. Hawkes. Pp. x+781. (London and New York: Pergamon Press, Ltd., 1965.) 200*s*. net.

AN author setting out these days to write a book on electron optics has to stand comparison with the established texts: on the theoretical side with Glaser's *Grundlagen der Elektronenoptik* (1952), on the experimental side with Klemperer's equally comprehensive account of practical devices, *Electron Optics* (1953), which almost burst the bounds of a Cambridge Monograph on Physics. Yet it has long been time for a more up-to-date treatment. A great deal has happened in the past ten years or so, in both the theory and the practice of electron optics. For example, quadrupole lenses are barely mentioned by Glaser, nor electron probe microanalysis by Klemperer. Prof. Grivet has now set out to fill the gap, not without some feeling that a French contribution was needed, since he speaks in his preface of "his delight at seeing that this book is going to present the ideas of the French school of electron optics to an English-speaking public".

The task of preparing an account of electron optics in all its major aspects is formidable. I (and, I suspect, Dr. Klemperer also) have quailed before the task of revising my own book, fifteen or twenty years after. With Glaser's untimely death, the only theoretical magnum opus has remained untouched. The subject is now so ramified that only a team of specialists in its different departments could do justice to it, and this is the solution adopted by Grivet.

The origin of *Electron Optics* goes back over ten years, in fact, for it is based on a French text which came out in two parts, in 1955 and 1958, under the general title of *Optique Electronique*. Part 1, subtitled *Lentilles Electroniques*, was written in collaboration with M. Y. Bernard and A. Septier, and Part 2, *Microscopes, Diffractographes, Spectrographes de Masse, Oscillographes Cathodiques*, with F. Bertein, R. Castaing and M. Gauzit, as well as Bernard and Septier. There was also a third volume, dealing with particle accelerators and β-spectrographs. The present work follows the same general scheme as Parts 1 and 2, with some material from Part 3, but it is much more than a straight translation of them. The treatment has been thoroughly revised and brought up to date by Dr. Septier, with help (so the preface hints) from the translator. The extent of the revision can be judged from the length of the English text, longer by almost a third than the original.

In the first part, dealing with electron lens theory, the chief changes have been the inclusion in Chapter 8 of a full treatment of the triode electron gun, as used in electron microscopes, and of an even fuller description of the properties of quadrupole ('strong-focusing') lenses in Chapter 10. These latter have become increasingly important, apart from their uses in particle accelerators, with the realization that they offer a means of correcting the spherical aberration which afflicts the conventional form of electron lens, whether magnetic or electrostatic. The amount of research now being done in this field, mainly in Britain, France and Russia, is reflected in an increase in the space given to it from 7 to 26 pages; this concise review is very timely.

Two completely new chapters have been added to Part 2, on electron probe devices (including a section on electron-machining) and on β-spectrographs, the latter taken from Part 3 of the original work. In addition, the chapter dealing with the effect of an electron beam on the specimen has been considerably extended with an exposition of the uses of velocity analysers and velocity filters in electron microscopy. The book is rounded off by four tables of useful data, including one of Legendre functions of fractional order, and a bibliography of twenty-five pages. A great improvement on the French edition, the latter is arranged by chapter topics, making reference much easier.

Taken as a whole, this English edition is the most complete account of electron optics available in any language. It will be invaluable as a text for introductory courses in the theory of the subject, previous treatments being either too cursory or too detailed. The coverage of applications, however, is likely to find more critics, depending on their particular specialism. The electron microscope gets very full space, in all its aspects, possibly because of the early interests of the senior author. Those concerned with mass- or β-spectrometers, on the other hand, may well feel that they have been neglected, though it must be recognized that these instruments have been adequately covered in other works, such as K. Siegbahn's α-, β-, *and* γ-*Ray Spectrography*. Similarly, specimen preparation for electron microscopy, the brief survey of which is indeed rather out of place here, is now fully covered in a number of manuals.

Technically the book is very well produced, the text being much easier to read than in the French edition. The diagrams have been re-drawn and have also gained in the process. As for the translation, it is rarely possible to detect that it is such. Dr. Hawkes started with the advantage of having spent some time in the laboratory of the École Normale from which the project originated, and so was familiar with the outlook of the French school of electron optics as well as with the language. He is to be congratulated on the easy flow and correctness of his English rendering of a long and, in parts, mathematically intricate text.

Two criticisms may nevertheless be made of this edition, in regard to its subject index and its price. The former is too small, the latter too large for those most likely to benefit from reading the book—postgraduate students and other beginners in research. It would have been better to produce the book in two separate volumes in paper-back, as was the original, one on the theory and the other on the applications of electron optics, which might have been priced at about £2 each. Such a course would have multiplied the usefulness, and also perhaps the total income from sales, of a work which has a large prospective readership. Having supplied the needs of libraries and electron optical laboratories with the present edition, the publishers might care to consider adopting this course for the next.

V. E. COSSLETT

PROBLEMS OF STRUCTURAL DESIGN

The Design of Structures of Least Weight

(International Series of Monographs in Aeronautics and Astronautics. Division 1: Solid and Structural Mechanics, Vol. 8.) By H. L. Cox. Pp. vii+134. (London and New York: Pergamon Press, Ltd., 1965.) 40*s*. net.

THE design of structures, as opposed to their analysis, has two principal facets. One is concerned with the optimum disposition of material in a member, once its

loading and a characteristic dimension are known; the other concerns the layout of the members—clearly much more difficult, as evidenced by the smaller amount reported in *The Design of Structures of Least Weight* compared with the former aspect.

In his introduction, the author relates how Fairbairn attempted a rational design for the Menai Bridge some 120 years ago, and refers back repeatedly in succeeding chapters as to how the bridge might have been designed a century of knowledge and thirty years of metal aircraft building later. Mr. Cox himself has pursued both aspects of the structural design problem for more than twenty years, so that his exposition of the underlying principles is quite sound.

In successive chapters, the search for the optimum configuration in which local and overall buckling coincide is treated exhaustively for struts, wide columns and panels in compression, beams under pure bending, cantilevers under tip load and very simple braced frames. In each case there is a ruling structure-loading coefficient (elsewhere called the structural index) which determines how high the nominal stresses can be before instability occurs, and therefore the lowest possible weight achieved. An interesting conclusion is that the weight of end fittings is more significant for heavily rather than lightly loaded structures.

In the chapter on braced frames, wide geometrical variations are considered and this, in effect, leads to the question of layout dealt with next. The procedure explained enables families of plane framework to be constructed which yield the minimum weight. However, this is only possible in a few restricted cases. Recent work along these lines with the aid of a computer reportedly takes us little further. A chapter devoted to layout in practical design indicates the amount of effort required to design a simple frame for only two loading cases. Where optimum configurations are determinable, they may not be practical. The author likens these optima to the Carnot efficiency for heat engines. The conclusion summarizes the gaps in knowledge and is coloured by the poem on the "one-hoss shay" illustrating the ultimate object in engineering design.

The book is well produced, but marred by a few misprints and odd wordings. A further blemish is the author's penchant for developing analysis and arguments in parallel. One has to search back to find the definition of a symbol, and sometimes it has not been defined at all.

N. K. BENSON

PHYSIOLOGY AND FERTILITY

The Control of Fertility

By Gregory Pincus. Pp. xvii + 360. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 72*s*.

IT is now widely accepted that there is a pressing need for controlling human fertility. As yet, however, relatively few laboratories are devoted to the investigation of reproductive physiology or to developing new methods of fertility control in man, and many major grant-giving agencies remain aloof for various reasons. All the more praise, then, to Pincus and his collaborators for discovering and developing oral contraception. Their work stands out as the one major successful application of scientific knowledge to the control of fertility, most of the other methods in use having devious origins in history.

It would be difficult to find another author who has contributed so much to pure and applied knowledge in the field. Pincus and his collaborators provide the major sources of data, yet a glance at the reference list shows the breadth of coverage. *The Control of Fertility* has three major subdivisions: a brief introduction to reproductive physiology of two chapters is followed by six chapters on animal studies and then five on clinical studies. In each chapter a wealth of detail is discussed in a clear concise manner, and supported by data in tables and figures. Brevity is the rule throughout, so that the actual text occupies only three hundred pages, and the book is written with considerable authority.

Since many approaches to the control of fertility have not yet reached the level of clinical trials, the animal studies cover the widest scientific disciplines. Here the author is clearly at his best in dealing with the endocrinological side of reproductive physiology, and not surprisingly this approach provides the constantly recurring major theme of the book. Massive lists of compounds, mostly steroids, with their relative potency for the inhibition of ovulation or with their activity as anti-gonadotrophins testify to the effort put into this field. Pincus emphasizes the lack of relationship between the ovulation-inhibiting potency of synthetic steroids and their structural and functional features, and the differing potency of many steroids when given orally or by injection. Successive chapters deal with various aspects of fertilization and free ovum development, including the effect of agents on embryos in the fallopian tubes, a potentially valuable approach to controlling fertility. This section of the book is completed by detailed chapters on the suppression of implantation, especially by steroids and anti-steroids, and the biological action of compounds affecting fertility, mostly describing effects on the reproductive system. More detail on several topics, for example, the metabolism of spermatozoa, the structure of antibodies and their migration through the body, or the ultrastructure of gametes and embryos, would have widened the scope of this section of the book.

Most readers will perhaps turn to the clinical chapters first, and notably to Chapters 11 and 12, for the fundamental data on fertility control in man. New approaches to the control of male fertility, all so far unsuccessful, by hormones and other agents are described first, including the *bis*(dichloroacetyl)amines as inhibitors of spermatogenesis which proved unacceptable because of side-effects in combination with alcohol. After a chapter describing what is known of ovogenesis and ovulation in man, Chapter 11 describes how the inhibition of ovulation is assayed, and the remarkable effectiveness of progestin–oestrogen combinations as contraceptives. The effects of the pill on reproductive organs, blood clotting, somatic tissues, etc., and the interplay between different endocrine systems are described in detail in Chapter 12, the longest in the book. Many of the medical objections raised against the pill are dealt with, and quite fairly; no doubt controversy will continue, but the evidence certainly suggests that the pill is safe. Notice, too, how the pill can be beneficial, for example, in the correction of various uterine malfunctions. The final chapter describes the effectiveness and acceptability of contraception; some women readers might have strong feelings when they learn that their 'reactions' (vomiting, dizziness, etc.) have a psychogenic basis. The intrauterine contraceptive device is also dealt with here, although insufficiently, for more detail on this second major new method of controlling fertility would have been welcome, for example, on cost, acceptability in different countries or by different people, chance of mass application. This omission is perhaps explained by the recent advances in this technique, especially in the past 2–3 years.

The main story in this book is of the successful application of the inhibition of ovulation to the control of human fertility. Data from other scientific areas also make abundantly clear the effort now being put into the field. Scientists, clinicians and laymen will find a wealth of reference and detail, an awareness of the breadth of the field, and a clear linkage between biological data and clinical achievement. And many facts in the text confirm

Pincus's thesis that the methods of Nature can be improved on by the intelligent application of biological discovery.

R. G. EDWARDS

COMPARATIVE INVERTEBRATE NEUROLOGY

Structure and Function in the Nervous Systems of Invertebrates

By Prof. Theodore Holmes Bullock and Dr. G. Adrian Horridge. With chapters by H. A. Bern, I. R. Hagadorn and J. E. Smith. Vol. 1: Pp. xx+1–798. Vol. 2: Pp. viii+799–1719. (San Francisco and London: W. H. Freeman and Company, 1965.) 540*s*. per set.

INVERTEBRATE neurophysiologists have been compelled to work with a large, scattered, and unwieldy literature; Hanstrom's *Vergleichende Anatomie des Nervensystems der wirbellosen Tiere* appeared in 1928, and there has been no comprehensive account of invertebrate neurophysiology. The authors of *Structure and Function in the Nervous Systems of Invertebrates* have attempted to survey the present state of both these fields of endeavour. While I am still concussed by the magnitude of the enterprise, its scope may be indicated by a brief summary of the contents.

Part 1 (429 pp.) establishes the general mechanisms and principles governing the operation of nervous systems, and includes sections on micro-anatomy, excitability and conduction, transmission and integration, and a contribution on neurosecretion by H. A. Bern and I. R. Hagadorn. Parts 2–5 describe the special features of the groups and deal respectively with the lower Phyla (365 pp.), the Arthropoda (469 pp.), the Mollusca (242 pp.), and the Deuterostomes (70 pp.).

It must be said at the outset that the bibliography alone makes these books indispensable. Throughout, they are lavishly illustrated with photomicrographs, electron micrographs and excellent line-drawings. In addition to a careful use of headings and summaries, bold type is deployed in the text in two ways: to emphasize key words which indicate the topic under discussion, and to underline phrases which the authors feel to be of particular importance. This device, in practice, works well enough, although I find it visually rather irritating; occasionally, a phrase stands out from its surroundings with merely eccentric effect: **"lower phyla are on an equal plane with the nervously more advanced animals"**, for example (Volume 1, p. 271). However, the ease with which a particular topic can be run down more than compensates for these disadvantages. In general, the text is lucid, although there are some startling lapses, which sometimes seem to result from too strenuous an attempt at concision. Thus, on p. 16 of Volume 1 a paragraph, clearly intended to stand by itself, reads: "Correlated with cell-types is the **histological architecture of nervous tissue.** Whenever it occupies the superficial, basepithelial position characteristic of the simplest systems (coelenterate, echinoderm, enteropneust, the epidermal plexus of nemerteans, even the brain and cord of some simple acoel flatworms, terebellids and limicolous oligochaetes), the diagnostic tissue, a stratum of nearly cell-free nerve-fibres, lies deep in the epithelium, just external to the basement membrane, if present, and to muscle-fibres. It is visible even in sections stained by common unselective dyes as a **layer of punctate texture** but little structure, unless locally there are too few fibres to form a distinct layer." The paragraph which precedes this discusses the classification of neurones in terms of the differentiation of their processes, and it is followed by a paragraph on the organization of ganglia. It is not immediately apparent that the section I have quoted is intended to define the characteristics of a basepithelial nervous system, for the subject is neither mentioned by name, nor given the benefit of bold type.

In fact, the merits of these volumes are distributed in a way which clearly reflects the interests of the two authors; both are neurophysiologists of distinction, and the sections which display our present understanding of neural function are admirably comprehensive and well organized. They can be used as a quick source of information and read for pleasure, and to combine both roles in one text is a remarkable achievement. Nevertheless, only a small proportion of invertebrate nervous systems has been investigated physiologically, and many chapters are, in the nature of things, almost solely concerned with structure. Whenever an equivocal anatomical concept or finding affects a physiological hypothesis (for instance, the neurone doctrine, or controversies opposing continuity versus contiguity at synapses), we are given a scholarly and historical summary of the several points of view. But it does not help the neuroanatomist to be told, somewhat baldly, that dendrites can be defined as "those processes of neurones specialised as though to act as receptor regions for the soma", for he is more concerned to find labels which will enable him to categorize the units which he sees in his preparations, and the physiological function of which is probably quite unknown. He should, perhaps, be warned against the rising dangers of applying rigid terminologies with functional implications to structures which, in invertebrates, are often physiologically ambiguous.

But the pitfalls of neuroanatomical interpretation go far beyond matters of definition: they are implicit in the very nature of the histological methods which are available. Where so much depends on the limitations of individual methods of metallic impregnation, and on the difficulties of combining the different kinds of information which they provide, it is disappointing to find only a brief discussion of these techniques and of their application in practice. This is particularly serious in the case of such structures as the optic lobes of insects, for the amount of reliance that can be placed on the early accounts by Cajal and Sanchez and by Zawarzin requires some knowledge of the vagaries of impregnations of the Golgi type and of methylene blue staining respectively. The authors do not always tell us how the information which they present was obtained.

Obviously, a single reviewer is not competent to assess all the chapters. Those dealing with the Insecta manage to cover a vast range of material, but it is not always well organized. There appear to be some inconsistencies in the nomenclature of the optic tracts, and here a table giving the usages of the various sources would have helped. There is one curious omission: despite the importance of the corpora pedunculata, and a good account of recent work on their physiology and fine anatomy, the beautiful and accurate figures from *Apis* which Kenyon published in 1896 are nowhere represented. The exact topography of the intrinsic neurones of these structures, and of the afferent and efferent endings which lie within them, are crucial to hypotheses about the ways in which they may work, and only in this early study have they been displayed by selective silver methods.

These comments may seem ungenerous. Against them may be set the difficulties inherent in this monstrous labour of love, and the improbability of anyone attempting it again. Few comparative physiologists could have achieved the very real merits of these volumes, or have scoured the literature with the diligence and thoroughness which are everywhere evident. A physiologist who works in any one of the fields covered by this treatise is naturally inclined to look for the kind of critical evaluation of the literature which he would hope to find in a specialized review. Such hopes are extravagant; we should be grateful for what the authors have given us.

A. D. BLEST

THE SOIL MAP

Soil Survey

A Guide to Field Investigations and Mapping of Soils. Edited by I. V. Tyurin, I. P. Gerasimov, E. N. Ivanova, and V. A. Nosin. Translated from the Russian by N. Kaner. Edited by Mary Singer. Pp. 356. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 90*s*.

THE scientific examination of soil profiles, as distinct from the surface layers of soil, has been in progress since the end of the nineteenth century, and, commonly enough, by dedicated investigators intent on the identification and distribution of dominant types of soil over a particular territory. When Governments appreciated that the soil was a national resource worthy of systematic recording the pedologist acquired respectable standing, at least in some of the larger and thinly populated continental countries where land was still being developed. It is perhaps of interest to mention that soil maps were carefully consulted by bank managers in the Middle West of the United States in the early 1920's.

International co-operation became highly important in reconciling differences in nomenclature and classification. Nomenclature has, naturally, always presented trouble between different countries, and this has led to the fairly recent production of a dictionary of pedological terms in five languages by the International Society of Soil Science. A complete re-appraisal of soil language has also been made in the *U.S. Seventh Approximation*.

The first soil map of Europe was printed some 40 years ago and presented a broad picture of the main soil groups throughout the Continent; we are now awaiting a new map arising from the combined labours of European pedologists, who have thrashed out the differences and similarities in the various regions in order to produce an acceptable classification for soils derived from widely differing parent materials and climatic influences.

Britain was a slow starter in soil mapping, for there was a genuine feeling that British farmers knew all that was necessary about the suitability of their fields for the normal crops. Successes in plant breeding and machinery development, and economic pressures, seemed to outweigh all else in any change in agricultural practice. Nevertheless, the soil survey in Britain has accomplished much, for example, in dealing with apparently sterile areas or planning afforestation programmes or producing large-scale soil maps around expanding urban areas in the hope of preserving the potentially most useful soils for agriculture.

There are several manuals written for the soil surveyor. *Soil Survey* is a most comprehensive treatment of principles, techniques and applications. It goes into details that might seem to be superfluous to anyone who has not taken part in an expedition to an inaccessible desert or mountainous region that is remote from base. In this book, from the Dokuchaev Soil Institute of the U.S.S.R. Academy of Science, soil cartography is regarded as the basis of the quantitative and qualitative description of the terrain, having in mind the complexity of the problems involved in production. It discusses the principles of soil classification based on genetic characteristics, and cartography based on the relationship between soils and soil-forming factors. It is intended to remove misapprehensions in classification and to improve techniques.

The volume is divided into two parts, the first covering such topics as mapping scales, programmes of work and equipment required, the actual techniques of field work, including descriptions of territorial features and soil sections, the special conditions of mountainous areas, the processing of field samples and the drawing of maps, and the interpretation of aerial photographs. In Part 2, the utilization of the maps is discussed with respect to land management and planning, to special studies for soil amelioration, irrigation, reclamation, and for afforestation for such purposes as protective strips in arid zones or along ravines. The appendixes describe procedures for measuring the physical properties of soils.

The text is based on conditions and experiences in the U.S.S.R. and the bibliographies seem to be comprised exclusively of Russian papers. The translation, editing and production, apart from a few photographs, are excellent.

A. M. SMITH

REVIEW OF MODERN DIVING TECHNIQUES

The Principles of Diving

By Mark Terrell. Pp. 240+27 photographs. (London: Stanley Paul and Co., Ltd., 1965.) 50s. net.

DIVING equipment and techniques have changed radically during the past few years. *The Principles of Diving*, in addition to covering standard diving procedure, describes many recent developments, and provides a welcome and very useful source of information for anyone wishing to study advanced diving methods.

The early chapters deal with aqualung and sporting diving equipment, but the major proportion of this book is devoted to industrial and deep diving problems, even going so far as underwater blasting and wreck recovery.

The modern diver is no longer limited to the copper-helmeted equipment used thirty years ago; he now varies the clothing and breathing apparatus to match the conditions he expects to encounter. Terrell describes various forms of breathing apparatus which use high and low pressure air supplies from the surface, and follows this with details of various forms of portable self-contained breathing sets of both open- and closed-circuit patterns. At depths below 240 ft., both oxygen and nitrogen exert certain toxic effects on the diver, and the author describes the techniques which are used to substitute oxy-helium or oxy-hydrogen mixtures for air at these depths, and so allow the diver to descend as deep as 1,000 ft.

At great depths the water temperature is almost stable at 39° F. This poses quite a problem on how to keep the diver warm and capable of working, without excessive clothing to restrict his movements. In addition to the cooling effect of the water, the oxy-helium mixture he uses conducts heat away from the body almost seven times as rapidly as air. As diving from offshore oil drilling rigs becomes more commonplace, I can envisage the various points raised by Terrell being considered in great detail.

After reading the chapter on underwater medicine, one is left with the feeling that the only sensible thing to do is to stay on terra-firma. The symptoms associated with pressure injury vary from hallucinations, epileptic fits to blue skin and paralysis. The following chapter on underwater fishing is a welcome relief, until you read that the conger-eel can bend an underwater harpoon like a hairpin.

The views expressed by Terrell on future developments are already in part coming true. The recent work by Commandant Cousteau and the American *Sea Lab II* are the early stages of what can be described as the underwater industrial revolution. His scheme for an underwater tent to cover oil drilling rigs is already within the bounds of possibility. Multi-cell recompression chambers and submersible chambers are already being made by Siebe, Gorman and Co. Ltd. for prolonged deep diving projects in the North Sea and elsewhere.

In conclusion, I can recommend this book to anyone who has an interest in the problems and techniques of diving. Some of the sections on respiration and medical effects are necessarily complex, but the range of subjects covered gives an insight into the problems and achievements of the diving world, and it provides a fascinating story.

L. R. PHILLIPS

The Invisible Government

By David Wise and Thomas B. Ross. Pp. 375. (London: Jonathan Cape, 1965.) 30*s*. net.

THIS book might well have been entitled, perhaps more appropriately, *Invisible Power*. This suggestion is not made to emphasize any features the book has in common with Mr. Cater's *Power in Washington* or Prof. R. E. Newstadt's earlier *Presidential Power*, but because it is concerned essentially with the theme of power and influence within the working of a reputedly democratic system of government and not directly with the Government itself. It is concerned, as are both those books, with the situation in the United States and with what can happen under the cloak of secrecy or security, especially if these two terms are not clearly distinguished, when institutions created for valid purposes become their own custodians or judges. The book describes in some detail the organization and functioning of the intelligence service of the United States, including Army Intelligence, the oldest service, the Office of Naval Intelligence, the smallest, Air Force Intelligence, mechanically the most sophisticated, the Atomic Energy Commission, the Federal Bureau of Investigation, the Bureau of Intelligence and Research, and finally the major institutions—the National Security Agency, the Defence Intelligence Agency and the Central Intelligence Agency.

For the British reader, the real interest of the book does not lie in these descriptions, nor in the account of various episodes of the past fifteen years which indicate their weakness and the acute difficulties of control which have resulted in them appearing on occasion to determine policy rather than to be ruled by it. It lies in the way the book raises the real questions and problems of control which confront a democracy in this age of rapid technological development. There is displayed, for example, even more insistently than in the recent report from the Estimates Committee on Electrical and Electronics Equipment for the Services, the problem which secrecy presents and the way in which it can react to endanger the security which secrecy itself purports to serve. There is the issue of advice, and insistently, naggingly, all the time the question of who shall control the controller. Nor are the issues confined to defence. The implications for the Fulton Commission are plain, and if the authors offer little in the way of constructive suggestions, their warnings are unmistakable. This sombre book should not be overlooked by anyone seriously concerned with the relations of Government and science, though it will challenge his thought rather than contribute to his peace of mind.

R. BRIGHTMAN

Fluorine Chemistry

Vol. 4. By Harold C. Hodge and Frank A. Smith. Edited by J. H. Simons. Pp. xviii+786. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 224*s*.

VOLUME 4 of *Fluorine Chemistry* is not a book which will be of primary interest to chemists who are engaged in the very broad field known as fluorine chemistry in the same sense that the first three volumes in this series were. It is a condensation of some 3,500 references on clinical information pertinent to the physiological effects of fluoride ion.

The first chapter deals with the biological properties of inorganic fluorine compounds which provide fluoride ion in solution, and *in vivo* may cause acute or chronic poisoning. The mechanism of fluoride poisoning, its treatment, and the nature of fluoride toxicity in organs, glands, blood and other parts of the animal and human anatomy are considered in detail. The purpose of the book "has been to collect information about the biological effects of fluorides in compact form . . . has not attempted to formulate and state critical opinion of the knowledge about every biological effect of fluorides".

The second chapter is concerned with the effect of fluorides on the bones and the teeth. The various factors effecting fluorosis, osteosclerosis and osteofluorosis are critically correlated. The relationship between fluoride ion intake, mottled tooth enamel and dental caries is covered extensively. In view of the many debates which have arisen in many communities concerning the topic of fluoridation of drinking waters, part of this chapter is most helpful in providing scientific evidence which can be used to point out the benefits and possible damage to tooth structure which may be associated with the adjustment and control of fluoride ion concentration in drinking water. The authors do not take a position on this controversial subject. The terminal portion of the book concerns itself with hard tissue metabolism of fluoride ion in bony structures and teeth.

This volume of *Fluorine Chemistry* is directed not to chemists but to medical and dental scientists. It contains a vast quantity of information on the causes of, possible preventive procedures against and possible cures for disabling physiological effects caused by various fluorochemicals as well as the harmful effects of fluoride ion deficiency. Nevertheless, it will be of more than passing interest to the fluorine chemist and of special interest to those concerned with water treatment and to practitioners of industrial medicine and dentistry.

It is most fitting that the authors and the editor of Volume 4 of *Fluorine Chemistry* have seen fit to dedicate their efforts to Prof. Kaj Roholm of Copenhagen.

RICHARD DRESDNER

Fair Isle and Its Birds

By Kenneth Williamson. With a List of the Birds of Fair Isle by Peter Davis. Pp. xvi+311+27 photographs. (Edinburgh and London: Oliver and Boyd, Ltd., 1965.) 30*s*. net.

FAIR Isle and Its Birds is a book for the general reader whose interests include remote places, wild birds and the scientific riddles of migration; it brings together, in a pleasant form, material that has appeared before in scattered articles and papers. The first part deals with the island, its people, its history, its general natural history, and the habits of some of its breeding seabirds—skuas of two species and the fulmar. The second part gives an account of the tremendous phenomena of bird migration that can be observed from this remarkable vantage point. In the third part Peter Davis provides an annotated systematic list of the birds of Fair Isle. John Peterson contributes excellent photographs of scenery, human activities and birds.

Fair Isle was made ornithologically famous by the visits of Eagle Clarke in the period 1905–11 to observe the spring and autumn passages. It provided part of the material on which his pioneer studies of migration were based, but there remained much more to be extracted from this rich source. In 1948 a regular observatory, manned except in mid-winter, was established by the efforts of George Waterston and others. Kenneth Williamson was appointed as the first warden, serving for eight years, and Peter Davis was his immediate successor.

In the middle part of the book the author describes the observatory and its work and gives an account of movements to be observed in spring and in autumn. He lays emphasis on the influence of weather on both the actual and the observable performance of the migrants. He attaches special importance to the effect of wind direction in causing lateral displacement of lines of flight; some of his views, he says, are personal. This theme is notably exemplified in a chapter called "Wheatears and Redwings", illustrated with weather maps relating to certain strongly marked autumn movements in which the origin of the birds was indicated by recognizable subspecific characters. A final chapter deals with some of the astonishing number of rarities that have been recorded from Fair Isle.

LANDSBOROUGH THOMSON

THE PLACE OF THE ENGINEER IN SOCIETY*

By LORD SNOW†

THE status of engineers in Great Britain is lower than in any country that I know of. This condition of things reflects a good deal that is wrong with our society. Right at the heart of this discussion there is the need which all sensible people increasingly feel for engineers all over the world to be close to all the decisions which are going to affect our human society.

To an extent, however, engineers get the rough end of the stick even in countries where they are more esteemed than in ours. There is the bitter American crack—invented by an engineer. You fire off a rocket and a satellite moves successfully around the world. That is a scientific triumph. On the other hand, if it flops on the launching pad, that is an engineering failure. The only country I know where they really do have maximum prestige is the U.S.S.R. It is hard to imagine an English or even an American engineer being given a State funeral—but Korovolov got one in Moscow this winter. The present President of the Soviet Academy of Sciences is an engineer. So, curiously enough, is the present Soviet Prime Minister. It is still difficult to imagine similar appointments to the Royal Society or to No. 10 Downing Street.

The position in Britain is much less favourable. Somehow, and soon, this position has to be altered. But the first thing I want to tell you is that engineers themselves cannot do much about it. The protest and change have almost certainly got to come from others. Unless we raise it to an extent commensurate with the importance of engineers to our society, then our society cannot possibly exist in economic health or in intellectual and moral health either.

There is not much that engineers can do for themselves, and I suspect that the less engineers talk about the problem, the better for all that we want to attain. I am entirely in favour of the new Council of Engineering Institutions. But formal organizations of this kind usually do not affect the status of an activity by 1 per cent. With some reserve, I am in favour of the new designation of Chartered Engineer. But again experience suggests that professions riding the crest of the wave tend to take this kind of designation rather lightly. Scientists in Great Britain, for example, enjoy a very high status, probably as high as in any country in the world. Our pure science continues to be remarkably successful. After the United States, we come a clear second in the Nobel Prize race.

It is no accident that among our scientists there is still a cheerful and relaxed attitude to qualifications. Cockcroft is a great physicist, but he has never taken a physics course in his life. Einstein and Dirac, two of the most profound theoretical scientists, not only of this century but of all time, started life as engineers. Crick has revolutionized modern biology; but he has had as much formal instruction in biology as he has in Hebrew. The point I wish to stress is that the scientific climate is easy-going and encouraging. It would be a mistake and to my mind a suicidal mistake if engineers, feeling, and rightly feeling, that they were undervalued, went on the defensive and, being on the defensive, became not less rigid but more rigid.

It seems to me probable that engineering has already suffered through the rigidity of its training. This is one factor, but an important one, in the lack of appeal of the profession to men of original and unorthodox minds. At all costs, we need to attract such unorthodox minds. I believe that constantly we ought to look over our shoulders and ask why pure science is so good at attracting them—and what is wrong both with the education and the career of engineers that acts as a negative inducement.

Pure scientists have been taken, although with some difficulty, into the main stream of British society. They can be depicted, with some hope of establishing communication, in films and plays and novels and in the mass media. With engineers the barriers are much more formidable. Why has this happened? And how are we going to put it right?

Why it has happened seems mainly a matter of our social history, but a good many of the reasons we still do not begin to understand. It is at first sight puzzling that the British, who began the first industrial revolution, one which was closely linked with the work of engineers, should during the nineteenth century come to think less of engineers and care less about their education: whereas in the United States and Germany, industrializing themselves about 20 or 30 years later, exactly the reverse was true. This is one of the oddest phenomena in English history. From it has followed many of our existing discontents. Relative to the United States and Germany, Britain was on the technological decline very early. One can even put a date to it. It was somewhere between 1851 and 1867. If Britain had put one-tenth of the effort into engineering as into the Indian Empire it would now be a very prosperous country, individually more prosperous than Sweden and able to look American technology in the face.

It is no use repining about where our ancestors went wrong. The important thing is not to continue to go wrong.

It is, however, going to take a long pull to get rid of the lack-of-insight-syndrome—the various symptoms which prevent us recognizing what is necessary for us in terms of rudimentary social health. Features of this syndrome are lack of awareness of who makes the social wealth; absence of interest in, or even active hostility to, the technological basis of our society; nonsensical patterns in education. These malaises are very deep. Even with good fortune it is going to take 10 to 20 years before we breathe a freer air and walk about with a more robust common sense.

Above all, we need a powerful educational effort, an educational effort which reaches to the people who have to make the decisions, and also produces a new generation of those who will make the decisions in 10 or 20 years. We need to produce new generations of

* Substance of the Graham Clark Lecture delivered at the Institution of Electrical Engineers on March 24.

† Lord Snow was Parliamentary Secretary to the Ministry of Technology in the British Government from October 1964 until April 1966.

engineers who have been taught engineering as a humane education.

Not that I want all our bright boys and girls educated as engineers—any kind of talent is worth training to the full. Our society would be immensely impoverished without full scope for its artists and linguistic scholars. But I am more than ever convinced: (1) that our secondary education is too specialized; (2) that we must search for and train—and probably specially train—every kind of really high ability; (3) that we have to make special efforts at the undergraduate level to make engineering education something which it is not at present or at least has scarcely begun to be.

It is not enough to think that someone who is a natural engineer will find his way into the profession. Very largely that is true of engineering, as it is true of pure science or music or painting. But the number of people with a deep and passionate vocation for any walk of life is quite small, a tiny fraction of 1 per cent. What is needed is to attract, to valuable social functions such as engineering, people who could do many other things. Most of us respond to the pressures of our society. Where the esteem and the rewards appear to be, there able people will go. Most of us, if we had been born 800 years ago, would not have studied engineering or science, for the very good reason there was no engineering or science to study. We should probably have become canon lawyers, however, just because that was the road to all the administrative jobs there were. In the same way the high-class professional English administrators in the nineteenth century studied Greek and Latin. Not because they could gain an intellectual training, which indeed they did, certainly not because of profound literary interests, but because that was the accepted training for anyone who aspired to run this country. Our task is to make engineering just as natural, just as accepted educationally—not the only way, but an important way—for young people of high ability who want to test themselves to the full.

It is surprising that engineering has not in fact become more of a humane education. The training is rigorous, and that is a good thing. No subject is really worth years of time for a good mind unless it is, in the old-fashioned academic sense, 'hard'. Engineering is certainly that. It is, or certainly ought to be, deeply concerned with human beings. That is, an engineer does not exist in a vacuum; his working life is going to be intimately concerned with people; the results of his activities are going to affect much larger numbers of people. And yet, somehow, engineering, like medicine, with which it has much in common, has up to now been something of a failure as an educational discipline in its own right.

I am not being abusive. I have spent much of my life among engineers and count some of them among my most intimate friends. By and large engineers turn out to be very good citizens, honourable, responsible and upright. But I think that most of us would agree that they are not by and large as fully educated as we should like. It is partly for that reason that they do not play the prominent part in British society that we should also like. There ought to be far more engineers where the decisions are really made—in Government—in Parliament and at the top levels of the Civil Service. This does not happen. In the United States it happens a good deal more, in the U.S.S.R. incomparably more. When we have good engineering education I believe it will begin to happen in Britain.

I believe one can identify two defects—there are probably many more—in contemporary engineering education. For one thing, it does not encourage enough the speculative and rebellious intelligence. This is its great handicap, and its great lack of appeal, as opposed to pure science. Engineers are good citizens. It is rare for engineering students to question everything under heaven or earth in the way that good scientific students will. Medical education also seems to repress the speculative intelligence. Engineering students and medical students are nearly always the most conservative-minded of any large student groups. This tells its own story. I am not asking the engineering profession or the medical profession to move as one man sharply to the left. What I am saying is that a uniform approach and a conformist approach to all the major problems of society suggests either that we are getting too homogeneous an entry in these professions or, alternatively, that the training itself has a rigidifying effect. I should like to see as part of all engineering education what one can already see at the Massachusetts Institute of Technology and the California Institute of Technology and some colleges of technology in Great Britain—a serious study of social history or economics or any subject which of its nature is bound to arouse the speculative mind.

The second of these two defects seems to me to be the lack of verbalism in engineering training. Engineers, as engineers can get on very comfortably without words. Engineering students can make do with a very small vocabulary. But engineers when they are not being engineers, when they are moving into management, boardrooms and government, are often handicapped just because they have neglected or despised the use of words. Language, verbal language, is a great invention. It is different from symbolic language, and a man is lucky if he is equally at home with both. But without some feeling for verbal language there is much of human wisdom shut off from one for ever. If engineering students are going to hold their own in 10 years' time with people of comparable intelligence but different training, they will have to be as good on paper and as good speaking on their feet.

I believe this widening of engineering training would of itself attract a great many students of high ability who at the moment are being drawn into pure science or economics. It is precisely such students that we need. Some of them will be among the decision-makers of the 'eighties.

If we get our education right, then in the long run the place of the engineer in our society will become right. But what a society recognizes is ultimately expressed in concrete terms. These terms are not only financial. To most sane persons, esteem is more important than pay. If we had a choice most of us, I hope, would prefer to be President of the Royal Society than the most successful pop singer in the world. Yet the most successful pop singer in the world has been out of proportion better rewarded financially than any of the Presidents of the Royal Society. Nevertheless, pay, in a qualified sense, does matter and is likely to continue to matter. Modest differentiations are well understood by people who do not expect to bring to the community the special contribution that a creative engineer can bring. If that is agreed, at present we certainly are not lavish with our awards to these creative engineers. Take one of my theoretical young people of high general ability who could become reasonably accomplished as a pure scientist or economist or engineer. At the moment, if he is thinking only of money, then engineering is not the first profession he would choose. His starting salary as an engineer would be as good as, or better than, the others. His terminal salary is likely to be appreciably lower. This is another surprising fact, but the evidence is overwhelming.

I am sure this cannot be right. Once again, it will not be adjusted overnight. The proper value placed on engineers will only happen when we who are interested contrive to get our side of the house right. And when we have persuaded the rest of society what engineers are like, what they can do, and how on them depends a large part of whether Britain flourishes or dwindles, not rapidly but imperceptibly, into decline.

LONG-TERM (GEOTECTONIC) STRESS GENERATION, PROPAGATION AND ACCUMULATION IN THE EARTH

By JEROME B. CARR*

General Dynamics Electronics, 1400 North Goodman Street, Rochester, New York

A GREAT deal of effort in the past has gone into the development of theories and hypotheses for explaining particular geotectonic expressions of stress relief in the Earth. For example, efforts have been made to explain where the stress for earthquakes originates and how continents maintain their above sea-level expression against the high erosion rates that are known to exist. Looking at the results of all this labour, one is faced with a geotectonic mechanism for each expression of stress relief in the Earth and quite often these mechanisms have little or nothing in common.

To reduce this multiplicity of mechanisms, one must be aware of the time spectrum of geotectonic stress relief (see Fig. 1). Given the existence of this spectrum, one would suspect that all the expressions of stress relief are due to the same source of stress generation. Thus it can be presumed that there is a single source of stress generation in the Earth and that the mechanisms giving evidence of this stress are a function not only of the origin of the stress, but also of the methods and limitations of stress propagation and accumulation within the Earth.

Among the elements of stress relief it is known that earthquakes are associated with plateau uplift, island arc formation, mountain building and continental maintenance. (The last-mentioned is defined as "the ability of a continent to maintain itself above sea level".) However, even though we know that interrelationships exist between geotectonic elements, the exact nature of these relationships cannot be fully understood by studying the extreme ends of the geotectonic spectrum because the relationships are masked by intermediate scale geotectonic components. Thus the logical place to start studying stress generation is with the meso-scale geotectonic structures which are direct indications of recently applied stress. If a mechanism can be uncovered which would explain the meso-scale geotectonic structures, then this same mechanism should also be capable of explaining some properties of the extreme ends of the geotectonic spectrum. At the same time, the finding of relationships between geotectonic elements should throw light on stress propagation and accumulation once the generating mechanism is understood.

Let us first direct our attention to plateau uplift. There are two types of plateau uplift—the first type being of moderate area but of very rapid and high to very high uplift. The Colorado Plateau and the Tibetan Plateau are two prime examples. The second type of plateau uplift covers a much greater area but is slower in rising and tends to be lower in elevation. Areas representative of this type of uplift are the Brazilian Highlands, the western half of Australia, and Africa south of the Congo Basin.

To produce these regions of plateau uplift, material must be volumetrically added to the sub-crustal areas where the plateau uplift mechanism occurs. The two causes of volumetric increase postulated at present are convection currents in the mantle and phase changes at the Moho. The three main objections to the concept of convection currents are: (1) the volume increases required by plateau uplift are too great to be produced by slow moving convection currents and rapid moving convection currents are precluded by the physical properties of the upper mantle[1]; (2) mantle-wide convection has been shown to be impossible due to the changes in the Earth's physical properties between 400 and 1,000 km (ref. 2); (3) studies of seismic surface waves show that continental and oceanic structural differences extend to 400 km depth[3], thus requiring mantle-wide convection to produce continental drift (see 2 above) and preventing convection cells from passing through continental borders to reach regions of plateau uplift.

For the reasons just listed, it is concluded that the eclogite-basalt phase change at the Moho offers the best mechanism for volumetric increase to produce plateau uplift. However, there is one major objection to interpreting the Moho as a basalt-eclogite phase change; that is, the Moho appears to be too shallow in oceanic regions for this explanation.

Recent work[4,5], which validates the concept of the world-wide shear pattern proposed by Vening Meinesz, clearly implies that the ocean bottom is much older and more stable than continental regions. This extreme stability of oceanic structure raises an important question. That is, "What is the effect of pressure on the eclogite-basalt phase change over very long time periods?". Put in other words, "What is the effect of a pressure of $3{\cdot}3 \times 10^9$ dynes/cm^2 over a time period of 2,800 million years or more?". Obviously the phase change experimentation that occurs in to-day's high pressure laboratories is completely incapable of evaluating the effects of such long periods of time. Thus, the Moho under the ocean could be a basalt-eclogite phase change that is in complete

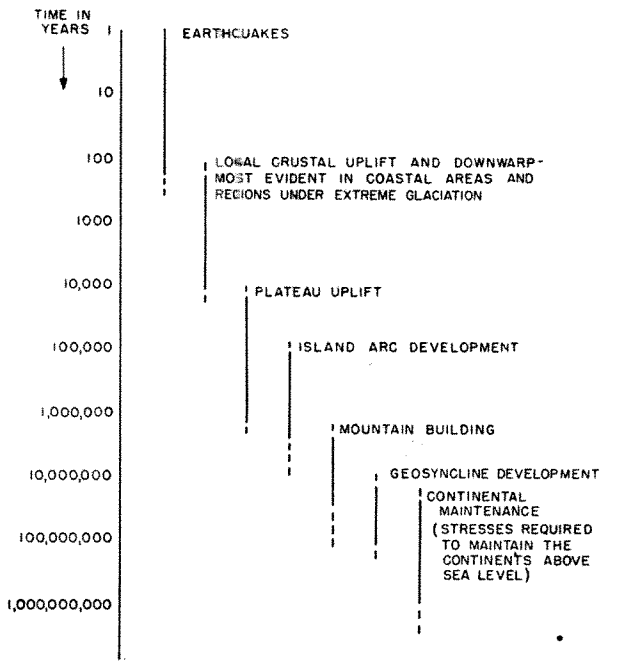

Fig. 1. Time spectrum of geotectonic elements

* The author wishes to acknowledge that all but the final preparation of this publication was made while he was at Sperry Rand Research Center, Sudbury, Massachusetts.

hydrostatic stability due to lack of vertical motions that are so prominent in continental areas.

Given that the foregoing statement is true, let us take the Colorado Plateau as a case study region. The Colorado Plateau is delineated in Fig. 2 and the major faults in the adjacent Basin and Range Province are also shown. From Cambrian time to middle and late Mesozoic time, sediments were deposited (though not continuously) on both the Colorado Plateau and the Basin and Range Province. The sediments, being poor thermal conductors, acted as an insulator and caused trapping of heat generated by the decay of the radioactive elements in the underlying sial. This heat expressed itself as vulcanism and plutonism in the Basin and Range Province due to the presence of faults and other zones of weakness which allowed the magmas to migrate towards the surface. The Colorado Plateau, however, is lacking these faults and zones of weakness and therefore the thermal energy at depth was used primarily to convert eclogite to basalt and uplift the region as a whole. The depth to the Moho under the Colorado Plateau averages 40 km (ref. 6) and this is some 10 km deeper than the location of the Moho underneath the Basin and Range Province. Since the phase change generates a 10 per cent increase in volume, the uplift due to volume increase alone would be 1·15 kilometres or some 3,600 ft. In addition to the volume increase, however, the phase change also causes a local reduction of g. The amount of uplift required to satisfy once again the geopotential conditions which existed before the phase change occurred is an additional 4 km. Thus there is easily enough energy generated by phase change to allow for the present 1·5 km (5,000 ft.) elevation of the Colorado Plateau and also enough energy left over to account for uplift and erosion in the past, uplift in the future, and propagation of energy into other locations at the present time.

Now that the case study region is found to satisfy the physical requirements of the uplift region, let us consider the geography of island arc regions as these regions also reflect stresses which are, or were, recently active. The most complicated island arc regions are the Indonesian and Caribbean regions. Indonesia is found between the Tibetan Plateau and the continental mass of Australia, while the Caribbean area lies between the Colorado Plateau and the continent of South America. Since there is an apparent geographical relationship between these two geotectonic elements, let us infer that this relationship includes a common stress source. Thus, at first glance, the development of complex island arcs appears to be due to: (1) stress generated in a region of plateau uplift; (2) this stress being propagated through the Earth until it strikes an immovable continent; (3) since the mass of the continent is too large for this stress to move, the oceanic crust close to the continent breaks; (4) it breaks along pre-existing zones of weakness which were generated as a part of the world-wide crustal shear pattern[4,5]. This is the initial picture which arises when the Earth is considered in Mercator's projection. Let us now switch our attention to a spherical Earth. First it is known that the initial phase change causing plateau uplift originates at the Moho at its initial depth of about 30 km. The change in volume at this depth will produce stresses which may be propagated rectilinearly in all directions. Looking at the two complex island arc regions it is seen that the distance from the closest border of the Colorado Plateau to the extreme limit of the Caribbean arc is 47° of arc and the corresponding distance to the Indonesian arc region from the edges of the Tibetan Plateau is 53° of arc. Plotting this larger figure (see Fig. 3) it is seen that the maximum depth of stress propagation is 690 km. The known limit for depth of earthquakes is 720 km and thus it is seen that the limit imposed by seismic data does not rule out the proposed new mechanism for island arc formation.

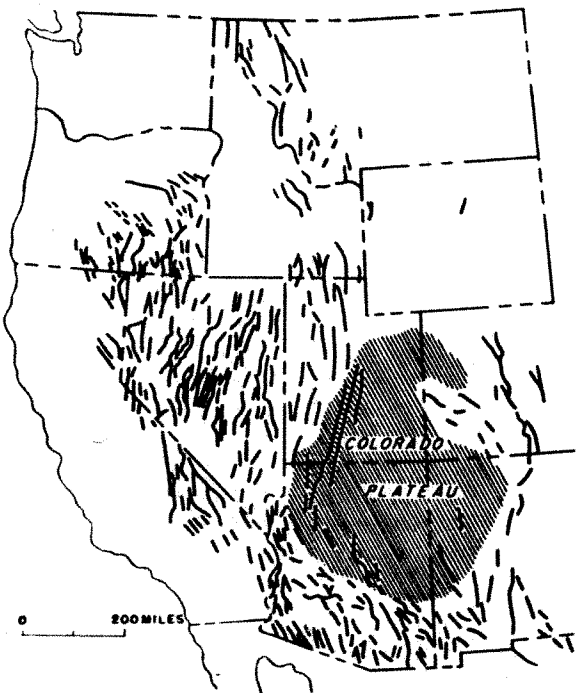

Fig. 2. Delineation of the Colorado Plateau (shaded area) and the faults of the Basin and Range Province (heavy lines). Figure taken from ref. 12

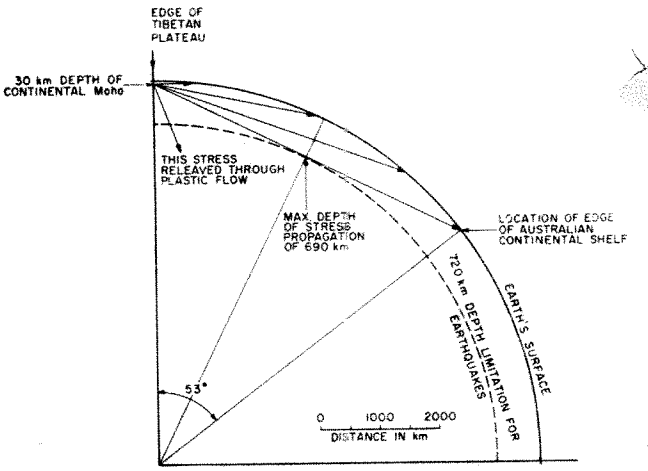

Fig. 3. Rectilinear stress propagation in a spherical Earth. This figure shows a spherical Earth with stresses propagating from a region of plateau uplift to the extreme limit of a complex island arc located 53° of arc from the edge of the plateau uplift

Looking again at Fig. 3, it is to be noticed that the stress propagated 53° just touches the continental shelf of Australia and that no stress is directly acting on Australia. Thus it is suspected that no continental backstop is needed for island arc generation, but that the backstop merely generates a more complicated set of arcs when the backstop is available. Checking the globe, it is seen that all the island arcs from Indonesia to the Kamchatka Peninsula are within 53° of the edge of the Tibetan Plateau. It is also seen that the island arc region located off the southern tip of South America is within 53° of the Brazilian Highlands and the Argentine Plateau. Lastly, the Aleutian Islands Arc, with the exception of the westernmost few islands, is within 53° of the Colorado Plateau. When the flattening of the poles is taken into account, the entire Aleutian Arc may be accounted for without exceeding the stress depth limitation. Thus, by examination of the globe, it is found that every island arc region in the world can be accounted for by stress generation from a region of plateau uplift.

Before checking this concept of island arc formation against the geological evidence, it should be noted that the arcuate structures observed in the Earth's crust are amazingly similar to the arcuate structures observed as crystal dislocations. In Fig. 4, some linear shears are shown with the arcuate structure rounding off the intersection of these linear shears. The same type of rounding off is observed when one superimposes the Mariana Islands Arc on Vening Meinesz's crustal shear pattern. The correlation coefficient between island arcs and the crustal shear pattern is 0·90, thus showing that island arcs fit the linear zones of weakness proposed by Vening Meinesz's crustal shear pattern[6]. Since the physics of shear can account for the arcuate nature of the island arcs, we need not try to propose one mechanism for arcuate structures and a second mechanism for linear structures.

The geological evidence concerning the island arcs is of two types. The first type of geological evidence is that the structures of the Earth are generally found to be due to compression. Thus, if the concept of island arc formation outlined here has any basis of reality, the directions of compression should point to regions of plateau uplift. With respect to the Indonesian Island Arc, it is known that the stress required to generate this structure came from the north-west[7]. Thus it is seen that the proposed mechanism of island arc formation agrees with the required direction of stress in at least one area that is structurally well explored.

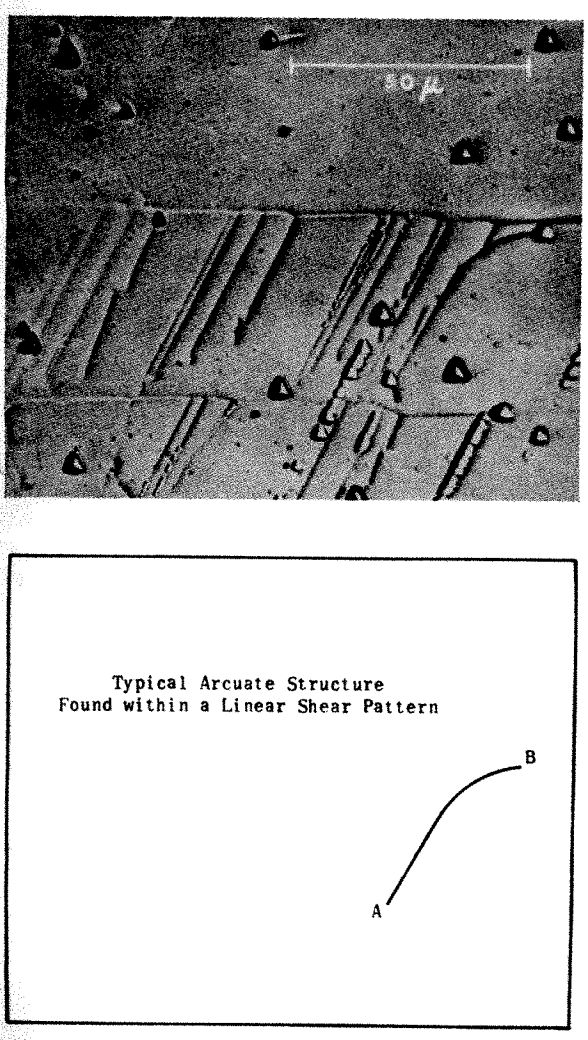

Fig. 4. Typical arcuate structure found in a linear shear pattern. The upper figure is a photograph of a shear pattern in a silicon crystal. The lower figure shows the location of the arcuate structure (line *A–B*). The relationship between this arcuate structure and the linear shear pattern is analogous to island arcs when compared with Vening Meinesz's crustal shear pattern

The second type of geological evidence which offers a check on the new concept of island arc formation is the relative ages of the structures involved. That is, if the island arcs developed before the plateau uplift areas began their ascent, then obviously the new concept is invalid. However, on examination of the data available, it is seen that the arcuate structures of Indonesia, the Mariana Islands and the Kamchatka Peninsula are all younger than the first uplift motions in Tibet and that the Japanese Islands Arc is younger or at least the same age (Upper Carboniferous) as this first uplift. Thus the independent evidence from geology offers no contradiction to the proposed mechanism for island arc formation and, in fact, the compression evidence from Indonesia substantiates the proposed mechanism.

To sum up the development of island arcs it appears that: (1) the stress generated in a region of plateau uplift is rectilinearly propagated into previously stable ocean regions over a distance not greater than 53° of arc; (2) this stress expresses itself in arcuate or linear structures controlled by a shear pattern produced in the Pre-Cambrian; (3) after initial stress relief has occurred, the Moho, which was previously in hydrostatic equilibrium, now acts as a local stress source in seeking to re-establish the lost equilibrium; (4) normal geological processes will be triggered by the initial disturbance, thus producing volcanoes, etc.; (5) should continental backstops be present, complex island arc regions develop—otherwise simpler structures are produced.

Now let us pay detailed attention to earthquakes—the high-frequency end-member of the geotectonic spectrum. With respect to earthquakes it is well known that shallow earthquakes (focal depth less than 70 km) dominate the seismic scene and that a large number of shallow focus earthquakes occur at the depth of the continental Moho. This latter fact strongly reinforces the concept of the Moho being a phase change because, if the Moho were only a change in material, it would be very difficult to explain the high number of earthquakes which occur near this discontinuity.

Also, since the continents are known to be continuously undergoing complex vertical movements (which we now assume are due to phase change at the Moho) and since we have also commented on the extreme stability of oceanic regions, it should be expected that earthquakes will occur anywhere on a continental mass and be severely restricted (numerically) in ocean regions. This is indeed what is seen in a plot of earthquakes. Fig. 5 shows a plot of earthquakes for a one-month period and it is seen that only 2·5 per cent of these earthquakes occur in open ocean regions; that is independent of island arcs and continental structure.

As stated earlier, there is an obvious relationship between individual earthquakes and meso-scale geotectonic elements. However, it remains to be seen if there is any gross relationship between the world-wide earthquake distribution and the phase change which occurs under plateau uplift regions. As it turns out, if the oceanic structure is indeed as stable as earlier work indicates[5], and if it is true that stress cannot be propagated more than 53° from its source, then there should be one or more regions of no earthquakes on the oceanic structure of the Earth. Fig. 6 shows the locations of the major regions of plateau uplift; and the area delineated in the centre of the Pacific Ocean is the only area on the surface of the Earth that lies outside of the 53° range of stress propagation. On investigation[8–11], it is found that within historical time there has never been an earthquake within the area delineated. At the present time, the probability of generating such a region by a random process is less than 0·02. Thus the concepts of phase change stress generation, rectilinear stress propagation and a stable ocean structure are strongly reinforced by the mapping

and satisfactory explanation of the "zone of no earthquakes". Since the ocean structure reflects the assumed stress propagation mechanism so nicely, perhaps some similar evidence can be found with respect to continental areas. Mapping the European earthquake distribution one would expect (based on area) about 25 per cent of all European earthquakes to occur at distances greater than 53° from the Tibetan Plateau. However, on plotting all European earthquakes during 1956 (ref. 9) and for the first half of 1963 (ref. 10), it was found that less than 1 per cent of them occurred at distances greater than 53° from the edge of the Tibetan Plateau (see Fig. 7). Thus major plateau uplifts are seen to be tied to earthquake distributions on continents as well as on oceanic structure.

Now that we have considered the two-dimensional distribution of earthquakes, let us extend our outlook to three dimensions. Figs. 8 and 9 show the distributions of intermediate (70–300 km) and deep (300–720 km) focus earthquake regions.

The results of this extension of the previous investigation of earthquakes lead to a preliminary classification of earthquake regions (see Table 1). Special notice should be paid to the 'Special Ocean Area', that is, the Fiji Islands. In the Fiji Islands Area the distribution of earthquakes with respect to depth is completely abnormal and unique when compared with all other areas of the world which possess deep focus earthquakes. Table 2 shows that the Fiji Islands are unique when comparing percentages of deep focus earthquakes to total numbers of earthquakes. Besides that, this region suffers approximately 70 per cent of all deep focus earthquakes in the world, and the deep focus earthquakes appear to be independent of shallow earthquakes because there is a singular lack of intermediate depth earthquakes. This latter fact implies that there is a unique source of stress in the Earth that is operational at depth in this region. The exact nature of this stress source may be surmised as one of two possible mechanisms, namely: (1) phase change is actively occurring in the region below 400 km; (2) that there is a convection cell operating in the lower mantle.

To compare the aforementioned two suspected causes, let us examine the areal extent of the high-frequency

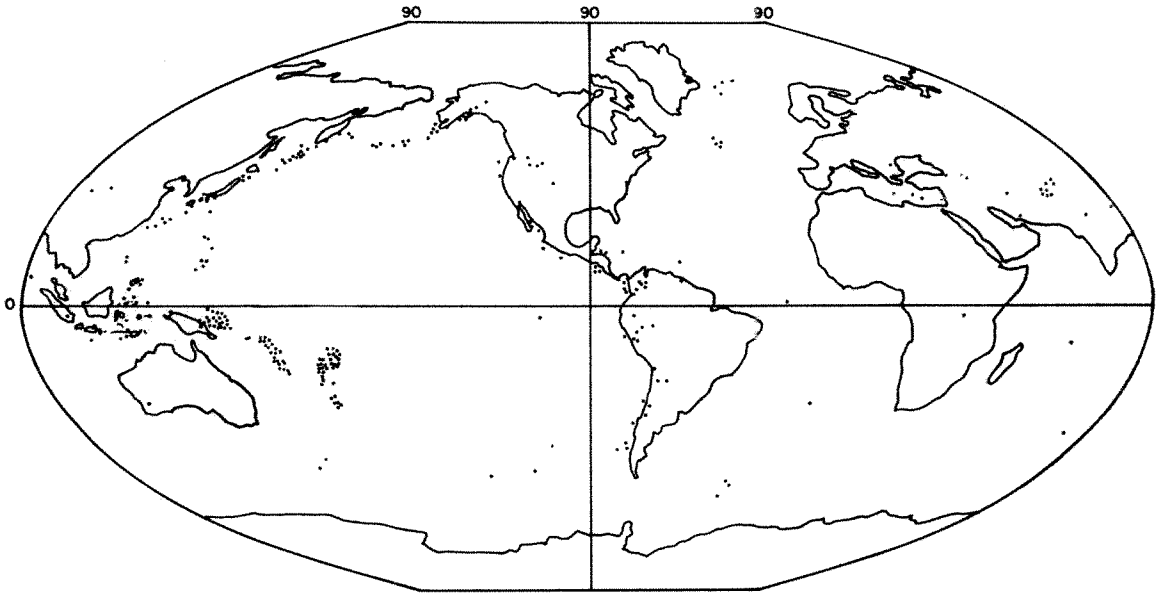

Fig. 5. Earthquake locations for a one month period (January 1963). Data from ref. 10

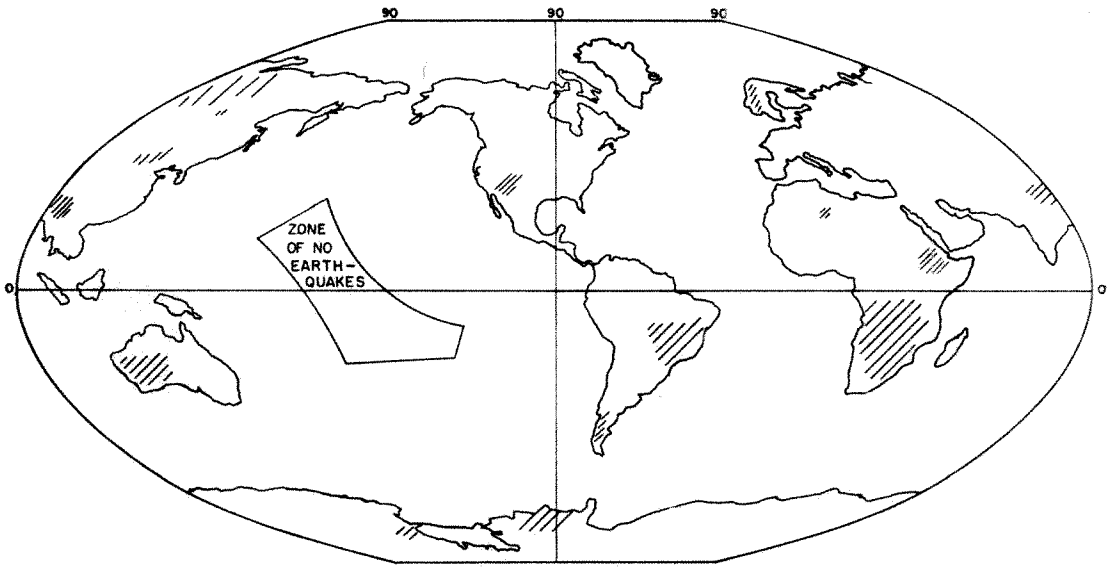

Fig. 6. Major areas of plateau uplift (diagonally lined areas) and the 'zone of no earthquakes'. This 'zone of no earthquakes' is delineated by striking off arcs of 53° from the borders of the plateau uplift regions

Table 1. GEOTECTONIC CLASSIFICATION OF EARTHQUAKE REGIONS

Region designation	Region description	Type locations	Stress mechanism
Very active mountains	Possesses shallow, intermediate and deep earthquakes; continental structure	Andes, Japan, Indonesia, Philippines	Mountain building
Active mountains	Possesses shallow and intermediate earthquakes; continental structure	Himalayas, mountains in the Mediterranean, area Aleutians (continental portion)	Mountain building
Less active mountains	Shallow earthquakes only, continental structure	Rockies, Appalachians, Atlas, Alps, Urals	Mountain building
Continents in general	Shallow earthquakes not associated directly with major mountain chains	Continental shields, old mountain roots, etc.	Local stress accumulations are due to general continental activity
Normal oceanic regions	Ocean areas in general with preference for stress release along mid-ocean ridges and less active island chains	Hawaii, Iceland, mid-ocean ridges	Stresses generated in regions of plateau uplift and propagated generally less than 53°. Majority of these earthquakes occur along mid-ocean ridges, as these ridges represent pre-existing zones of weakness generated as part of the world-wide shear pattern
Active oceanic areas	Possesses shallow and intermediate earthquakes; few deep earthquakes; oceanic structure often with associated deep ocean trench	Mariana Islands, New Hebrides, Aleutians (oceanic portion), Kermadec Islands, Philippine and Indonesian Oceanic structures	Island arc generation
Special ocean area	Possesses a very high number of deep earthquakes relative to shallow earthquakes; 70 per cent of all deep earthquakes that occurred in the first six months of 1963 occurred here	Fiji Islands	Stress mechanism located in mantle; suspected cause of stress generation is phase change in the 400–1,000 km region (*C* region)
Completely inactive oceanic region	No earthquakes, region completely inactive	N.W.–S.E. area in Pacific area. See Fig. 5	Lack of stress accumulation because this area is located more than 53° of arc from all plateau uplift regions

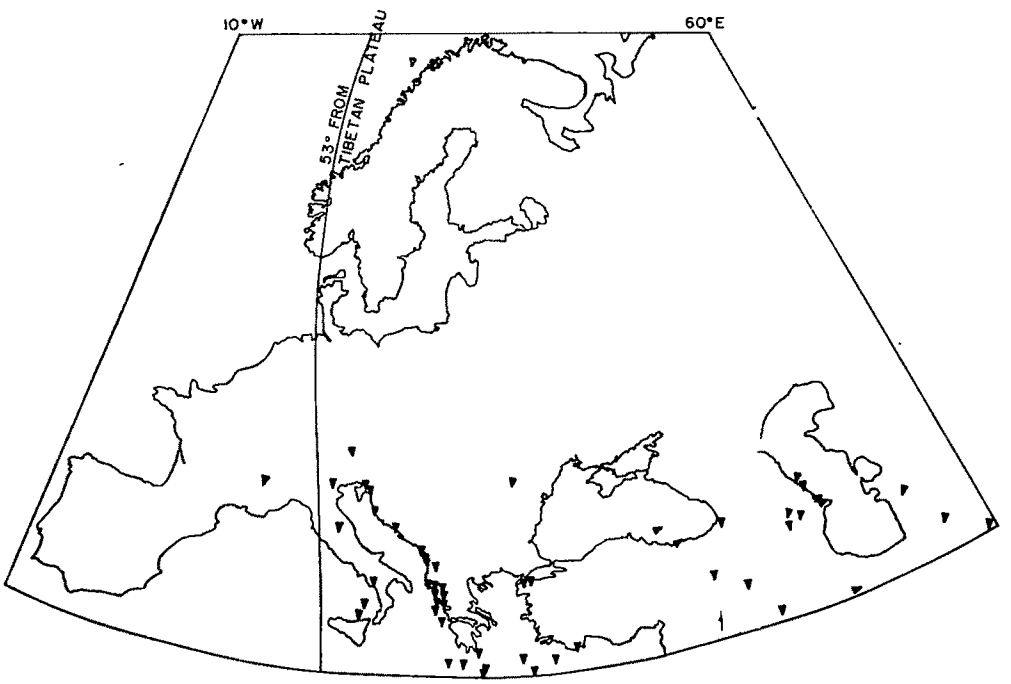

Fig. 7. European earthquakes for the first half of 1963. Data from ref. 10

deep-focus earthquake region. On examination, it is found that the area of deep focus earthquakes is small and has a distinct N.N.E.–S.S.W. trend. If large-scale convection was operational in the lower mantle, then one would expect to find the area of high-frequency deep-focus earthquakes to be very large. However, the surrounding island groups—the New Hebrides, the Tonga Islands, the Kermadec Islands and the Samoa Islands—all have normal earthquake distributions while the Ellice Islands are comparatively earthquake-free.

Table 2. EARTHQUAKES OF THE SPECIAL OCEAN AREA VERSUS THE NORMAL EARTHQUAKE DISTRIBUTION

Earthquake range (km)	Normal earthquake distribution (per cent)	Fiji island earthquake distribution (per cent)
0–100	63	17
100–300	31	6
300–720	6	77

The figures for the normal earthquake distribution are the average percentage of earthquakes from all other regions containing deep focus earthquakes. (Data from ref. 10.)

This consideration of the areal extent of the high-frequency deep-focus earthquake region indicates that the stress generation mechanism is indeed a phase change located below 400 km and is expressed along a zone of weakness which penetrates the entire crust. The presence of a phase change below 400 km—which should be capable of propagating a stress into very deep regions—and the fact that the 720-km depth limitation on earthquakes is not exceeded, strongly implies that geotectonic stress cannot be accumulated or propagated below this depth. Any geotectonic stresses arriving below this depth limit must therefore be released, not through normal geotectonic expression, but by plastic flow or some other related phenomenon.

Finally, it is to be stated that the phase change at the Moho in continental areas is somewhat sensitive to changes in temperature and pressure. Thus, phase change can most likely explain how many kilometres of sedimentary rock can be deposited in a shallow water environment and how mountain ranges can maintain themselves as sediment sources for tens of millions of years in excess of their expected erosional lifetimes. This pressure and temperature sensitivity should also yield a basis for developing a detailed explanation of continental maintenance.

The conclusions that can be drawn from this investigation of stress in the Earth are:

(1) Geotectonic stress generation is due to phase change at two levels in the Earth—(i) the Moho and (ii) the '*C*' Region, that is, 400–1,000 km depth.

(2) Geotectonic stress propagation is limited to 53° of arc and is probably rectilinear in nature.

(3) Stress accumulation required for geotectonic expression is limited to regions above 720 kilometres depth and that below 720 kilometres stress is dissipated in some form of plastic flow.

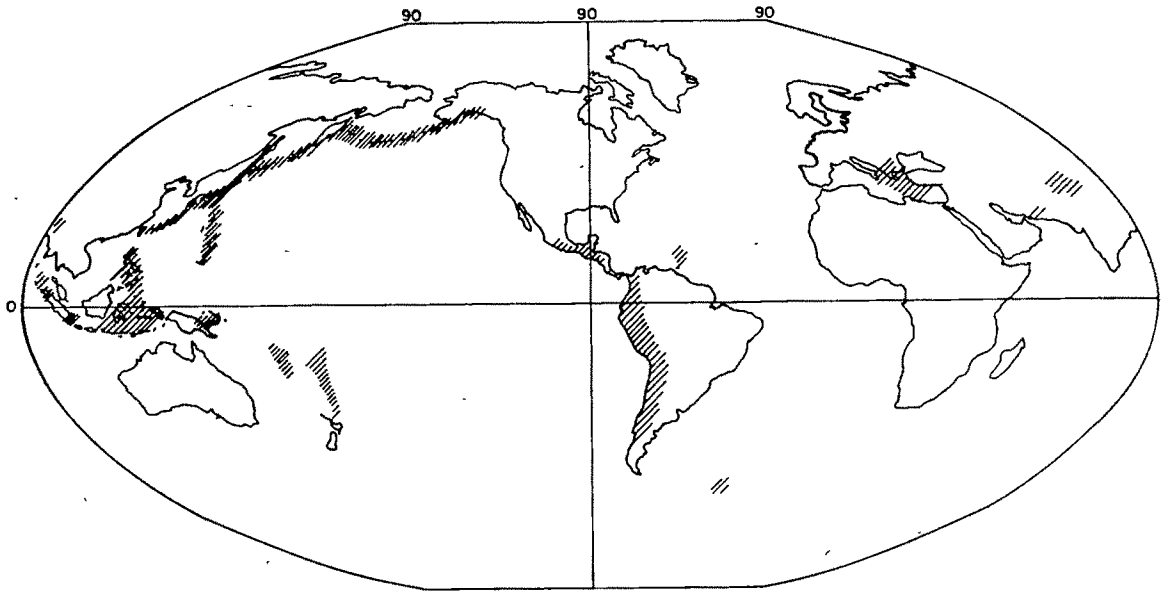
Finally, it is concluded that the entire geotectonic spectrum of stress relief may be explained by the stress generation, propagation and accumulation as described here, and that convection currents are not needed to explain any geotectonic phenomenon.

The verification of the foregoing conclusions may be based on resolution of the following predictions:

(1) That earthquakes will eventually be observed: (*a*) in continental Antarctica; (*b*) between Hawaii and the Aleutian Islands; and (*c*) between Hawaii and California and between Hawaii and Mexico further west than has been observed so far.

(2) That earthquakes will not be observed in the 'zone of no earthquakes' between now and the time required to satisfy predictions 1*b* and 1*c*.

(3) That project Mohole, if successful, will find that the Moho is indeed due to a basalt-eclogite phase change.



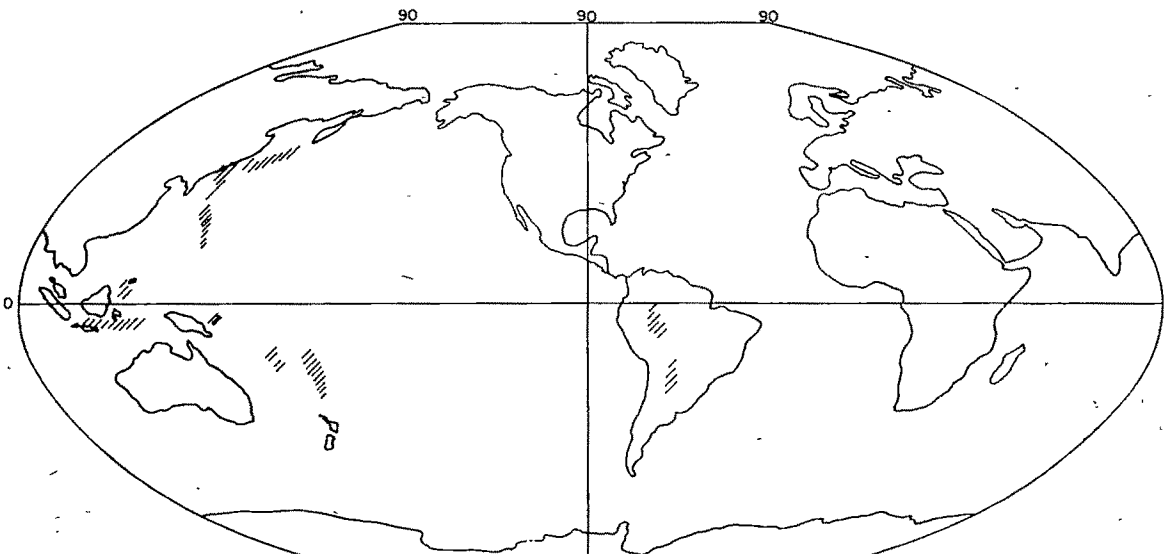


Fig. 8. Distribution of intermediate depth earthquakes

(4) That a Moho will be found on the Moon at a depth that is, from the point of view of pressure, comparable to the depth of the Moho under the stable ocean regions on Earth. Preliminary calculations (which assume a surface density on the Moon of 3·0) give the approximate depth of the lunar Moho as 50 km.

DATING OF POTTERY BY THERMOLUMINESCENCE

By ELIZABETH K. RALPH and MARK C. HAN

University Museum, University of Pennsylvania, Philadelphia

EXPERIMENTS with thermoluminescence as a possible technique for the dating of pottery have been pursued actively for the past 3 years as one of the projects of the Applied Science Center for Archaeology.

The suggestion that thermoluminescence might provide a means of dating pottery was made by Farrington Daniels[1] and also by F. G. Houtermans[2] some years ago. The technique was investigated further by George Kennedy[3] and is now being engaged in actively at the Research Laboratory for Archaeology and the History of Art, University of Oxford[4], as well as in the Applied Science Center for Archaeology and other laboratories.

Thermoluminescence in pottery is due to the fact that radiations from the traces of radioactive elements in pottery bombard the other constituents of the clays and raise electrons to metastable levels. When the pottery is heated, such as in firing, each electron falls back to its stable position and emits a photon of light. On being reheated, the amount of thermoluminescence observed is, therefore, representative of the accumulated radiation damage and hence of the time elapsed since the original firing of the pottery.

Once an object has been heated to a temperature of 400°–500° C and its electrons have emitted their thermoluminescent light, no further light may be obtained by reheating after a relatively short time. Consequently, recently fired ceramic ware or freshly cooled lava, all of which have all electrons in stable sites, should show no thermoluminescence.

The basic principle is, therefore, straightforward, but there are a number of uncertainties which must be investigated or circumvented before it can definitely be stated that thermoluminescence will provde a means of dating pottery. Some of the major uncertainties are as follows: (1) Is the radiation damage caused primarily by α-bombardment, or is it a combination of α-, γ- and β-particles ? (2) How many metastable electrons are lost, especially near the surface, during the passage of time ? (3) How, and how much, do the susceptibilities of clay to radiation damage vary ? (4) How do the differing transparencies of clays affect the detection of the photons emitted on heating ? (5) Does the bombardment from radioactivities in soils cause significant radiation damage to potsherds from external sources ? (6) What is the effect of the grinding of the pieces of pottery, a necessary preliminary to thermoluminescent detection ?

Our first concern has been to assemble apparatus sufficiently sensitive and reliable to make a start on measurements. We have proceeded, therefore, in an over-simplified way at first, and have succeeded in making quantitative measurements with adequate sensitivity.

First of all, we have assumed that the major damage is caused by α-bombardment or is proportional to it, and have, therefore, constructed special low-background zinc sulphide screens and associated components for this low-level detection of α-particles. The α-emissions are counted in 'infinitely' thick samples with the result that only comparative values are obtained.

For the detection of the thermoluminescent photons emitted on heating, our numerous preliminary experiments indicated that very rapid heating rates of thin layers of powdered potsherds would allow detection of the maximum light output. Since the accumulation of metastable electrons is very small, very high sensitivity is required to detect the light output in the visible range. However, this high sensitivity enables the apparatus to detect also the longer wave-lengths of the heat radiation even at temperatures considered usually well below the emission of visible light. These are the reasons why rapid heating (now 13° C/sec) is essential—namely, to drive out all the photons before the surrounding materials get too 'hot'.

The apparatus for detection of thermoluminescence is shown in Fig. 1. Samples are heated in a nitrogen atmosphere to prevent possible combustion of organic particles and also to prevent spurious changes in intensity due to oxygen. To obtain very thin uniform layers of powdered pottery, the pottery is ground in a ball mill to less than 200 mesh. Separate pre-baking experiments have shown that the grinding induces negligible thermoluminescence. Then the powder is mixed with silicone oil and applied to aluminium foil on a $\frac{3}{4}$-in. diameter 'spot' by means of a No. 10 silk screen. This produces a uniform, thin and stable coating of pottery on the foil. The size of the 'spot' of powdered pottery was dictated by the area that could be heated uniformly by the furnace.

One of the important unknown factors is the quantitative relationship between the bombardment and the resultant metastable electron accumulation in ancient pottery. It may be determined empirically, however, with series of pottery of known ages. The first series run consisted of fourteen samples, representative of five different ages, from the Solduz Valley, Iran. The archaeological layers from which these samples were excavated were dated by carbon-14 techniques from associated charcoal samples[5]. Even though carbon-14 dating is not so precise as tree-ring or historical dating, this series affords a long range in time, from 5500 to 900 B.C. The obvious advantage of this is that the older samples give more light output, but, additionally, a long range should afford more information about the possible loss or decay of metastable electrons with time, one of the basic uncer-

tainties. The results of the fourteen thermoluminescent measurements when plotted against age showed poor correspondence and inconsistencies in replicate runs of the same sample.

The determination of potassium contents affords an indirect measure of the relative bombardment rate from β-radiations (due to potassium-40) within the pottery. The results of eight measurements (percentage potassium range was 2·14–3·29) indicate that this factor is not the cause of the discrepancies in age correspondence for the series of pottery from Iran.

The lack of consistency was thought to imply different susceptibilities. The obvious way to obtain a measure of the susceptibility of a potsherd to radiation damage is by the application of an external dose, from a source with much greater intensity than the natural bombardment in order to duplicate the original radiation damage in a short time. On the basis of the low rates of α-bombardment in this series of pottery, we estimate that the natural thermoluminescence is caused primarily by the filling of lattice imperfections with metastable electrons rather than by the creation of new 'holes'. Therefore, with a relatively small artificial dose, it should be possible to repopulate the lattice vacancies. If the dose is increased, then it might be possible to note when the dose becomes sufficient to create new radiation damage.

Our initial susceptibility experiments were carried out with low-voltage X-rays. Duplicate samples of pottery were pre-baked for 1 h at 600° C, and then mounted on aluminium foil in the usual manner for irradiation with X-rays. After several experiments made at various energies and intensities, the effects of these variables appeared to be linear. Subsequent tests were made at 30 kV and 12·7 m.amp (G.E. model *XRD*-5 X-ray unit) and the times of bombardment were varied. From these measurements, the amount of irradiation required (measured in seconds) to produce the same amount of light output as that obtained naturally was determined. If these times of irradiation are then used as correction factors for varying susceptibilities, the results obtained, if anything, are slightly worse.

Experiments with longer times of irradiation and applications of these results in various ways as correction factors for susceptibilities did not significantly improve the age correspondence. Then, during the past year, two important observations were made. First, it was found that even though replicate samples were taken from a single piece of pottery that had been ground and mixed thoroughly, there were large variations in susceptibilities among the replicate samples from the one piece. This indicated that the correction by artificial bombardment should be applied to the identical samples that were measured for natural thermoluminescence. Fortunately, our mounting technique with silicone oil on aluminium foil allows this to be easily done. Therefore, when each sample was heated and measured for natural thermoluminescence, bombarded with X-rays (for 60 sec at 30 kV and 12·7 m.amp), and then reheated, the area of the artificial glow curve, applied as a correction factor, gave some improvement toward consistent results. The reduction of the overall uncertainty in a series of replicate runs is shown in Table 1. For this particular sample, the statistical deviation of the ratio of natural divided by artificial thermoluminescence is only ± 5 per cent whereas the individual spreads were 20 and 17 per cent.

Table 1. EXAMPLE OF REPLICATE RUNS AND CALCULATION OF DEVIATIONS FOR ONE SAMPLE

The uncertainties for each column represent $\sqrt{\frac{\Sigma(n_i-\bar{n})^2}{N-1}}$

Sample No 6. From. Plain of Sybaris, Italy

18	16·5	45·0	0·367
Average	19·1 ± 3·8 ± (20%)	51·3 ± 8 6 ± (17%)	0·370 ± 0·019 ± (5·1%)

Calculation:
Specific thermoluminescence = 0·370/32·5 = 0 0114.
Percentage deviation of the specific thermoluminescence = $\sqrt{(5·1)^2+(3·7)^2}$ = 6·3 per cent. 6 3 per cent of 0·0114 = ± 0·0007.
Result: specific thermoluminescence = 0 0114 ± 0·0007.
Abbreviations: Nat., natural, Art., artificial; Th-L, thermoluminescence.

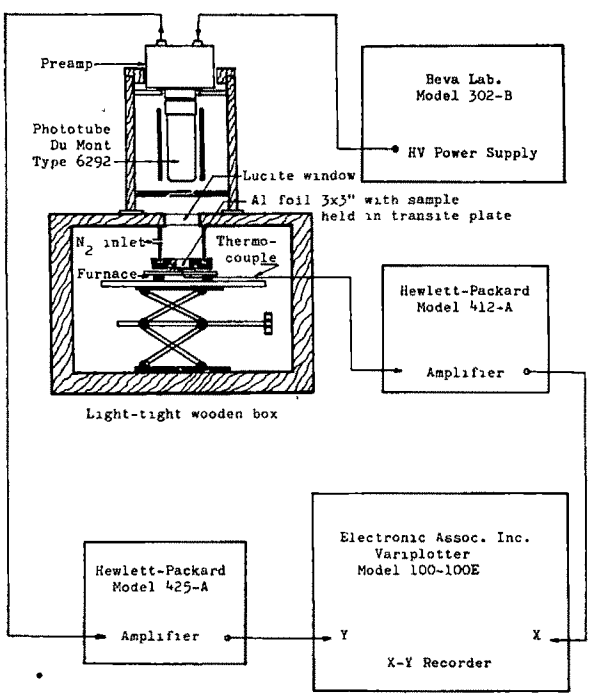

Fig 1. Block diagram of the glow curve apparatus

More important, however, is the second observation made within the past 6 months, namely, that the low-temperature peak or peaks in the glow curves induced by X-ray bombardment are unstable and decay within a period of 1–2 weeks. In the natural glow curves these unstable low peaks have already disappeared due to thermal environment, and possibly decay. Therefore, one must wait for these to decay after the artificial bombardment in order to obtain a reliable correction factor. Alternatively, ideally one could measure only the area under the high-temperature peaks, but with the rapid heating rates which we have found necessary to use for this weak thermoluminescence, the peaks become integrated together into one single peak. A week or two after X-ray bombardment, however, the low temperature part of the integrated peak does decay and a small discernible second peak appears (see Fig. 2). When the area of the latter is used as the correction factor, significant improvement in age correspondence is achieved. This is shown in Table 2 and Fig. 3, where measurements of samples (Nos. 6, 7, 12 and 13) from Italy are included as well as those from Iran. The samples from Italy, representative of classical periods, are more firmly dated.

Recently several examples of thermoluminescent decay have been reported. Zeller and Ronca[6] mentioned that workers engaged in thermoluminescence research have had the impression that inconsistent results were obtained if glow curves were run immediately after samples were irradiated. They suggested that this was the result of the thermal decay of the lowest temperature peak. This effect was reported also by J. M. McNellis[7]. B. E. Sabels[8], in studies of basaltic lava flows, has estimated a hypothetical half-life of thermoluminescent decay for these lavas

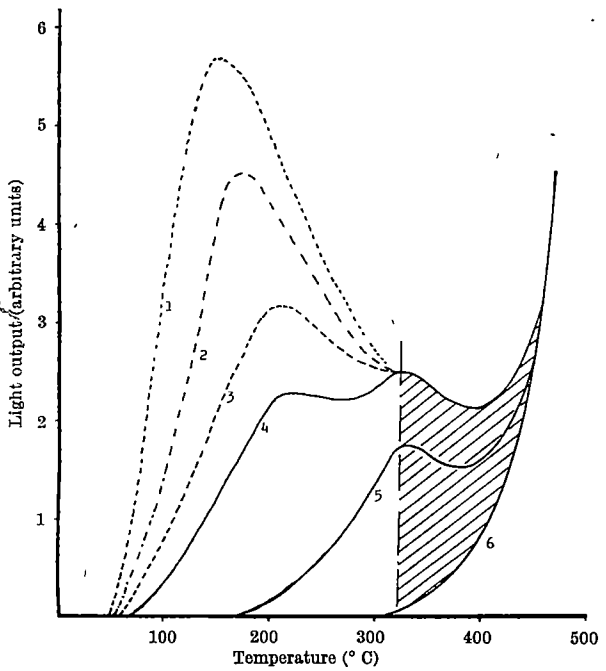

Fig. 2. Typical glow curves. (1) Artificial glow immediately after irradiation with X-rays; (2) artificial glow 24 h after irradiation with X-rays; (3) artificial glow one week after irradiation with X-rays; (4) artificial glow two weeks after irradiation with X-rays; (5) natural glow curve; (6) background (heat radiation only) curve. The hatched regions are the significant areas for both the natural and artificial thermoluminescence

The postscripts *A*, *B*, etc. (column 1), represent different sherds of the same age for each number listed.

Abbreviations as for Table 1.

to be 20,000 years. After various experiments, Sabels concluded that the loss in thermoluminescent output was due to natural decay rather than limitations of storage capacity for excited electrons. Although this limits the dating range for basaltic lavas, it should not be a serious problem for pottery, most of which was fired much more recently than the lavas studied. However, some evidence of decay in pottery has been observed by Ichikawa[9]. Decay of the high-temperature peaks in pottery has not been observed in our laboratory as evidenced by the linear correspondence of age with time (Fig. 3), and it has been reported to be insignificant in a recent article by Aitken[10].

With the application of the X-ray induced correction factor after time allowance for decay, the improvement in age correspondence is encouraging. This is especially true for the pottery from Italy, which is representative of classical periods, and presumably made of finer and more homogeneous clay. For the four samples from Italy (Nos. 6, 7, 12 and 13), the average uncertainty is ± 0·0006 or ± 300 years.

If, after the completion of several different series of pottery, it is found that the time-scale derived from the series now completed (based on sherds from Iran and Italy) is applicable for all, there will be no question that thermoluminescence will provide a reliable means of dating pottery. Additionally, if the consistency of the measurements is improved, the precision may be comparable with carbon-14 dating. It affords the extra advantage that the pottery itself (abundant and primary) may be dated rather than something (such as charcoal) associated with it.

We thank Prof. Froelich Rainey, director of the Applied Science Center for Archaeology, and Prof. William E. Stephens, chairman of the Department of Physics, for their guidance and encouragement. We also thank Dr. Martin Aitken, associate director of the Research Laboratory for Archaeology and the History of Art, University of Oxford, for his many helpful suggestions and advice. This work was supported by the National Science Foundation.

NEWS AND VIEWS

New Fellows of the Royal Society of Edinburgh

THE following have been elected Fellows of the Royal Society of Edinburgh: PROF. G. H. BEALE, Institute of Animal Genetics, Edinburgh; PROF. F. F. BONSALL, Department of Mathematics in the University of Edinburgh; DR. G. S. BOYD, senior lecturer in biochemistry in the University of Edinburgh; PROF. A. BUXTON, Royal (Dick) School of Veterinary Studies, Edinburgh; DR. J. A. CRANSTON, formerly principal lecturer in physical chemistry in the Royal College of Science and Technology (University of Strathclyde), Glasgow; PROF. E. C. ELLWOOD, Department of Metallurgy, University of Strathclyde; PROF. W. N. EVERITT, Department of Pure Mathematics, Queen's College, Dundee; MR. H. FERGUSON, chief of the Agricultural Research Division, Sudan Ministry of Agriculture; DR. G. A. GARTON, Rowett Research Institute, Aberdeenshire; DR. J. A. K. HAMILTON, a partner in Messrs. Mott, Hay and Anderson, civil engineers, Edinburgh; MR. D. M. HENDERSON, principal scientific officer, Royal Botanic Garden, Edinburgh; PROF. L. G. JAEGER, head of the Department of Mechanical Engineering in the University of Edinburgh; MR. B. R. S. MEGAW, director of the School of Scottish Studies in the University of Edinburgh; DR. B. MELTZER, reader in electrical engineering in the University of Edinburgh; DR. C. F. MILLS, Rowett Research Institute, Aberdeenshire; PROF. J. M. MITCHISON, Department of Zoology, University of Edinburgh; PROF. E. O. MORRIS, Department of Applied Microbiology and Biology, University of Strathclyde; PROF. W. MULLIGAN, Department of Veterinary Physiology, University of Glasgow; PROF. D. R. NEWTH, Department of Zoology, University of Glasgow; DR. A. S. PAINTAL, director of the Valhabhai Chest Institute in the University of Delhi; PROF. M. R. POLLACK, Department of Molecular Biology, University of Edinburgh; LORD POLWARTH, chairman of the Executive Committee, Scottish Council (Development and Industry); DR. A. ROBERTSON, Unit of Animal Genetics of the Agricultural Research Council, Edinburgh; PROF. A. P. ROBERTSON, Department of Mathematics, University of Keele; PROF. H. F. W. TAYLOR, Department of Chemistry, University of Aberdeen; DR. P. L. WILLMORE, senior seismologist, Royal Observatory, Edinburgh; SIR CHARLES WILSON, principal and vice-chancellor, University of Glasgow; MR. R. B. WILSON, principal geologist, Geological Survey and Museum.

Deputy Directors at the National Physical Laboratory

THE Minister of Technology, Mr. Frank Cousins, has appointed Dr. N. P. Allen and Dr. O. Simpson to be deputy directors at the National Physical Laboratory with effect from April 1, 1966. Dr. N. P. Allen will become deputy director (*A*) and Dr. O. Simpson deputy director (*B*). The deputy directors will have a collective responsibility for advising the director on the work of the Laboratory as a whole, but will also have functional responsibilities for particular areas of the work. Thus, initially Dr. Allen will be concerned with materials science, and Dr. Simpson with measurement science.

Dr. N. P. Allen

DR. ALLEN graduated in metallurgy at the University of Sheffield in 1923, and after a period at University College, Swansea, became a member of staff in the University of Birmingham. He obtained the D.Sc. degree in 1934 for his work on gases in metals. Dr. Allen transferred to the Mond Nickel Company in 1935 to take charge of various research projects connected with alloy steels and creep-resisting nickel–chromium alloys, and remained there until 1944, when he joined the National Physical Laboratory as superintendent of the Metallurgy Division. Dr. Allen's interests at the National Physical Laboratory have ranged over a wide field, but particular mention may be made of his work on pure iron, and on fatigue, creep and fracture of metals and alloys. He was awarded the Grand Médaille F. Osmond by the Société Française de Métallurgie in 1963, and the Bessemer Gold Medal by the Iron and Steel Institute in 1965. The honorary degree of Doctor of Technical Sciences was conferred on him in 1964 by the Technical University of Prague. Dr. Allen was elected a Fellow of the Royal Society in 1956, and was president of the Institution of Metallurgists in the period 1961–62.

Dr. O. Simpson

DR. SIMPSON graduated at Trinity College, Cambridge, and joined the Admiralty Research Laboratory during the Second World War to work on lead sulphide infra-red detectors. He returned to Cambridge after the War to continue research on photoconduction in semiconductors, and went on to become a Fellow of Trinity College. In 1949 Dr. Simpson was appointed assistant professor of physics at the University of Michigan, and returned to England in 1952 as Imperial Chemical Industries research fellow in the Department of Theoretical Chemistry at the University of Cambridge. He joined the Services Electronics Research Laboratory of the Admiralty in 1953 to initiate research on organic semiconductors, later becoming head of the solid state physics group. Dr. Simpson transferred to the National Physical Laboratory in 1963 as superintendent of the Basic Physics Division, and in 1965, following the merger of the former National Chemical Laboratory with the National Physical Laboratory, became superintendent of the newly formed Division of Molecular Science.

National Physical Laboratory

PROF. B. H. FLOWERS, Langworthy professor of physics in the University of Manchester, has been appointed chairman of the National Physical Laboratory Steering Committee. Eight members of the Steering Committee have now been appointed: R. G. Clayton, General Electric Co., Ltd.; H. G. Conway, Bristol Siddeley Engines, Ltd.; Dr. H. N. Finniston, International Research and Development Co., Ltd.; Prof. G. Gee, University of Manchester; Dr. H. Kronberger, U.K. Atomic Energy Authority; Vice-Admiral Sir Frank Mason; Sir James Taylor; and the director of the National Physical Laboratory. Two further members will be appointed in due course. The Steering Committee will submit annually to the Minister of Technology a research programme for the following year, together with proposals for budgets and staff to carry out that programme. It will be responsible to the Minister of Technology for advising on the selection of projects and for the allocation of effort to them within the financial and other resources allocated to the laboratory.

Sir John Leslie (1766–1832)

SIR JOHN LESLIE, the noted physicist and mathematician, was born in Largo, Fifeshire, two hundred years ago on April 10. He entered the University of St. Andrews at the tender age of thirteen, to study for the Church, and later went on to the University of Edinburgh. Here, Leslie began the scientific investigations which he was to follow for the rest of his life. His first paper concerned electrical theory, but his most notable contributions

were in the field of heat radiation. He invented a differential thermometer, and 'Leslie's Cube' appears in every school physics textbook. He wrote a number of papers and books including *Experimental Inquiry into the Nature and Properties of Heat* and *Radiation of Heat* and also published on geometry, analysis and trigonometry. In 1805, Playfair resigned his chair of mathematics in Leslie's favour, and in 1819, Leslie became professor of natural philosophy at Edinburgh. Leslie was a first-class experimentalist and designer of apparatus, but a poor lecturer. He travelled widely and took a considerable interest in European, especially French, science. He died on November 3, 1832.

Science and Parliament

UNDER the title *Science and Parliament*, the Organization for Economic Co-operation and Development has published an admirable final report, presented by P. Piganiol, on the Second Parliamentary and Scientific Conference, organized jointly with the Council of Europe, at Vienna, during May 23–27, 1965 (Pp. 177. Paris: Organization for Economic Co-operation and Development; London: H.M.S.O., 1965. 8 francs; 12*s*. 6*d*.; 2 dollars). Besides M. Piganiol's report on the debates and the formal conclusions of the Conference, it includes the text of the five addresses, of which those of Prof. G. Hess, Mr. K. Lindsay, Mr. Quintin Hogg and Mr. G. Palewski are outstanding. Annexes include a list of participants, the programme and the recommendations and resolutions for following up the Conference. The recommendations direct attention to the conclusion that there should be in each country a Minister charged solely, or together with other responsibilities, with the promotion and co-ordination of science policy in all its aspects. They invite the national Parliaments to set up, without delay, parliamentary and scientific committees where they do not exist; to examine, where the need arises, the advisability of changing their procedure and the organization of their work by setting up standing parliamentary committees for science; and to strengthen the machinery for informing their members about scientific questions. The first resolution is concerned with the development of European co-operation in the scientific field and advocates the organization of a general debate on the activities of international and European organizations in this field and their more effective co-ordination. The second suggests a study programme to follow up the Parliamentary and Scientific Conference. Prof. G. Hess's opening address dealt with "Science and Society"; Mr. K. Lindsay's survey, "Science and Parliament", included brief accounts of scientific policy in France, Belgium, Western Germany and the United Kingdom. Mr. Hogg discussed specific present and foreseeable impacts of science on political life; Mr. G. Palewski "A Scientific Research Policy in the World of Today"; and Mr. K. Czernetz described the common tasks of parliamentarians and scientists in drawing up a science policy.

Experimental Cartography

THE Natural Environment Research Council has awarded a grant of £11,035 to Mr. D. P. Bickmore, director of the Cartographic Department of the Clarendon Press, for a detailed survey of the needs and problems of the various users of cartographic methods and of the techniques being developed in Britain and overseas. Mr. Bickmore is a senior Research Fellow of the Royal College of Art. The survey, which will last 18 months, will be in two main parts; the first will be concerned with appraising needs, problems and present techniques, and the second with proposing the direction of further work. Besides the information traditionally converted into maps, the study will also be concerned with other information that could usefully be mapped; this includes oceanographic surveys, surface water records and information from satellites to archaeological surveys, population and health censuses and traffic planning probably using animated cartography. The survey will also be concerned to keep abreast of the flow of new information over the range of physical and social sciences. This will involve the application of automatic data processing techniques to cartography. A programme of experiments on the perceptual processes of map reading will be undertaken to assess the most efficient presentation of information. Animated maps showing changes with time will be necessary to aid, for example, planning and traffic studies.

Building Social Institutions

DR. H. V. PERLMUTTER'S essay, *Towards a Theory and Practice of Social Architecture: the Building of Indispensable Institutions*, is based on his experience at the Centre for International Studies at the Massachusetts Institute of Technology, at the Division of Industrial Mental Health of the Menninger Foundation, Yale University School of Industrial Administration, at the Institut pour l'Etude des Méthodes de Direction de l'Entreprise, and as consultant to some world organizations (Tavistock Pamphlet No. 12. Pp. vii+60. London: Tavistock Publications, 1965. 12*s*. 6*d*.). It is in three parts: the first outlines the need for a theory and practice of social architecture, starting from the assumption that men need to understand not only how to change the attitudes of individuals in desirable directions but also how to create social institutions which guarantee valued actions to meet the indispensable needs of society. It is also assumed that the measure and locus of enduring social progress and human welfare depend on the viability of indispensable social institutions. Such institutions, Dr. Perlmutter thinks, are themselves better understood and more easily created if increasing attention is given to the interdependence of the theory and practice of institution-building. The social part outlines the essential steps to be taken towards a theory of social architecture, including the conceptual requirements and the integration of the various dimensions involved. The third part is concerned with the actual practice of social architecture and describes the collaborative relation between the social architects, or persons trained in the applied behavioural sciences, and their clients, the actual institution-builders. The essay defines an area of study in which the theories and practices of building institutions could receive direct and concentrated consideration both by research workers and practitioners. In conclusion, Dr. Perlmutter defines social architecture as involving the development of concepts leading to research which guides men to create institutions that embody positive values and remain responsive to the needs of individuals within and without the institution, and the practical building of such institutions. In the contemporary situation, more than ever before, the hope for civilization lies in improving man's talent to create institutions which guarantee peace and security and promote economic and social development.

Organo-mineral Complex in Soils

FOR a full appreciation of the mechanism of the formation of complexes of clay and organic matter, a better knowledge of the structure and composition of the organic matter is required. The properties of this matter may, however, vary with soil or extraction technique. A further well-documented review of the present position, entitled "Interaction between Clays and Organic Compounds in Soils". Part 2: "Adsorption of Soil Organic Compounds and its Effect on Soil Properties", by D. J. Greenland, is presented in *Soils and Fertilizers* (28, 521; 1965). The humic acid fraction is composed of polymers of amino-acids and phenolic compounds. These are mainly of molecular weight 20,000–50,000, roughly spherical and relatively rigid, and give aqueous solutions of low viscosity. The fulvic acids are mainly phenolic sub-

stances, of lower molecular weight, and polysaccharides of molecular weight 120,000–400,000. They are linear and flexible, giving solutions of high viscosity. Humic acids are held at positive sites and do not penetrate the interlamellar regions as do the polysaccharides. The soil properties are changed by the formation of the complex. Organic material lining the coarse pores increases the strength of the aggregates. Organic cations are less strongly hydrated than inorganic cations and reduce the affinity of the surface for water; this may account for the common phenomenon of non-wetting sandy soils, certain soil regions becoming hydrophobic. Some organic compounds increase the swelling of clays, some organic anions cause flocculation of clay, some polysaccharides increase the stability of aggregates. Microbiological activity may be stimulated even though interlamellar protein is only slowly attacked by enzymes. This is of importance in relation to toxins added to the soil as pesticides, since positively charged organic matter is likely to be strongly adsorbed and liable to accumulation.

Manganese at Groote Eylandt, Australia

GROOTE EYLANDT is in the Gulf of Carpentaria, off the east coast of Arnhem Land, Northern Territory, Australia. Apart from a limited potential for development of fishery, pearl culture and some tourist trade, the principal asset of the island is now known to be manganese ore deposits, proved by an extensive geological survey in 1960 by P. R. Dunn (Bureau of Mineral Resources) and P. W. Crohn (senior resident geologist, Northern Territory Administration). The survey was followed in 1963 by an exploration programme, ultimately involving more than 300 pits and 600 drill holes. The deposit is regarded as a most important source of manganese, by far the largest yet known in Australia, and similar in many technical respects to those of the Ukraine and Georgia, in the U.S.S.R. (The latter contain the largest deposits and greater part of the world's reserves of manganese.) Under title "Manganese Ore Deposits at Groote Eylandt", W. C. Smith, assistant exploration geologist, The Broken Hill Proprietary Co., Ltd., has given a brief account of the Australian deposits (*The B.H.P. Technical Bulletin*, 24. The Broken Hill Proprietary Co., Ltd., Newcastle, N.S.W. 9, No. 3; November 1965).

Like the Russian manganese deposits (except in geological age), the Groote Eylandt deposits represent primary sediments, laid down under shallow-water, restricted marine conditions, on a platform, stable from Cambrian times until the beginning of the Lower Cretaceous marine transgression. The ore occurs as a single bed or zone within what are called the Mullaman Beds (Lower Cretaceous). It consists commonly of loose pisolites of pyrolusite and cryptomelane, ranging in size from 1 mm to 12 mm and associated with quartz sand, clay and fine pyrolusite. Another type comprises hard pebbles and boulders of the same minerals, again with pisolitic texture. There is wide variation in thickness, grade and distribution of these types of ore within the manganese zone; where both types are present together, however, the lump ore is found to overlie the loose, smaller, pisolitic material. The average grade of crushed and wet-screened lump ore ranges from 46 to 48 per cent manganese; the loose pisolite ore contains 44–46 per cent of manganese.

Royal Irish Academy

AT the stated meeting of the Royal Irish Academy on March 16 the following officers were elected: *President*, Dr. M. Dillon: *Treasurer*, Dr. V. C. Barry; *Secretary*, Dr. B. Ó Cúiv; *Secretary of the Science Committee*, Dr. W. Cocker; *Secretary of the Irish Studies Committee*, D. Greene.

The Scientific Estate

OXFORD UNIVERSITY PRESS has written to the Editor stating that it is the publisher in the United Kingdom of Prof. D. K. Price's *The Scientific Estate*, which was reviewed on p. 115 of the January 8 issue of *Nature*. The price of the book in the United Kingdom is 48*s*. net.

Appointments

MR. J. A. RATCLIFFE, formerly director of the Radio and Space Research Station of the Science Research Council, has been appointed by the Council of the Royal Society to be Rutherford Memorial Lecturer for 1966 in Australia, and to deliver the Lecture in Sydney on April 26.

DR. J. W. KING, a physicist at the Radio and Space Research Station, Slough, Bucks, has received the 1965 Wolfe Award for his work on "the analysis of results obtained from 'topside sounding satellites' and their interpretation in terms of ionosphere theory".

MR. RONALD W. CLARK is preparing a biography of the late Prof. J. B. S. Haldane and would be glad to receive any reminiscences or other material concerning him. Such information should be sent to 10 Campden Street, Kensington, London, W.8.

Announcements

THE new Engineering Research Station of the Gas Council is to be established at Killingworth near Newcastle upon Tyne.

A MEETING of the Biological Engineering Society will be held at the National Physical Laboratory, Teddington, on April 29. Further information can be obtained from W. J. Perkins, the National Institute for Medical Research, Mill Hill, London, N.W.7.

A MEETING on "Thermodynamics of Ceramic Systems" will be held by the Basic Science Section of the British Ceramic Society in London during April 19–21. Further information can be obtained from Dr. J. P. Roberts, Houldsworth School of Applied Science, University of Leeds, 2.

A MEETING on "Soil Moisture—Physical and Biological Aspects", organized by the British Society of Soil Science, will be held in University College, London, during April 19–20. Further information can be obtained from Dr. D. V. Crawford, University of Nottingham School of Agriculture, Sutton Bonington, Loughborough, Leicestershire.

THE twentieth annual Frequency Control symposium, sponsored by the Electronic Components Laboratory of the U.S. Army Electronics Command, will be held in Atlantic City, New Jersey, during April 19–21. Further information can be obtained from the Director, Electronic Components Laboratory, U.S. Army Electronics Command, Fort Monmouth, New Jersey.

AN international symposium on "The Radiological Protection of the Worker by the Design and Control of his Environment" will be held by the Society for Radiological Protection in Bournemouth during April 18–22. Further information can be obtained from D. B. B. Janisch, Production Group, United Kingdom Atomic Energy Authority, Risley, Warrington, Lancashire.

COURSES in metrology and quality control will be offered at the University of Aston in Birmingham during 1966. A course on "Measurement and Quality Control" will be held during April 25–May 6, and a course on "Statistical Quality Control and Acceptance Sampling" will be held during June 13–July 1. Further information can be obtained from the Department of Production Engineering, University of Aston in Birmingham, Gosta Green, Birmingham.

CORRIGENDUM. It was announced on p. 1073 of the March 12, 1966, issue of *Nature* that Dr. P. W. Kent had been appointed to the chair of biochemistry in the Queen's University of Belfast. It has been brought to the Editor's attention that Dr. Kent will not, in fact, be taking up this position.

ADMISSIONS TO UNIVERSITIES

IN the third annual report, for 1964–65, of the Universities Central Council on Admissions, its chairman, Dr. G. Templeman, reports a year of solid and encouraging progress*. The ten colleges of advanced technology entered the scheme in September 1964, while final preparations were made for the entry of the universities of Oxford and Cambridge into full membership in September 1965.

The medical and dental schools of the University of London have agreed to enter the scheme from September 1966, and from that date all university institutions in England and Wales will be full members of the Council. The technical difficulties of managing the multitudinous dealings between candidates and universities have been surmounted quickly and accurately, and the handling of these large numbers of decisions by universities and replies from candidates is now done by computer.

Beginning with the present report, the information at the disposal of the Council is being published in two parts. The main report, to be issued as soon as possible after the end of the period covered, contains essential information about applications and admissions, analysed in reasonable detail, as well as the customary survey of the operations of the Council, details of the participating institutions and of membership of the Council and the annual accounts. Supplementary tables, including analyses of the performances in the General Certificate of Education of those admitted in the year under review, will be published later and separately, probably in the early summer.

In May 1965 the universities hoped to admit a total of 49,000 candidates in October 1965, and in fact 45,500 were admitted. Except in science, where 430 fewer candidates were admitted than expected, the numbers of candidates actually admitted in October differed only marginally from the May estimate.

In the autumn of 1964 the Council for the first time received applications from all overseas students. The experience during the past winter suggests that the concern for the difficulties of overseas candidates in understanding the full United Kingdom procedure which had led the Executive originally to recommend separate procedure for handling their applications was unnecessary. After September, the separate overseas scheme will be abolished.

* The Universities Central Council on Admissions. Third Report, 1964–5. Pp. 19. (London: The Universities Central Council of Admissions, 1966) 6s.

In 1965 the number of candidates applying through the Central Council of Admissions increased by 37·2 per cent to 80,033, including applicants from colleges of advanced technology and all overseas applicants. The year 1964–65 was the first of full computer operation, and progress made in passing information to candidates was swift; more than 97 per cent of the candidates knew by September 10 how they stood with respect to their original applications. Every possible effort was made by the clearing panels to find alternative courses for candidates for whom it was certain that places would not be available in the subject of their choice. Some hundreds of candidates who had applied to read medicine but clearly had no chance of a place in a medical school had their applications considered for pure science or for a medical science. Transfers from pure science to technology were, however, successful in only a few cases because the unsuccessful candidates for science usually lacked the necessary qualifications in mathematics and physics to be acceptable for entry in technology. Of the 80,033 candidates, 8·7 per cent were from overseas, of whom 15 per cent were women, compared with 30 per cent of home candidates. According to their first preference, about 25 per cent of all candidates intended to read social, administrative and business studies, 25 per cent of all candidates opted for art subjects; about 20 per cent of the total chose pure science, and a further 15 per cent engineering, technology, and applied science.

Men candidates applied for pure science and technology in similar proportions, 22·1 and 21·8, respectively, but for women the corresponding proportions were 17·8 and 0·8 per cent, respectively. Of the 16,061 candidates considered by the Clearing Panels because they were not accepted by any university originally named by them, 9,051 did not possess the qualifications stimulated by universities for acceptance, and of the remainder 3,276, including 936 women, were offered a place at a university.

The universities of Great Britain received 480,342 applications for entry in October 1965, and if the colleges of advanced technology are omitted, this represents an increase of about 40 per cent overall between 1964 and 1965. Total admissions to universities in Great Britain in 1965–66 were 49,510, of whom 13,515 were admitted to pure science courses and 8,760 to technology courses.

THE PAST IN THE PRESENT

IN recent years considerable effort has been made by archaeologists and those anthropologists interested in material culture to trace and study groups of people who have maintained a hunting-gathering economy and to whom the use of metals is unknown. These groups may be said to represent a major source of information to the archaeologist about the methods of survival probably practised in Pleistocene and early post-Pleistocene times. Few prehistorians to-day would claim that these modern primitives represent to any appreciable degree the modes of existence in prehistoric times, when climate and environment may have been different from that of to-day. Nevertheless, the results of recent investigations on groups of people still practising a formally Stone Age existence have yielded valuable evidence, not so much on the social and political organization of the people, but on their hunting and gathering exploits, and on their techniques of production of stone, wood and bone tools. Such studies have occasionally resulted in specific interpretations of the functions of certain prehistoric tools on the basis of exact analogues with modern material, fortified of course by examination of traces of wear and utilization on both sets of tools.

A recent expedition to the northern Kaokoveld of South West Africa by the State Museum, Windhoek, has opened up a new field in these studies, and in a particularly valuable region*. It is well known that several groups of indigenous peoples in southern Africa were still formally in the Stone Age at the time of the arrival of the first Europeans; the recorded history of some of these groups is mainly concerned with their extermination by the whites, and there is a lamentable lack of information about the details of their basic hunter-gatherer existence.

* *Cimbebasia* No. 13: Preliminary report of two stone-working Ovatjimba groups in the Northern Kaokoveld of South West Africa. By H. R. MacCalman and B. J. Grobbelaar. Pp. 39 (16 plates). (Windhoek, South West Africa: Staatsmuseum, Posbus 1203)

The groups recently contacted and studied by the State Museum expedition probably represent the only stone-using indigenous peoples in the whole of southern Africa. Two groups calling themselves OvaTjimba were contacted; the first of these, the Okombambi group, consisted of fourteen individuals who normally lived in the heights of the Baynes Mountains. Details of their appearance, dress and decoration, and habitations were recorded by the expedition, and specific information about the equipment used for hunting and gathering was obtained. Nothing could be ascertained of their religion, and they appeared to have neither art nor music. The second group, called Otjinungua, consisted of only four individuals, but in general terms these seemed to conform to the Okombambi group in physical appearance and in material culture. Both extensively utilize the products of their limited high-altitude environment, using wood, skins, bone and stone, supplemented in both cases by scavenging in abandoned OvaHimba villages for cloth and iron. The stone-working methods observed consisted of direct percussion and block-on-block; the differences in detail between the two groups may have been due as much to the limited quantity of the evidence as to different traditions.

The authors of this report have also succeeded in establishing the true indigenous nature of these groups, by producing evidence which seems to show that these people do not represent OvaTjimba who have lost their cattle, but must be considered as a group whose economy has never been based on domestication. Further expeditions are planned, and it is to be hoped that this unique opportunity to investigate an isolated group living under conditions which must be relevant to those of prehistoric times will be fully exploited.

JOHN M. COLES

DRIFT REHABILITATED

AFTER many years of suspicion and acrimonious discussion the seal of respectability has firmly been set on the theory of continental drift by the publication of *A Symposium on Continental Drift** as a volume of the *Philosophical Transactions of the Royal Society*. For the first time Continental Drift is discussed with as little reference to Wegener as was formerly accorded to Taylor. It avoids the Scylla of inconclusive discussion of geological and palaeontological data on the Wegener–Du Toit models, and the Charybdis of inadequate mechanism. The first pitfall is avoided by discounting data so obviously insufficiently precise and relying on data from palaeomagnetism to establish a prima facie case for drift, and the second by concentrating on the most plausible mechanism so far proposed, mantle convection currents, and assembling the variety of data from modern petrology—petrochemistry, oceanographic geophysics, physics and geochemistry which have a bearing upon it.

The contributions to the Symposium are divided under four heads, each with discussion. These are "Continental Reconstructions", "Horizontal Displacements in the Earth's Crust", "Convection Currents and Continental Drift", and "Physics of Convection Currents in the Earth's Mantle".

The first section, largely introductory, opens with articles by P. M. S. Blackett, T. S. Westoll and S. K. Runcorn, which, if they present little that is new, nevertheless set the stage for the Symposium. This section is completed by Creer's survey of data from the southern hemisphere, much of it his own, and the article by E. Bullard, J. E. Everett and A. G. Smith on the fit of the continents around the Atlantic. In view of Westoll's exposure of the inadequacy of many of the geological data used in earlier discussions and the claim in each of the first three articles that there is good agreement between palaeoclimates and palaeomagnetism, it would perhaps have been of value if the quantitative work on palaeoclimates by Irving or Blackett had been recorded. For, in the fourth article, Creer's discussion of Devonian reconstructions overlooked the siting in polar regions of a North African Devonian fauna similar to one considered in Europe as a warm water fauna on palaeontological grounds and tropical on palaeomagnetic grounds, and results in the austral fauna generally considered as a cold water fauna in South Africa coming to rest in latitude 30°.

The article by Bullard, Everett and Smith removes once and for all from the realms of speculation the fit of the continents bordering the Atlantic. This fit for the North Atlantic is used by contributors to the third session (J. A. Miller and F. J. Fitch), whose assembly of radiometric and tectonic information would have gladdened the heart of F. B. Taylor. However, the attempt to reassemble the whole Atlantic, as J. L. Worzel points out, runs into difficulties as far as Central America and Mexico are concerned. The geological history of the Atlantic forms part of an article by J. T. Wilson.

The second section, on "Horizontal Displacements in the Earth's Crust", covers recent oceanographic work on transcurrent faults, ridge-rise systems, and rifting. The section title unfortunately precludes a review of the heat flow data. This section is completed by an article on continental transcurrent faulting. Mostly factual, the data are objectively described and tentative interpretation is attempted.

The final section, on "The Physics of Convection Currents in the Earth's Mantle", provides the geologist with present-day views of geophysicists on the state of the mantle, and although G. J. F. MacDonald shows that another interpretation in terms of mantle strength is possible, overwhelmingly, discussion is of convection. The conditions for thermal convection for a mantle of non-Newtonian viscosity are described by E. Orowan, while J. Verhoogen considers the effect of phase change on convection. Convection involving the whole mantle is proposed by Runcorn, and Tozer discusses convection confined to the upper part of the mantle. The former puts forward a general theory to account for "the most puzzling feature of continental drift; that it should have occurred in the last 5 per cent of the Earth's life", for it is hard to see why, if drift has been active during the past 250 m.y., it should not have occurred in earlier times. J. T. Wilson suggests, on the other hand, that "periodic break-up of continents . . . may have happened several times", a view with which the reviewer concurs. The reconstructed North Atlantic as shown by Bullard must have been broken through during much of the Palaeozoic by a geosyncline bordered by shelf seas. The steady sinking and later folding and uplift have to be explained in some way. If Wilson is right, the convection pattern suggested by D. C. Tozer may provide a better explanation than Runcorn's. Questions of this nature will continue to stimulate research and indicate how ideas are moving away from the initial simple pattern to the recognition of a more complex, and as yet uncertain, design.

In stimulating such interest, the Symposium succeeds, and thanks are due to the organizers and editor for the assembly of so much interesting material. If the price, at more than £2 per hundred pages, seems high, was respectability ever cheaply bought?

* *Phil. Trans. Roy. Soc.*, *A*, **258**, No. 1088, 1965: Organized for the Royal Society by Prof. P. M. S. Blackett, F.R.S., Sir Edward Bullard, F.R.S., and Prof. S. K. Runcorn, F.R.S. Pp. x+1–323+*A*1–*A*6. (London: The Royal Society, 1965.) 140*s*.; 21 dollars.

SOME NEW MATERIAL ON ROBERT DICK, BAKER OF THURSO, GEOLOGIST AND BOTANIST

IN December 1866, Robert Dick, baker of Thurso, geologist and botanist, died after a few weeks of illness. Forgotten and neglected by most of his townsmen, his name was a household word to many of the learned men of his day. He was the great shadow behind Hugh Miller (author of the *Old Red Sandstone*), and many of Dick's fossils were figured in later editions of this book. Dick discovered two new fishes: *Coccosteus minor*, now known as *Millerosteus minor* (Hugh Miller), and *Homosteus milleri*, erroneously ascribed to *Asterolepis* by Louis Agassiz, the Swiss naturalist. It has since transpired that the fish known to Dick as *Coccosteus decipiens* is, in fact, a new genus: *Dickosteus thrieplandi* (Miles and Westoll, 1963).

Sir Roderick Murchison, controller of the Geological Survey of Great Britain, visited Dick on several occasions and was instructed by him on the geology of Caithness, Dick making a geological map out of flour in his bakehouse. When Lucien Buonaparte called on Dick at his bakehouse he sent word that the prince must call at a more convenient time as the bread would wait for no man.

His entire collection of fossils had to be sold to pay for the loss at sea of a cargo of flour—he received £60 for them. He made a very thorough collection of botanical specimens from Caithness and confounded many experts with his knowledge. Among other things he discovered *Hierochloe borealis* (now called *Hierochloe fragrans*), the Northern Holygrass, growing near Thurso. He also made a collection of insects of Caithness which has, unfortunately, perished owing to neglect. A further collection was of native shells; the collection was lost.

Recent work by volunteer labour on the Dick collection has brought to light hundreds of botanical specimens, the existence of which was hitherto unknown, together with a collection of shells, some identified in Dick's handwriting, which must be the Dick collection of shells.

If further proof of the authenticity of the new material were required there are three envelopes containing botanical specimens addressed to Mr. Robert Dick, Baker, Thurso; two are postmarked 1859 and 1860, but the third is far older and bears an imperforate penny red. This must date from between 1841 and 1850. The letter was originally sealed with red wax and appears to have come from Prof. Owen.

There is also a parcel of grasses from a Mr. Notcutt, druggist, addressed to Mr. Dick, Thurso. Notcutt is mentioned in the biography by Smiles.

There are several pieces of paper which refer to correspondence in *The Witness*, and are concerned with a difference of opinion between a Mr. Rhind and Hugh Miller. They appear to be the draft of a reply to Rhind's criticisms and clearly refer to a press cutting signed "A Country Geologist". The subject is the Deluge and geological evidence that the sea level has not always been in its present position with regard to the dry land.

There are also notes on a stratigraphical succession concerning gneiss, quartzite, red conglomerate and limestone. This would seem to refer either to the area round Scaraben or to the vicinity of the Moine thrust plane.

OBSERVATIONS OF SUDDEN IONOSPHERIC FREQUENCY DEVIATIONS AT WIDELY SEPARATED PLACES

By D. M. BAKER, DR. K. DAVIES and L. GRIMES*

Institute for Telecommunication Sciences and Aeronomy†, Environmental Science Services Administration, Boulder, Colorado

RAPID fluctuations are sometimes observed in the received carrier frequencies of ionospherically propagated high-frequency radio waves[1–4]. Some of these frequency fluctuations, which can be readily identified from the records, have been called sudden frequency deviations, and have been attributed primarily to electron content changes in the *E* and *F* regions of the ionosphere caused by ionizing radiation from solar flares[1,2]. Munro[5], however, has suggested that the observed effects may be the result of travelling ionospheric disturbances. The purpose of this report is to present a few examples as evidence to show that these frequency deviations are indeed produced directly by fluctuations in solar ionizing radiation at the time of a flare rather than by some form of local ionospheric disturbance.

Munro[5] pointed out: "that since the ionospheric effects of a solar flare are due to ultra-violet radiation they should all be observed simultaneously over the sunlit surface of the earth". This is a crucial point, and an opportunity has arisen to verify that the frequency-deviation effects are simultaneous over a large area of the Earth through a network of radio circuits established by the Institute for Telecommunication Sciences and Aeronomy. A list of the relevant circuits is given in Table 1, from which it

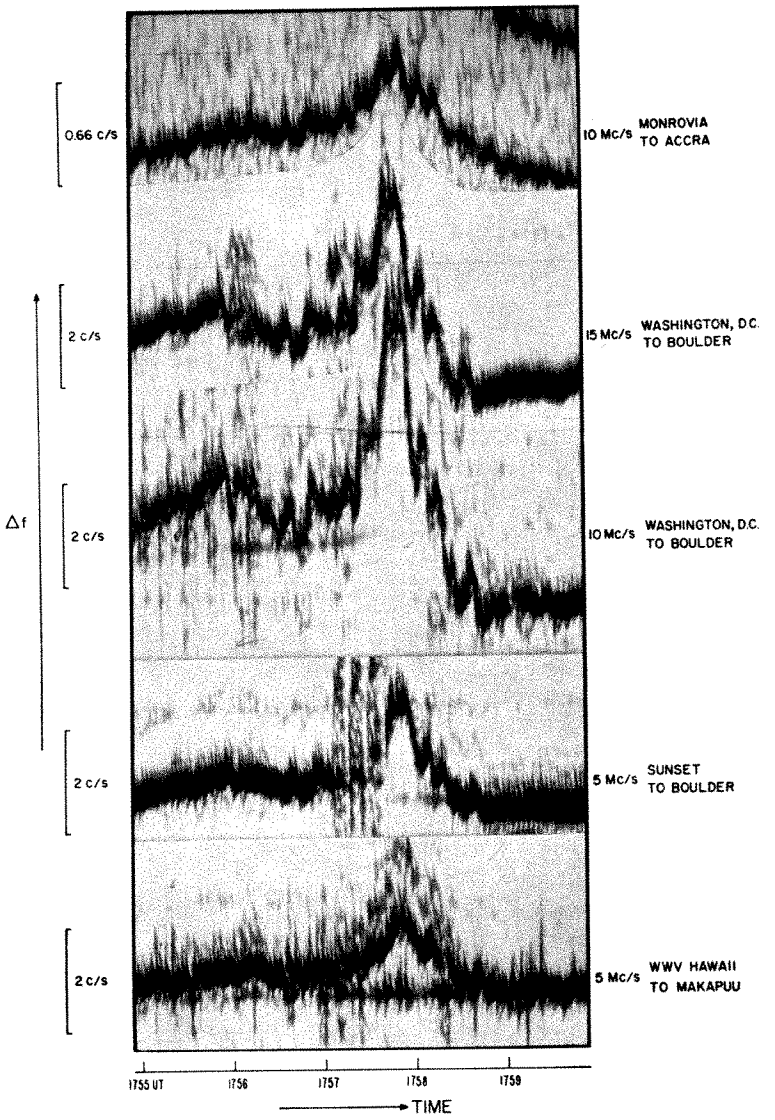

Fig. 1. Degree to which the fine structure of sudden frequency deviations is reproduced over a wide area of the sunlit hemisphere. Differences in magnitude are due to differences in solar zenith angle, path length, carrier frequency, reflexion height, etc. A solar flare of importance 1 began at 1756 U.T., reached maximum at 1800 U.T., and ended at 1837 U.T.

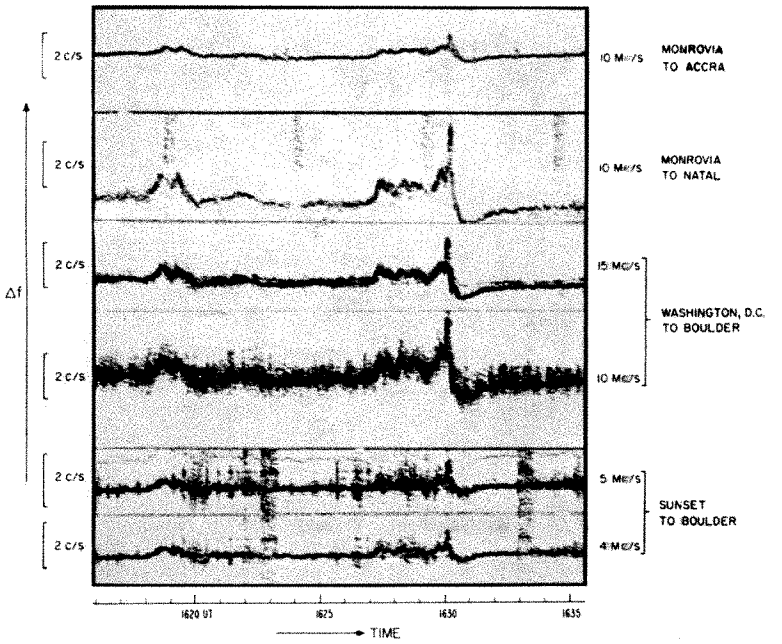
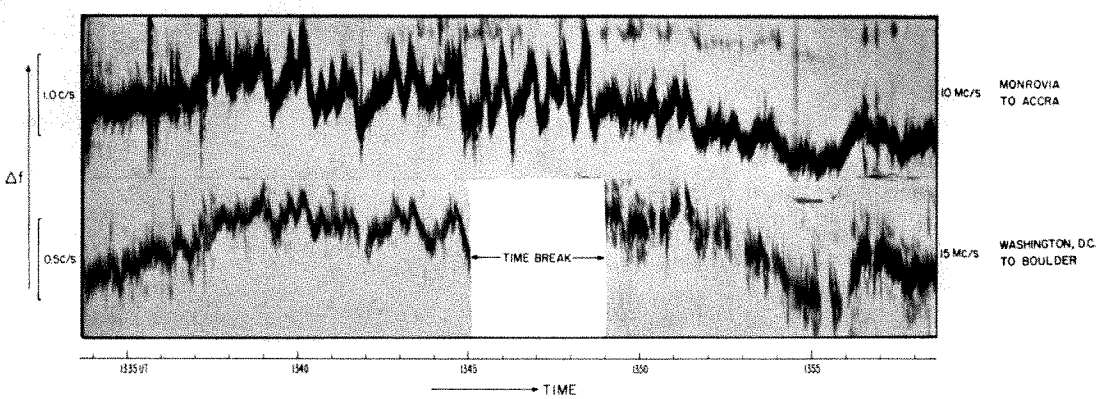
will be seen that the most widely separated receivers differ in longitude by nearly 160°.



Figs. 1, 2 and 3 give examples of sudden frequency deviations observed over the paths listed in Table 1. The sudden frequency deviations shown in Figs. 1, 2 and 3 indicate that, in addition to the general increase in the frequency, there is a great deal of fine structure. The question which naturally arises is, are these fluctuations due to variations in the electron production or are they the result of some instability in the structure of the ionosphere? If the fluctuations are due to the incident solar radiation, they will be closely reproduced over the whole sunlit hemisphere; whereas if they are due to some ionospheric instability, the instantaneous frequency would largely depend on local atmospheric conditions which would scarcely be identical over the entire hemisphere.

Close examination of Figs. 1, 2 and 3 shows that the fine structure is reproduced, in remarkable detail, at stations as far apart as Accra, Ghana, and Honolulu, Hawaii, and at intermediate receiving locations. The exact magnitudes of the frequency shifts are, of course, different because they depend on such factors as solar zenith angle, path length, wave frequency, and ionospheric layer height. Detailed comparisons have been made of twenty-nine events recorded simultaneously on two or more different paths, and it has been found that in all cases the temporal fluctuations in the instantaneous frequency were reproduced over the various sunlit paths. Occasionally, the records were affected by local ionospheric conditions, for example moving irregularities[6,7], sunrise and sunset effects etc., but these were insufficient to obscure the salient features of the sudden frequency deviations.

Over the period October 1960—December 1962, 91 per cent of all observed sudden frequency deviations were accompanied by visible $H\alpha$ flares. This percentage is partly limited by the difficulty in seeing some of the small optical flares. Thus, it would appear that sudden frequency deviations are closely related to solar flare activity rather than to chance coincidence with ionospheric travelling disturbance.



We conclude from our investigations that even the detailed features of sudden frequency deviations are the direct result of fluctuations in the flux of solar ionizing radiations.

So far as we know, the Doppler technique is the only one which has detected the fine structure in the iono-

REACTION OF HYDROGEN ATOMS WITH *CYCLO*PROPANE AND WITH ALLENE AT 77° K

By DR. A. N. HUGHES and DR. J. H. PURNELL
Department of Physical Chemistry, Lensfield, Cambridge

WE have studied the reactions both by thermal generation of hydrogen atoms on a tungsten filament, following the method of Klein and Scheer[1–6], and by photolysis (2537 Å) of hydrogen iodide in admixture with hydrocarbon. No reaction could be induced with either hydrocarbon using the thermal technique. This finding, for *cyclo*propane, apparently conflicts with the observation of reaction between H atoms and *cyclo*propane by

Moser and Shores[7]. In recent studies[8], however, these authors indicate that, in their earlier work, there was probably direct radiative heating of the film, with consequent vaporization and cracking on the filament.

Both hydrocarbons reacted readily with photolysed hydrogen iodide. Details of apparatus and technique are given elsewhere[9]. Typical analytical results are given in Table 1.

Table 1. PRODUCTS OF PHOTOLYSIS OF FILMS OF *Cyclo*PROPANE OR ALLENE WITH HYDROGEN IODIDE AT 77° K ($\lambda = 2537$ Å)

Film composition (μ mole)	*Cyclo*propane = 35 hydrogen iodide = 40	Allene = 20 hydrogen iodide = 65
Photolysis time (min)	30	30
Products (mole per cent of total)		
Propane	16	14
Propene	—	25
Methyl acetylene	—	41
n-Propyl iodide	80	—
isoPropyl iodide	4	20
Trace products (< 1 per cent total majors)	Methane, methyl iodide, propene	C_1–C_3 iodides, a hexane
Absent (< 0·1 mole per cent)	Hexanes, allyl iodide	Allyl iodide

The failure to induce reaction by the thermal method may be due to (i) a high activation energy of the initial hydrogen atom addition or (ii) ready reversibility of the addition. The formation of $C_3H_5\cdot$ from allene is about 70 kcal mole^{-1} exothermic and it is possible that, following initiation, on account of this high energy, the reverse reaction occurs exclusively. However, even in great excess of carbon dioxide no reaction occurred and further, in the photochemical method, if the radical is directly formed, it would be even more energy-rich since hydrogen iodide is photolysed with 41 kcal mole^{-1} excess energy at 2357 Å. Finally, there is abundant evidence to show that thermalization of large excess energies is rapid in frozen films[1–6,10,11]. It thus appears most probable that the thermally induced reaction of allene is subject to an activation energy barrier in excess of 5 kcal mole^{-1} ($T_{fil} = 1800$ °K). Accepting this, the same explanation must hold for *cyclo*propane since an even higher activation energy would be anticipated because of the need to open the ring on addition of hydrogen. The reality of activation energy barriers in Klein–Scheer-type experiments is shown[3] by the lack of reactivity of 2-olefines whereas 1-olefines hydrogenate readily.

It might then appear that the postulate of 'hot' hydrogen atoms would explain the occurrence of reaction in the photochemical system. However, if an initial activation energy barrier of 5 kcal mole^{-1} can be overcome, other reactions, particularly hydrogen atom abstraction, in these and in olefinic matrices ($E = 5 - 10$ kcal mole^{-1}) would be likely to occur. We find no evidence for such processes in these or in olefinic matrices[9]. Further, we find no hydrogen atom abstraction from 1-olefines by photochemically generated methyl radicals (possibly 32 kcal mole^{-1} hot) in confirmation of the findings of Ayscough and Evans[10], who also showed that the energetically slightly more favourable abstraction from branched or 2-olefines occurs. Again an activation energy barrier is indicated. We thus conclude that the explanation of the reactivity observed in the photochemical experiments is not associated with 'hot' atoms.

Irrespective of the detailed mechanism of the processes occurring, one general conclusion, relevant to many alkyl radical-containing cryogenic systems, may be drawn from the results of Table 1 for *cyclo*propane. The addition of hydrogen to *cyclo*propane clearly offers the cleanest route to 1-propyl radical formation and perhaps the most nearly unambiguous means to generate any alkyl radical. The upper limit for the hexane yield (detectability limit) is about 0·1 mole per cent of total product and, accepting the largest estimate[1–6] of the relative rates of disproportionation to combination ($k_d/k_c \simeq 10$) at 77° K, admittedly for 2-propyl, no more than 1 per cent of the total products of propene could arise by radical-radical disproportionation. The experimental value is about half this amount and the propene, in fact, is highly likely to arise by way of secondary photolysis of *n*-propyl iodide since the trace products correspond to the products of that reaction. Since no products of hydrogen abstraction reactions are found, the large yield of propane must arise by successive hydrogen atom additions or reaction with hydrogen iodide. In the unlikely event that isopropyl iodide arises entirely by way of secondary processes involving addition of hydrogen iodide to propene, the hydrogenation reaction must still be three times as important as the sum of all disproportionations. The results thus show that combination and disproportionation reactions of radicals have only trivial importance in cryogenic systems such as those used in this work. This points clearly to immobilization of radicals.

Pimentel[11] has proposed that most if not all photochemically induced reactions of organic molecules in frozen films occur exclusively at the site of light absorption. These, and other investigations completed by us[9], lead us to accept this proposition with the single reservation that hydrogen atoms must usually be regarded as mobile and can therefore react outside the cage of formation. This view alone, however, does not offer a ready explanation of the discrepancy between the thermal and photochemical experiments described here, of the complexity of products often observed[11,14] or of other anomalies described elsewhere[9]. Predominant among the latter is the finding that at 77° K, conventional methyl radical sources in olefinic matrices yield products characteristic of reactions of methylene radicals. We thus extend Pimentel's hypothesis by suggesting that the primary photochemical act is either instantaneously followed by or directly involves formation of excited absorber-matrix complexes, their formation perhaps depending on excess energy of photolysis being available. It has several times been shown for individual reaction systems that reactant-matrix complexes must be formed, and Jacox and Milligan[12] have discussed features common to likely structures in some systems. In previous work when a complex has been proposed it has been formulated in terms of a matrix molecule and a photo-produced radical or atom. In contrast, we propose that all the nominal products of photolysis are involved in the complex which may contain also any species present in the matrix, and with which is associated the whole absorbed energy. In a loose complex, such as is usually proposed, relative motion of the constituent parts would give rise to numerous configurations (transition states) each of which on deactivation or decomposition could proceed via preferential paths to yield specific products which might not readily be visualized as arising from the obvious initial products of absorber photolysis. This unified view removes difficulties which arise in explaining the relative absence of hot atom or radical effects, the localization of reactive species at the absorption site, the unexpected reactivity of 'inert' matrices in some photolyses (for example, carbon dioxide and carbon monoxide in the photolysis[13,14] of CH_2N_2), the relative scarcity of free radicals and the kinetics of production of the often complex products of low temperature photolyses such as, for example, those of methyl iodide, ethyl iodide and nitromethane.

On this basis we suggest a tentative mechanism for *cyclo*propane + HI photolysis:

$$[c\text{-}C_3H_6 + HI]_c + h\nu \rightleftarrows [c\text{-}C_3H_6\cdots H\cdots I]_c \quad (1)$$

$$[c\text{-}C_3H_6\text{---H---I}]_c \longrightarrow [1\text{-}C_3H_7\cdot + I]_c \quad (2)$$

$$[c\text{-}C_3H_6\text{---H---I}]_c \longrightarrow [c\text{-}C_3H_6 + I]_c + H \quad (3a)$$

$$\longrightarrow [C_3H_6\text{---I}]_c + H \quad (3b)$$

$$\longrightarrow [C_3H_6\text{---H---I}]_c \rightarrow 2\text{-}C_3H_7I \quad (3c)$$

$$\longrightarrow C_3H_6 + HI \quad (3d)$$

$$[1\text{-}C_3H_7\cdot + I]_c \longrightarrow 1\text{-}C_3H_7I \quad (4)$$

$$[1-C_3H_7\cdot+I]_c+H(HI) \longrightarrow C_3H_8+[I]_c([I_2]_c) \quad (5)$$

$$[C_3H_6---I]_c+H \longrightarrow 2-C_3H_7I \quad (6)$$

$$2[I]_c \xrightarrow{\text{warm up}} I_2 \quad (7)$$

The subscript c designates the cage of initial absorption while bracketed entities connected by broken lines, represent activated complexes. Evidence for reaction (5) has been presented; reaction (3*a*) is included to account for the fact that $C_3H_6 \ll C_3H_8$; reaction 3(*b*) provides an energetically feasible route to what is in effect the radical $C_3H_6I\cdot$ (the thermalized equivalent is scarcely likely since $E > 5$ kcal mole^{-1}). Reaction (7) is supported by the observation that reacted films are of lighter colour at 77° K than test mixtures of *cyclo*propane and iodine, and darken more rapidly on warm-up. Reaction (3*d*) must obviously be trivial.

The corresponding mechanism for allene is:

$$[C_3H_4+HI]_c+h\nu \rightleftharpoons [C_3H_4---H---I]_c \quad (1)$$

$$[C_3H_4---H---I]_c \longrightarrow [CH_2=C-CH_3---I]_c \rightarrow [C_3H_5\cdot+I]_c \quad (2a)$$

$$[CH_2=C-CH_3---I]_c \longrightarrow CH_3-C\equiv CH+HI \quad (2b)$$

$$[C_3H_4---H---I]_c \longrightarrow [C_3H_4---I]_c+H \rightarrow C_3H_4+H+[I]_c \quad (3)$$

$$C_3H_5\cdot+I]_c+H(HI) \longrightarrow [C_3H_6+I]_c([I_2]_c) \quad (4)$$

$$[C_3H_6+I]_c+H \longrightarrow [2-C_3H_7\cdot+I]_c \quad (5)$$

$$[2-C_3H_7\cdot+I]_c+H(HI) \longrightarrow C_3H_8+[I]_c([I_2]_c) \quad (6)$$

$$[2-C_3H_7\cdot+I]_c \longrightarrow 2-C_3H_7I \quad (7)$$

The absence of allyl iodide from the products means that hydrogenation by way of (4) is very fast. Obviously, the predominant reaction is (2*b*) which accounts for nearly half the products, and this shows that hydrogen atom addition to allene is largely terminal. This reaction may be regarded as a disproportionation, the view usually taken in interpreting the formation of olefines in alkyl iodine photolysis, but it is to be noted that this reaction does not occur in the *cyclo*propane reaction although the radicals nominally present are those of the photolysis of *n*-propyl iodide. This may be attributed to the loss of energy consequent on the opening of the *cyclo*propane ring and for this reason reactions (2) in the two mechanisms are represented differently. Thus, reactions of the type (2*b*) are probably better regarded as hydrogen atom expulsion from the hydrocarbon radical in a fashion analogous to that known[15] to occur in the gas phase reaction of C_2H_4+T and in the reactions of halo-ethylenes with halogens in solution.

It is, of course, possible that methyl acetylene arises via alternative disproportionation reactions. Since no molecular hydrogen is formed these would have to involve radicals only. On the evidence of the *cyclo*propane $-HI$ reaction, the propyls of (6) and (7) would be immobile and thus would not disproportionate. Hence, at most, one disproportionation step, involving two $C_3H_5\cdot$ radicals, could occur (replacing (4)); there would, therefore, still have to be three direct hydrogen addition steps in forming C_3H_8. On the general evidence presented and because of the requirement of relatively high mobility of $C_3H_5\cdot$ for its self-disproportionation to compete with (4) (which itself is very fast compared with $C_3H_5\cdot+I \rightarrow C_3H_5I$) we reject this possibility.

We thank the Department of Scientific and Industrial Research for the award of a maintenance grant to A. N. H.

A POSSIBLE RING STRUCTURE IN VITREOUS SILICA

By DR. P. DEAN
National Physical Laboratory, Teddington, Middlesex

RECENT work on the structure of vitreous silica suggests that the Si–O–Si linkages differ considerably from the collinear form proposed in early work. Thus, neutron diffraction studies[1] lead to an average value for the Si–O–Si angle of 146° (ref. 2), and the X-ray work of Zarzycki[3] gives the value 143° ± 17°. On this basis it seems likely that the structure of vitreous silica contains, among the many possible local atomic configurations, almost planar six-membered silicon–oxygen rings similar to those which occur in various solid[4] (and possibly liquid[5]) silicates.

One can see the possibility for the existence of such rings in the following way. Consider any two SiO_4 tetrahedra connected through a common oxygen ($O_{(0)}$) as in Fig. 1. The atoms $Si_{(1)}$, $O_{(0)}$ and $Si_{(2)}$ are taken to be in the plane of the paper and, therefore, the remaining oxygen atoms of the $Si_{(1)}O_4$ and $Si_{(2)}O_4$ tetrahedra are confined to positions on circles C_1 and C_2, respectively, both perpendicular to the plane of the paper. Now, if all orientations of the $Si_{(1)}O_4$ and $Si_{(2)}O_4$ tetrahedra about their respective three-fold axes, $Si_{(1)}O_{(0)}$ and $Si_{(2)}O_{(0)}$, are regarded as more or less equally probable, then there is a small, but certainly non-negligible, probability that an oxygen atom ($O_{(1)}$) on the circle C_1 and another ($O_{(2)}$) on the circle C_2 will lie close to the plane $Si_{(1)}O_{(0)}Si_{(2)}$. We can be rather more specific. Let the angle between the line joining $O_{(1)}$ to the centre of C_1 and the projection of this line on the plane $Si_{(1)}O_{(0)}Si_{(2)}$ be ϕ_1, and the corresponding angle for $O_{(2)}$ in the circle C_2 be ϕ_2. Then the probability that ϕ_1 and ϕ_2 are both less than 15° is about 0·06, and the probability that both are less than 6° is 0·01 (assuming that all orientations of the tetrahedra are equally likely).

Let us now take Fig. 1 to represent a local structure (in a randomly connected network of SiO_4 tetrahedra) in which ϕ_1 and ϕ_2 are, in fact, fairly small angles. Then just one further condition—that the angle $Si_{(1)}O_{(0)}Si_{(2)}$ be about 130°—ensures that the distance $O_{(1)}O_{(2)}$ is of roughly the correct magnitude for these two oxygen atoms to be bridged by a single silicon atom, that is, to be members of the same SiO_4 tetrahedron. Moreover, if this silicon atom ($Si_{(3)}$, as in Fig. 1) lies close to the plane of $Si_{(1)}O_{(0)}Si_{(2)}$, then the angles $Si_{(1)}O_{(1)}Si_{(3)}$ and $Si_{(2)}O_{(2)}Si_{(3)}$ will both be about 130°. The three Si–O–Si angles of about 130° which occur in this configuration of atoms are a little below the suggested value for the mean Si–O–Si angle in vitreous silica[2,3], but they are almost certainly within reasonable bounds.

Some results of calculations on the geometry of this structure of adjacent SiO_4 tetrahedra are summarized in

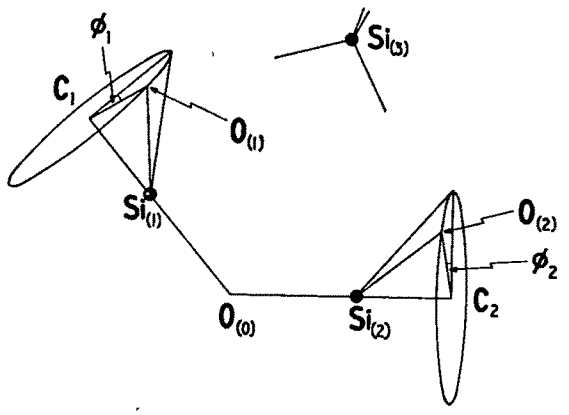

Fig. 1. Diagram illustrating the possibility of almost planar rings in vitreous silica

Table 1. θ_0, θ_1 and θ_2 are the Si–O–Si angles of the six-membered ring $O_{(0)}Si_{(1)}O_{(1)}Si_{(3)}O_{(2)}Si_{(2)}$ at $O_{(0)}$, $O_{(1)}$ and $O_{(2)}$, respectively. ϕ_1 and ϕ_2, defined earlier, have the same sign when $O_{(1)}$ and $O_{(2)}$ are both on the same side of the plane $Si_{(1)}O_{(0)}Si_{(2)}$. The distance d of $Si_{(3)}$ from the plane of $Si_{(1)}O_{(0)}Si_{(2)}$ is in terms of the Si–O bond length as a unit.

Table 1. TYPICAL DATA FOR ALMOST PLANAR SIX-MEMBERED RINGS

ϕ_1	ϕ_2	θ_0	θ_1	θ_2	d
0	±20 8	128·0	129·7	125 4	0 17
+ 5	−17·5	128·0	129·0	126·2	0·10
+10	−13 4	128·0	128·0	127·2	0·03
+15	− 8·2	128.0	126·8	128·4	0 05
+ 5	+23 3	128·0	127·9	119·8	0·08
+10	+24·9	128 0	127·7	120·2	0 16
0	±30·7	125·0	125·0	108·6	0

(All angles are in degrees; d is in terms of the Si–O bond length.)

These particular results have been chosen to illustrate various almost planar configurations of the six atoms of the ring. The calculations also show that other, less planar, arrangements are certainly possible but that these involve one or more Si–O–Si angles substantially smaller than about 130°. Although such structures may occur, the almost planar ring will be appreciably more likely if the overall distribution of Si–O–Si angles in the glass is one which falls away fairly rapidly to zero at angles very much smaller than the mean. We shall leave open, however, the question as to whether significantly non-planar six-membered rings actually occur; the object of this article is to put a case for the existence of the almost planar rings. In passing, we note that 8-, 10- and higher-membered rings are geometrically quite possible, even probable, but one would not expect these larger ring structures, in general, to be planar.

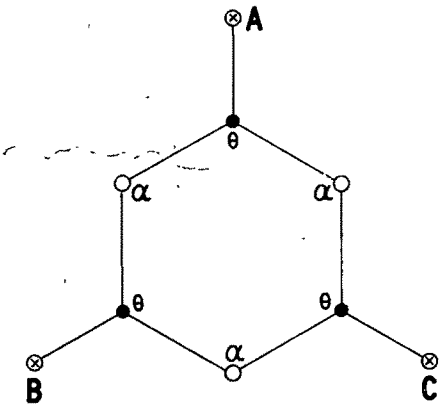

Fig. 2. A planar six-membered ring formed from three SiO_4 tetrahedra. Each of the open circles with crosses (at A, B and C) represents two oxygen atoms, one above and one below the plane of the paper. In the diagram $\theta + \alpha = 240°$, and for exact tetrahedra $\theta = 2\sin^{-1}\sqrt{6}/3$. ●, Silicon; ○, oxygen

Consider now a particular six-membered ring, as in Fig. 2. Let us first regard this ring as truly planar and symmetrical, and the SiO_4 structures as exact tetrahedra. Then, on a nearest-neighbour central force model, analysis shows that there exist two modes of vibration which are strictly localized to the atoms of the ring and involve no displacements from equilibrium of other atoms in the network. (The pairs of atoms represented by the points A, B and C in Fig. 2 are to be regarded as part of a large network of connected SiO_4 tetrahedra.) The characters of the localized modes are indicated diagrammatically in Fig. 3: one is an infinitesimal ring rotation, of zero frequency (ν_1), and in the other adjacent atoms vibrate out of phase as shown, with a frequency:

$$\nu_2 = \frac{\gamma^{\frac{1}{2}}}{2\pi}\left\{2m_1^{-1}\sin^2\frac{\theta}{2} + m_0^{-1}\left(\frac{1}{2} + \cos^2\frac{\theta}{2} + \sqrt{3}\sin\frac{\theta}{2}\cos\frac{\theta}{2}\right)\right\}^{\frac{1}{2}} \quad (1)$$

where m_1 is the mass of a silicon atom, m_0 that of an oxygen atom, γ the Si–O central force constant and θ the O–Si–O angle ($2\sin^{-1}\frac{\sqrt{6}}{3}$ for exact tetrahedra). The important point about these modes—and one which should be emphasized—is that they are strictly localized to the six atoms of the ring. This exact localization is an unusual property for vibrational modes in condensed matter. Strongly localized modes usually involve non-zero atomic displacements away from the centres of localization, although the amplitudes may fall away extremely rapidly with increasing distance.

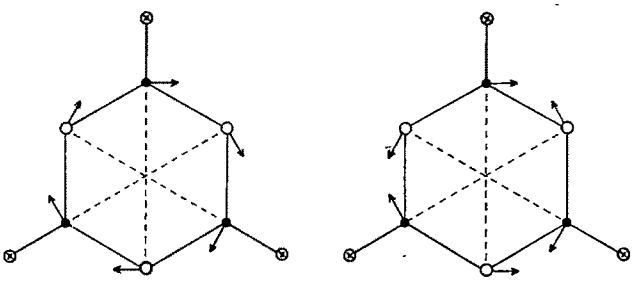

Fig. 3. Localized vibrational modes associated with six-membered rings. The arrows, which represent atomic displacements, are perpendicular to the (broken) lines joining the atoms to the centre of the ring

As so far described, this model (with exact localization) is an idealized one. In the real physical situation, there will be coupling of the modes to the network by way of the asymmetry in the ring, non-central—and also longer range—forces, and other effects. However, the fact remains that to a first approximation the normal vibrations of frequencies ν_1 and ν_2 involve only the displacements of the six atoms of the ring.

If we take the value of γ (Si–O bond stretching force constant) to be $4{\cdot}0 \times 10^5$ dynes/cm, then equation (1) leads to a value of ν_2, in wave numbers, of 1,010 cm^{-1}. A force constant of $\gamma = 4{\cdot}5 \times 10^5$ dynes/cm leads to a ν_2 of 1,060 cm^{-1}. The idealized symmetric ring structure of silicon-oxygen atoms has symmetry D_{3h} and the modes of interest are of species A_2', and therefore inactive in both the Raman and infra-red. However, in view of the distortions from symmetry which occur in the real physical situation one would expect infra-red activity, although over a fairly broad range of frequencies in view of the numerous possible ring environments.

The band at about 950 cm^{-1} in the observed infra-red spectrum of vitreous silica[6] can be accounted for by the ring mode ν_2. We have not attempted to identify observed infra-red activity with the low-frequency mode ν_1; this mode will be particularly sensitive to angular forces and local atomic geometry. However, if this mode does

retain some of its character in spite of coupling with the network, then it will contribute (and as a non-acoustic mode) towards the low-temperature specific heat of vitreous silica and thus may partially account for the well-known discrepancy between the observed heat capacity and that as calculated from elastic data[7-9].

I thank Drs. A. J. Leadbetter and T. H. K. Barron, of the University of Bristol, for a helpful discussion at the start of this work. I also thank Dr. G. W. Chantry and R. J. Bell, of the National Physical Laboratory, for their advice.

PHYSICO-CHEMICAL PROPERTIES OF SILICA IN RELATION TO ITS TOXICITY

By T. NASH

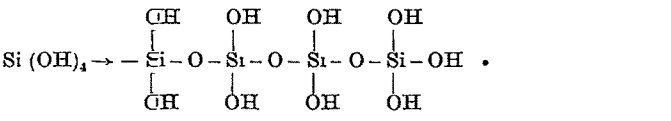
IT has long been recognized that silica dust is much more fibrogenic in man and experimental animals than is most other material. The fibrogenic activities of different substances are related to their capacity to kill the phagocytic cells ingesting them, as can be shown by observations of cytotoxic effects on cultures of macrophages[1,2]. Silica, in fact, provides a remarkable model of selective toxicity for one cell type by a substance of simple chemical composition and low chemical reactivity. Detailed investigations of the mechanism are of theoretical as well as practical interest in explaining the cause of the disease silicosis.

We have elsewhere presented evidence that silica and non-toxic particles such as diamond dust of comparable size are engulfed in the same way by macrophages[3]. Recently, engulfed particles have been located in phagosomes, into which hydrolytic enzymes from lysosomes are discharged. However, silica particles and lysomal enzymes soon escape from the phagosomes into the surrounding cytoplasm, rapidly causing cell damage, whereas non-toxic particles and the associated enzymes remain within phagosomes. It was suggested that the capacity of silica particles to react with, and make permeable, the lipoprotein membrane surrounding the phagosome is responsible for its toxicity. That silicic acid can react with lipoprotein or protein films has long been known[4,5], and the fact that colloidal silica is haemolytic[6] shows that it can induce changes of permeability in biological membrane systems.

It has also been found that a number of substances reduce the toxic effects of silica on macrophages *in vitro* and also its fibrogenic effect *in vivo*. Coating the silica particles with aluminium reduces these effects, and two other efficient protective substances are compound 48/80 (ref. 7) and polyvinyl-pyridine-*N*-oxide (ref. 8). The chemical structure of the latter is illustrated in (I); the basic unit, pyridine-*N*-oxide, has an oxygen atom with a high negative charge which is capable of forming strong hydrogen bonds without actually being able to abstract hydrogen from water to form ions. The polymer is very effective in suppressing silicosis in animals, where it reduces considerably the production of collagen. Macrophages are also protected by the compound against *in vitro* damage by silica



Portion of chain of polyvinyl pyridine *N*-oxide (PVPNO)
(I)

The aim of the present investigation was to determine the extent to which the toxicity of silica can be explained on the basis of hydrogen donor activity in the formation of complexes, and to find how far the protective effects of various compounds can be explained by their preferential formation of hydrogen bonds with silicic acid.

Hydrogen bonding. One of us has discussed hydrogen bonding in greater detail elsewhere[9]. Briefly, there are two classes of hydrogen bonding compounds. The larger class comprises hydrogen acceptors such as ethers and ketones and other compounds with active lone-pair electrons on oxygen or nitrogen. The smaller class comprises the hydrogen donors of which only the phenols are important among organic compounds, and silicic and one or two other very weak acids among inorganic compounds. Compounds of one class interact with those of the other, so that it is not surprising to find that there is one class (the former) the members of which are in general compatible with living cells, sometimes in very high concentration[9], whereas those of the other class are not. Large hydrogen donor molecules are, in fact, tanning agents, and it has already been suggested that silicic acid is one of them[5]. The hydrogen donor properties of tannic and of silicic acid are very similar, if measured by their acid dissociation constants[10].

State of solution of silica[10]. Silica (silicon dioxide) dissolves in water to form mono-silicic acid, probably $Si(OH)_4$, a saturated solution containing about 0·01 per cent. Much higher concentrations can be obtained by acidifying sodium silicate solution, or by ion-exchange, but the solution then polymerizes at a rate depending on temperature, *p*H, concentration, etc.:

The chains can cross-link by further elimination of water, to give a network (silicic acid jelly) and finally colloidal silica with —OH groups on the outer surface. The earlier products of polymerization resemble to some extent tannic acid as regards molecular weight and proportion of active hydrogen, and in view of this similarity the interactions of silicic and of tannic acids with 'tannable' compounds were examined.

Interactions of silicic and tannic acids with hydrogen acceptors and quaternary compounds. Silicic acid was prepared by treating 0·1 M sodium silicate with a sulphonic acid resin in the hydrogen form until the solution was slightly acid to litmus. Half was then diluted to 0·01 M in physiological buffered saline, and used immediately in the experiments, while the rest was made slightly alkaline and kept for a few days to allow the silicic acid to polymerize. It was then made weakly acid again and diluted in buffered saline to 0·01 M as before. The tannic acid solution used was 0·1 per cent strength.

Each solution, in lots of 6 ml., was treated in test-tubes, with gradually increasing amounts (up to 1 ml.) of 1 per cent (w/v) solutions of the following: polyethylene glycol 6000 (PEG), polyvinyl pyrrolidone 20,000 (PVP), poly-2-vinyl-pyridine-*N*-oxide (PVPNO, unknown molecular weight, kindly supplied by Prof. H. W. Schlipköter), and tetradecyl trimethyl ammonium bromide (TTAB). The maximum turbidities were read in an absorptiometer, calibrated in terms of optical density, and the results are shown in Table 1.

Table 1. TURBIDITIES DEVELOPED IN MIXTURES CONTAINING SILICIC OR TANNIC ACID AND HYDROGEN ACCEPTOR OR QUATERNARY COMPOUNDS, IN APPROXIMATELY 0·1 PER CENT SOLUTION IN PHYSIOLOGICAL BUFFERED SALINE

	PEG	PVP	PVPNO	TTAB
Fresh silicic acid	0 06	0 07	0·16	0·02
Aged silicic acid (sol)	0·015	0·02	0 07	0·04
Tannic acid	0·75	0·35	0·50	Zero

Figures are optical density read on 1·5 cm tubes with a green filter.

Relative strengths of interaction between various chemical groups and active hydrogen. In a study[9] of the chemical constitution of compounds able to protect living cells against freezing damage, it was shown that the common hydrogen acceptor groups showed a wide variation in their ability to interact with active (phenolic) hydrogen in aqueous solution. The strength of the interaction was estimated as the ratio of the solubility of a model compound in water to its solubility in 1 per cent phenol solution. It was not appreciated at the time of the study that there might be a significant difference in the behaviour of primary and secondary amide groups, so that the secondary amide (peptide) group was not tested; the expected large difference was found between primary amide and tertiary amide. The tests have now been completed and some of the results of the experiments are shown in Table 2. It can be seen that, in agreement with the results obtained by Holt and Went[5] for monolayers, there is some interaction between the peptide group and phenolic hydrogen, though apparently none between the latter and the primary amide group.

Table 2. A GRADED SERIES OF HYDROGEN-BONDING INTERACTIONS IN AQUEOUS SOLUTION

(*a*) Model for peptide group; (*b*) model for phosphate ester group; (*c*) model for protective compound PVPNO

Compound	Solubility in water	Solubility in 1 per cent w/v phenol	Ratio
Hexoamide	2·5	2·7 (approx.)	0·9
Ethyl ether	7·5	4·6	1·6
N-acetyl *cyclo*hexylamine	3·5	1·75	2·0 (*a*)
Diethyl ketone	5·5	2·5	2·2
s-Collidine	1·0	0·16	6
N-Dipropyl propionamide	5·0	0·3	17
Dibutyl sulphoxide	11·0	0·4	28
Tributyl phosphine oxide	4·0	0·05	80 (*b*)
Benzylpyridine *N*-oxide	∞	0·04	> 100 (*c*)

Solubilities are v/v per cent except for hexoamide which is solid at room temperature and was dispensed by weight.

Interaction between tannic or silicic acid and quaternary compounds. Both silicic and tannic acids will interact with quaternary compounds. The negative result shown in Table 1 for tannic acid simply means that the ionic conditions were in this instance not quite suitable. In the presence of sulphate ion (a micelle-promoting anion) tannic acid and the quaternary long-chain compounds show marked interaction. The fact that sulphate, and not halide, is the promoting agent shows that the interaction is probably between the micelles and tannic acid, rather than between individual molecules of the quaternary compound and tannic acid.

Silicic and tannic acids are only 0·1 per cent ionized in neutral solution, so that the interaction cannot be explained in terms of simple attraction between positive and negative charges. The interaction is of a secondary nature, possibly as a result of the 'structure forming' properties of quaternary groups in aqueous solution[11]. Compounds such as tannic acid are 'structure breaking' because they introduce plane trigonal regions in the normally tetrahedral structure of water. In other words, the factors causing the interactions under consideration are geometric rather than energetic, and are similar to those involved in the denaturation of protein by urea or guanidinium ion[12].

Tanning. We are probably near to being able to make a comprehensive definition of tanning. On one hand, there are the 'hydrophilic' polymers (hydrogen-attracting) such as gelatine, polyethylene glycol, polyvinyl pyrrolidone, some but probably not all of the polyamines (if they are too ionized hydrogen donor properties will begin to appear), and also the quaternaries and other structure-formers.

On the other hand, we have tannic acid and its analogues (silicic acid and any other polymers having active hydrogen with *pK* 9–11) and also large structure-breaking anions such as perchlorate, dichromate, hexafluorophosphate, tetraphenyl-boron and Nessler's reagent. These compounds are of very varied constitution but should have the common features of physical toxicity, and ability to precipitate or interact in some way with the first group of compounds[13].

With silicic acid the structure-breaking factor is probably size rather than shape, that is, the hydrogen bonds from silicic acid to water are probably tetrahedral in direction, but introduce disorder for some distance all the way around because none of the bond lengths fits into the water structure.

Most probable site of attack of silicic acid. From Tables 1 and 2 it appears that the interaction of silicic acid with the peptide group is likely to be considerably weaker than its interaction with phospholipid, which contains both quaternary and phosphate ester groups. Interactions with phospholipid are readily demonstrable experimentally. Egg lecithin forms an almost clear sol in water if mixed in from methanol solution. Both silicic acid and tannic acid cause a rapid increase in turbidity. Interaction of phospholipids with silicic acid in polar solvents contributes to the effectiveness of this system for chromatographic separation of phospholipids. Polymerized silicic acid on the surface of silica particles ingested by macrophages, or that reconstituted from soluble diffusing monomeric silicic acid in patches on the phagosomal membrane of the cell, could therefore react with the membrane to produce strong local modification of surface tension and increased permeability. Since PVPNO very readily forms hydrogen bonds with silicic acid it would be expected to protect biological membranes against the effects of the latter, and this protection is readily demonstrable experimentally.

Interaction of silicic acid with hydrogen acceptors. As silicic acid is a stronger acid than water, it will displace water from its bonds to lone-pair compounds such as those tested in Table 2. The interaction can be represented as follows:

$$Si - OH : \ddot{O} \quad \text{— lone-pairs on oxygen (as in pyridine } N\text{-oxide)}$$

$$Si - OH : N \quad \text{lone-pair on nitrogen (as in compound 48/80)}$$

When polymers interact with silicic acid there is the likelihood of multiple bonding making the whole process more efficient and leading to the more or less complete removal of the polymer from the aqueous phase. For example, PVPNO should adsorb on the surface of colloidal silica with so many uniformly strong hydrogen bonds that the complex should be stable. In accordance with Bronsted's principle[14] concerning the properties of polymers in solution, neutralizing agents of the type of PVPNO or PEG should show all-or-none properties, that is, PEG and PVP (polyvinyl pyrrolidone) can be expected to be completely inactive, if their affinity for active hydrogen is below a certain limit.

Haemolysis of red blood cells by colloidal silica, and the protective effect of a neutral polymer. A silica sol was prepared by passing 0·1 M sodium silicate solution through the hydroxyl form of a strongly basic ion-exchange resin, 'Zeo-Carb 225', until it began to come through alkaline, heating to 60° C in order to stabilize the sol and allowing to cool. The slightly alkaline solution was neutralized and diluted tenfold with buffered physiological saline. The same batch of sol was used both for tests with polymers and tests with human red blood cells.

The cells were washed three times in buffered saline, and suspended in saline. After exposure to various concentrations of silica for 1 h at room temperature, with repeated shaking to keep the cells in suspension, the liquid was centrifuged and the percentage haemolysis estimated by photometric measurement of haemoglobin in the supernatant. As shown in Table 3, concentrations of silica above 0·01 mM produce considerable haemolysis. As expected, good protection against haemolysis was ensured by first mixing equivalent weights of PVPNO solution with the colloidal silica, and then adding red cells to the mixture. Other experiments were carried out to discover if PVPNO can form relatively stable complexes with the cell membrane and so protect it against haemolysis. Washed red cells were pre-treated with a 0·1 per cent solution of PVPNO, spun down and washed twice, and then exposed to silica as before. The results in Table 3 show that no protection was afforded against high concentrations of silica, but that there was some against low concentrations which might have been due to the presence of small amounts of slowly released PVPNO. From these results it seems unlikely that PVPNO forms a stable complex with cell membranes.

Table 3. PERCENTAGE OF TOTAL HAEMOGLOBIN IN HUMAN RED CELLS FOUND IN SUPERNATANT AFTER EXPOSURE FOR 1 H TO VARIOUS CONCENTRATIONS OF SILICA SOL

Red cells	ml. 0·1 M silica/6 ml. final solution 0·3	0·1	0·03	0·01	0·003	0·001	Saline control
Untreated	51	75	75	81	49	10	0
Pretreated with PVPNO	64	83	73	61	31	1	0

Some cells were pretreated with 0·1 per cent PVPNO for 30 min and washed, before exposure.

Haemolysis was apparently less than 100 per cent at any silica concentration. This is because the cells were disrupted and the contents were partly precipitated; inspection of the precipitate showed that there were no intact cells. The reading on the supernatant was less than that which would have been obtained had the cells been haemolysed by distilled water, because some of the haemoglobin had been precipitated.

It is concluded that the toxic effects of silica are due to the capacity of polymeric silicic acid to act as a hydrogen donor in the formation of hydrogen-bonded complexes with active groups such as quaternary and phosphate ester groups of phospholipids or, to a lesser extent, secondary amide (peptide) groups of proteins. Polyvinylpyridine-*N*-oxide preferentially forms hydrogen bonds with silicic acid and prevents the permeability changes induced by the latter in biological membrane systems. Other substances protecting against the toxic effects of silica, such as compound 48/80, would be expected to act in an analogous way. Recently, Stalder and Stöber[15] investigated the haemolytic activity of various dusts and concluded that lipids are involved. They also found that PVPNO afforded good protection against haemolysis by powdered quartz, though possibly not so good as that which we found against haemolysis by chemically prepared silica sols.

From Table 2 it is clear why compounds such as polyethylene glycol or polyvinyl pyrrolidone should not be such good protective agents as PVPNO. The corresponding active groups, ether and dialkylamide, respectively, have less affinity for active hydrogen than has pyridine-oxide. Compound 48/80 has an even higher affinity for active hydrogen than PVPNO, but in this case the affinity is too high and some of the active centres are ionized. This is probably why the compound is rather toxic. The general aim in using or selecting neutral protective compounds would be to have as high an affinity as possible for active hydrogen without actually ionizing in water. A limit would be reached at about aliphatic amine oxide, R_3NO, the pK of which is 4, as compared with 1 for pyridine oxide.

Experiments are in hand to determine the effect on macrophages of water-insoluble derivatives of tannic acid which could be ingested in particulate form and then be slowly hydrolysed back to tannic acid inside the cells. In this way it should be possible to explore further the analogy between tannic and silicic acids. Finally, if the main suggestions of this article are correct, good protective action against the toxicity of silica should be afforded by polybetaines such as would result, for example, from the condensation of ethyl chloracetate with polyvinylpyridine and subsequent hydrolysis of the ester. Tests in this laboratory showed that long-chain monomeric betaines interacted with silicic acid but were haemolytic, as might be expected from their formal resemblance to lysolecithin. The polymeric betaines without any long alkyl chain should, on the other hand, be comparatively harmless, just as heparin is harmless compared with the long-chain alkyl sulphates.

One of us (J. S. H.) thanks the Anna Fuller Fund for full-time support. We are also indebted to Cyclo Chemicals, Ltd., for samples of long-chain betaines.

HIGH-SENSITIVITY POLARIMETRY AND ITS APPLICATION TO THE STUDY OF SMALL CONFORMATIONAL CHANGES IN PROTEINS

By D. A. CHIGNELL and DR. W. B. GRATZER
Department of Biophysics, King's College, 26–29 Drury Lane, London, W.C.2

THE measurement of optical rotation offers probably the most generally useful method for the observation of conformational changes in proteins in solution. The optical rotation is highly sensitive to solvent and other environmental perturbations[1], and the conformational changes which it will detect are therefore by no means limited to those involving α-helix ⇌ random coil transitions[2]. There is now abundant evidence, which is supported by the crystallographic studies on haemoglobin[3] and lysozyme[4], that when an enzyme combines with its substrate, a conformational change is frequently induced; it has indeed been suggested[5] that this might occur in all cases. It is supposed that small conformational changes are the general means whereby enzyme action is controlled by the non-competitive binding of activators and inhibitors[6–8]. A similar conformation-dependence may be anticipated in aggregation processes, such as are involved in the self-assembly of viruses, interaction of muscle proteins, and other systems. In consequence, increasing attention has been focused on the problem of detecting, following and interpreting such changes in conformation, which are expected to be small, and evidently do not in general involve significant breakdown or formation of α-helical structure. We describe here a technique for the application of polarimetry to the study of such small changes, and we give some examples of the type of information that can be obtained.

In a modern recording spectropolarimeter (Cary 60, Bellingham and Stanley 'Polarmatic', Jasco) full-scale rotations of the order of 0·1° can be measured. The precision of measurement varies with the circumstances, being under favourable conditions (stability of source and electronics, low strain in cell windows, constant sample temperature and clear solutions), generally about 2–4 per cent, outside the region of absorption bands. This makes it possible to detect a change in molar residue rotation $[m']$ of the same order.

When the Moffitt equation[9]:

$$[m']_\lambda = a_0\left(\frac{\lambda_0^2}{\lambda^2-\lambda_0^2}\right) + b_0\left(\frac{\lambda_0^2}{\lambda^2-\lambda_0^2}\right)^2 \qquad (1)$$

is applied to the optical rotatory dispersion curves, the constant b_0, which is considered to reflect the content of α-helix, can be determined with a precision of perhaps 5 per cent at best (depending on its absolute magnitude). Indeed, standard deviations in much of the published data are evidently a good deal higher. A similar limit can be set on measurements of the amplitude of the ultra-violet Cotton effects associated with the α-helical conformation, whether these be measured by optical rotation[10] or circular dichroism[11,12], depending on the relative magnitudes of absorption and rotation (that is to say in practice the actual α-helix content, and to some degree the proportion of aromatic amino-acids). Limits are thus set for the magnitudes of the conformational changes—whether reflected in b_0, or only in a_0 or a specific rotation or ellipticity—which can be observed.

In order to increase the sensitivity of polarimetric measurement of small changes, we proceed in the following manner. If the mean residue rotation of a protein $[m']$ be changed by some small amount $\delta[m']$, the measured rotation, α, will change by δα, such that $\delta[m']/[m'] = \delta\alpha/\alpha$ If the protein concentration (or the path-length) is now multiplied by a factor of say 10, δα will also be increased by the same factor; α, however, will now be immeasurably large. We therefore compensate out the rotation α with a dextrorotation of equal magnitude. This is most simply achieved by introducing into the beam, in series with the sample cell, a cell containing sucrose solution of appropriate concentration. Thus, a 5 per cent change in $[m']$, which would normally result in a measured rotation change of 0·005° (when α = 0·1°), will give instead a measured change of 0·05°. On the basis of the instrumental precision which we have indicated, this will make possible the measurement of a 0·2–0·4 per cent change in $[m']$ for a tenfold increase in protein concentration, and a 0·02–0·04 per cent change for a hundredfold increase. It will be noted that even such protein concentrations, giving, say, 5° actual rotations in the near ultra-violet region, are entirely reasonable. The limiting factor in measuring such small rotational changes ceases then to be polarimetric precision, and becomes instead one of volumetric accuracy, if reagents have to be added to effect the change in $[m']$. We may express the error in measured rotation, dα, resulting from an error dc in concentration in the following terms: $d\alpha/\delta\alpha = [m']\, dc/\delta[m']c$, where δα is the change in rotation to be measured. Thus, if it is proposed to measure a 0·1 per cent change in $[m']$, it follows that $d\alpha/\delta\alpha = 10^3\, dc/c$, so that if a 1 per cent precision of measurement is required, dc/c must be 10^{-5}. Such volumetric accuracy is, of course, entirely feasible, if small volumes of reagent can be added to large volumes of protein solution (for example, 10 μl. samples in 10 ml. samples of protein).

We have considered so far only rotations at single wave-lengths. For measurements of optical rotatory dispersion on a difference basis, the protein and the dextrorotator must remained balanced, or sufficiently nearly so to keep the rotation on scale, over a range of wave-length. This could be achieved by changing the sucrose concentration where the divergence becomes too great, or better by the use of a rotation compensator coil in place of the sucrose cell. We have found, however, that we can make use of the compensation from a single sucrose solution over the range 330–500 mμ. We are to some extent aided by the Verdet constant correction, which has to be applied to measured rotations in our instrument (Bellingham and Stanley 'Polarmatic' 62), to compensate for the wave-length variation of the Faraday cell rotation. This has the effect of flattening the recorded rotatory dispersion curves, and keeping the net apparent rotation on scale over such a large wave-length range. By determining $\delta[m']$ as a function of wave-length, we are now in a position to express our data in terms of 'difference' Moffitt plots, and to determine, within the limits of the Moffitt equation, to what extent differences in rotation result from changes in α-helix content. For a ten-fold increase in protein concentration, changes in b_0 corresponding to a change in apparent helix content of some 0·5 per cent should be measurable. (Clearly the measurements must not extend into the regions of absorption because of the very large absorbances which such concentrated systems would have.)

We give now some examples of applications of the difference method. We have observed first the activation of chymotrypsinogen with trypsin[13]. This gives rise to a

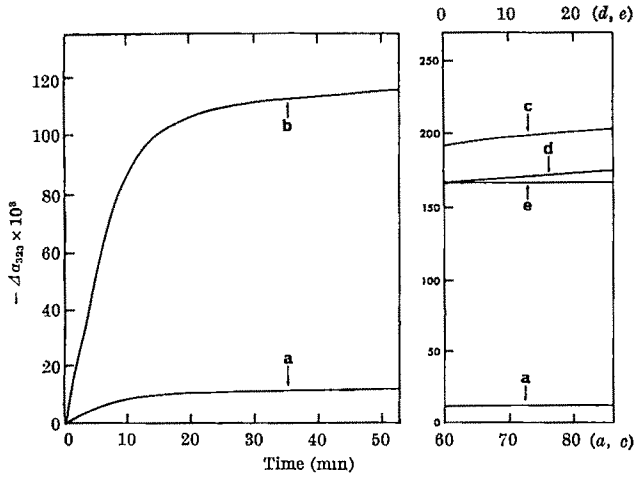

Fig. 1. Change in optical rotation (323 mμ) accompanying activation of chymotrypsinogen with trypsin: (*a*) observed directly, 3·5 mg/ml., 1 cm path; (*b*) 35 mg/ml. in 1 cm path, compensated by sucrose; (*c*) 26 mg/ml. in 1 cm path, compensated by sucrose, (*d*) α-chrymotrypsin under the same conditions as (*c*); (*e*) as (*d*), without sucrose. (Lower scale refers to (*a*), (*b*) and (*c*); upper scale to (*d*) and (*e*))

quite large rotational change, which is apparently not accompanied by any change in α-helix content, since both b_0 and $[m']_{333}$, as well as the far ultra-violet hypochromicity, remain essentially unchanged[14,15]. (The difference in specific rotation between chymotrypsin and its zymogen must be supposed, therefore, to arise from changes in anomalous optical rotatory contributions of aromatic residues, from environmental effects arising out of changes in the extent of exposure of residues to solvent, or from a combination of both.) The change of rotation as a function of time is shown in Fig. 1, measured both directly and by the difference method, at a ten-times higher protein concentration. It will be noted that after the initial steep change in rotation, there is a slower and smaller change, which soon becomes immeasurably small when observed directly, but can easily be followed by the sucrose technique. This slow change is inconsistent with the kinetics of the initial rapid change, and therefore represents a separate process. Fig. 1 shows also the time-course of the optical rotation of α-chymotrypsin in the presence of the same concentration of trypsin, and a similar slow change is observed. Over the same period no change could be detected in the absence of trypsin. We conclude that the activation of the chymotrypsinogen is accompanied by a perceptible proteolysis of the chymotrypsin which is produced on activation.

As a second example, we consider the slow denaturation of ovalbumin in urea solutions[16]. At low urea concentrations the rotational change is both slow and limited in extent. The inset in Fig. 2 shows the small changes measured by the difference technique as a function of time. The reaction at a urea concentration of 6 M was selected for more detailed study. We have measured the change in optical rotatory dispersion as a function of time by the following procedure: the wave-length is altered stepwise and at timed intervals, returning after the last wave-length to the first, and so on. By joining the rotations measured at each wave-length, we obtain the curves shown in Fig. 2, which then represent the time-course of the reaction at the indicated wave-lengths. The ordinates at a given time value now give the optical rotatory dispersion at that time, and from them Moffitt plots can be constructed. Fig. 3 shows the change of b_0 and a_0 with time: it is seen that b_0 after a rapid change reaches a constant value, whereas a_0 continues to fall. It will be noted that the overall b_0 change is about 25, and that one may accurately read off changes of about 1–2. In ovalbumin (*c.* 600 residues) this will correspond, on the scale of the Moffitt equation, to 1–2 residues leaving the α-helical conformation. Since we are here by no means working near the limit of the method (a 1·25 per cent ovalbumin solution in 1 cm path, and only a moderate instrumental scale expansion, were used), there seems little doubt that the effect of a single residue entering or leaving an α-helical segment would easily be observable. (In the case of short helices end-effects on anomalous rotatory dispersion become important; their magnitude may be assessed in terms of the data of Goodman *et al.*[17].)

We can further analyse the data of Fig. 3 with the aid of a variant of the Moffitt equation due to Doty[18], namely:

$$[m']_\lambda = (fa_0^H + \Sigma a_0^R)\left(\frac{\lambda_0^2}{\lambda^2 - \lambda_0^2}\right) + fb_0^H\left(\frac{\lambda_0^2}{\lambda^2 - \lambda_0^2}\right)^2 \quad (2)$$

where f denotes the fraction of residues in the α-helix, b_0^H the value of b_0 for a fully helical chain (usually taken as -630 for $\lambda_0 = 212$ mμ), and a_0 has been broken down into two components, a_0^H being the contribution of a fully helical chain arising only from the peptide chromophores in the helical state, and Σa_0^R the total intrinsic residue rotations, compounded of all side-chains, and modulated by the microscopic environment. Since, as has been noted, a_0 is changing regularly after b_0, and therefore the hypothetical fa_0^H, has ceased to change perceptibly, it appears that two denaturation processes are operating. If we assume these to be additive and independent, we may extrapolate back the change in a_0 which continues when b_0 has become constant. Towards shorter times the curve is seen to be not far from linear, and we therefore extrapolate linearly as shown in Fig. 3.

The difference between the extrapolated and observed a_0 curves should be fa_0^H, and this should be directly proportional to fb_0^H. The inset in Fig. 3 shows the two

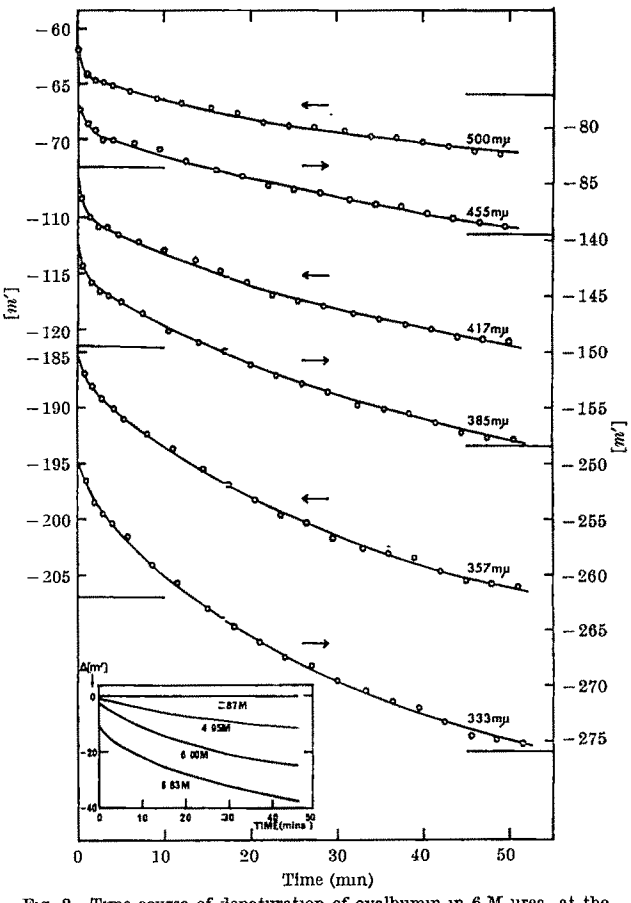

Fig 2. Time-course of denaturation of ovalbumin in 6 M urea, at the indicated wave-lengths. Protein concentration, 12·5 mg/ml., 1 cm path, compensated by sucrose. Readings were begun 1 min after mixing. Inset: denaturation rates as a function of urea concentration, all followed at 333 mμ using sucrose compensation to magnify the change. Protein concentrations, 25 mg/ml.

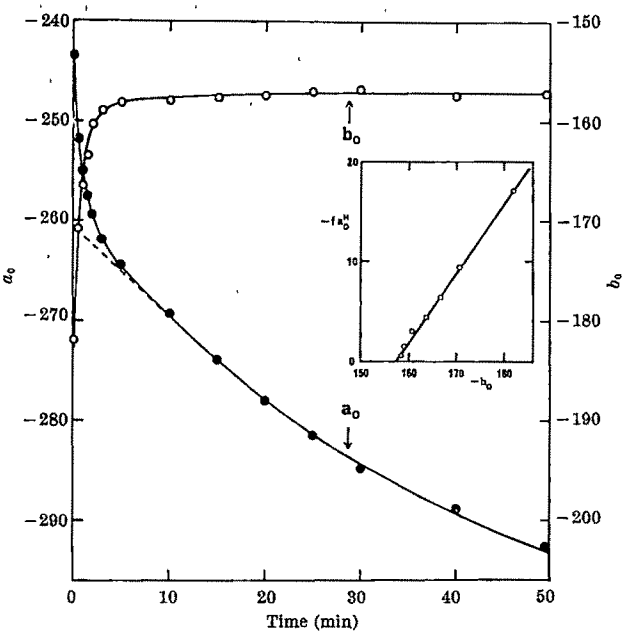

Fig. 3. Changes with time of optical rotatory dispersion parameters, a_0 and b_0, for ovalbumin, calculated from the Moffitt plots derived from the data of Fig. 2. Inset: plot of fa_0^H (equation 2) against b_0

functions plotted against each other, and a linear relation appears indeed to obtain. We deduce that the two steps in the reaction represent, respectively, disruption of an α-helical portion without appreciable change in Σa_0^R, and a much slower general unfolding of the molecule, with exposure of the internal residues to the new environment.

It is interesting to note that in 1954 Kauzmann[19] suggested from an investigation of the denaturation kinetics alone of ovalbumin in urea solutions that a helical segment was first unfolded, without major change in the molecule as a whole, and that this was then followed by a process of general expansion (as well as perhaps disulphide interchange), reflected in increased reduced viscosity. This interpretation, made before the advent of the Moffitt treatment of optical rotatory dispersion, is satisfactorily borne out by our experiments.

These examples illustrate the potentialities of the sucrose technique for the detection and elucidation of small conformational changes in proteins, and suggest possibilities in the sphere of enzyme function, where it is hoped the method will commend itself. Investigations of enzyme systems are in progress in this laboratory.

We thank Sir John Randall and Prof. M. H. F. Wilkins for support of this work and interest. D. A. C. is the recipient of a Science Research Council research studentship.

DEOXYRIBONUCLEIC ACID VALUES IN DIVIDING AND NON-DIVIDING CELLS OF MALE AND FEMALE LARVAE OF THE HONEY BEE

By DR. URSULA MITTWOCH, DR. H. KALMUS and W. S. WEBSTER
Galton Laboratory, University College, London

IN the honey bee (*Apis mellifera*), the males, or drones, normally arise from unfertilized haploid eggs, while the females, both workers and queens, originate from fertilized diploid eggs[1]. The chromosome numbers have been estimated as 32 and 16 in diploid and haploid cells respectively[1,2].

Recent work suggests that polyploidization occurs in the somatic cells of both male and female honey bees. Risler[3] concluded from chromosome counts as well as measurements of spindle sizes in dividing cells of larvae that during the first instar (that is, up to about 24 h after hatching[4]) the cells of the drones remain haploid and those of workers remain diploid, but that during subsequent instars different tissues become polyploid to varying degrees. Merriam and Ris[5] studied the deoxyribonucleic acid (DNA) contents of Feulgen-stained cells in interphase by microspectrophotometry and found that the DNA values of cells in both males and females fell into successive multiple classes.

We have carried out microphotometric studies on Feulgen-stained nuclei of young drone and worker larvae during the first instar. Even at this early stage some of the interphase nuclei showed considerable degrees of polyploidy, but the dividing cells were almost exclusively haploid in the males and diploid in the females.

The larvae, from an Italian hybrid strain, were removed from drone and worker cells of the hive and fixed in Carnoy's solution. For the present investigation we used younger larvae not more than 5 h after hatching, and older larvae aged 10–20 h. Feulgen staining was carried out in bulk, but whereas the younger larvae were stained *in toto*, the older larvae were first cut in half. Males and females which were to be compared were processed concurrently. The fixed larvae were hydrated and hydrolysed in N hydrochloric acid at 60° C for 10 min and stained in Feulgen solution for 1 h. They were then washed in water and placed in 45 per cent acetic acid kept on ice. The stained larvae were squashed gently between a siliconed slide and a clean cover slip, and the preparations were made permanent by the dry ice technique[6].

The DNA values, in arbitrary units, were measured on a Barr and Stroud integrating microdensitometer, type '*GN*. 2', at a wave-length of 5500 Å. In addition, the lengths of the two main axes of the nuclei were measured with an eye-piece micrometer and transformed into micra with the aid of a stage micrometer. The results were converted into nuclear areas using the formula Πab, where a and b are half axes. For diagrammatic representation, the readings of DNA values were converted into logarithms to the base 2.

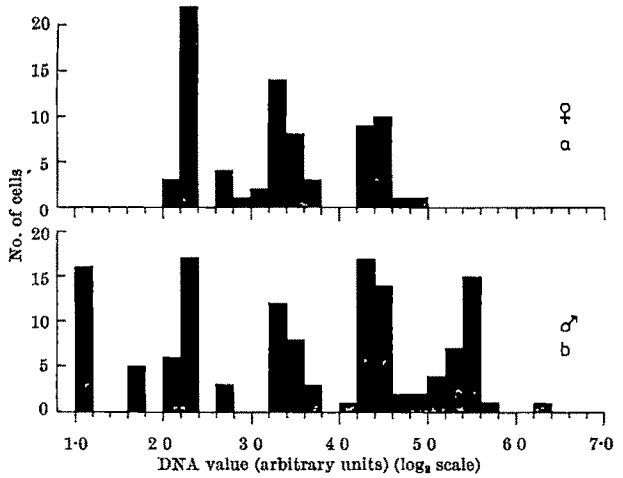

Fig. 1. DNA values of non-dividing cells of two larvae aged less than 5 h. (*a*) Female; (*b*) male

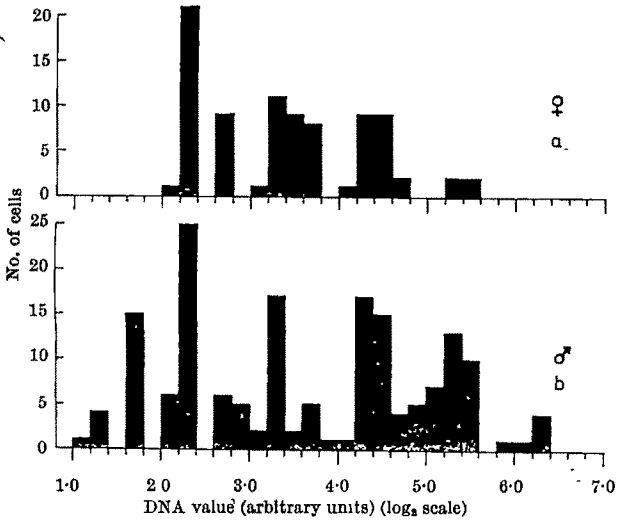

Fig. 2. DNA values of non-dividing cells of two larvae aged 10–20 h. (*a*) Female; (*b*) male

The distributions of DNA values of interphase nuclei of a male and a female larva aged less than 5 h are shown in Fig. 1 and those of a similar pair of larvae aged between 10 and 20 h are given in Fig. 2. All the histograms contain a number of peaks at distances of about one unit, corresponding to successive duplications of DNA values. Each of the two distributions of DNA values from males contains a peak on the left-hand side which is not present in those of the females, and we regard these peaks as corresponding to the haploid DNA values. In addition, the males also contained cells in the 32-ploid range, which were not found in the females. Although we cannot exclude the possibility that the males were slightly older than the females, the data suggest that the rate of polyploidization in drone larvae may be faster than that in worker larvae.

The DNA values of cells in mitosis taken from the same larvae are shown in Figs. 3 and 4. Bearing in mind that nuclei in prophase and metaphase contain the duplicated amount of DNA, it will be seen that the mitoses found in the female larvae were all diploid. By contrast, the mitoses in the younger male larvae were almost all haploid, although a few of the anaphases and telophases might have been diploid; in the somewhat older male, the majority of mitoses were still haploid, but a smaller proportion were undoubtedly diploid.

The nuclear areas of cells divided roughly according to their DNA values are given in Tables 1 and 2. Although there was considerable variation in nuclear sizes between the different larvae, the mean nuclear area of each individual is nearly doubled for each successive DNA class. A somewhat unexpected finding in the present data was that for each DNA class the nuclear sizes of the female larva from each pair was almost double that of the male, but this relationship was not borne out by some of our other material. Thus, while it is clear that successive duplications of DNA values are associated with correspondingly larger nuclei, the exact relationship between these two variables remains to be worked out.

Our results show that a large proportion of the non-dividing cells of both drone and worker larvae of the honey bee become polyploid soon after hatching. This may possibly be associated with their rapid growth, for it has been estimated that a worker larva increases its initial

weight 1,500 times within 4·5–5 days[4]. The nuclei become polyploid through the process of endoreduplication, which involves successive duplications of the chromosomal material in the absence of cell division. This process was originally discovered by Geitler[7–9] in insects belonging to the order Heteroptera and subsequently in other organisms and given the name 'endomitosis'. In young honey bee larvae, endoreduplication does not affect the dividing cells, for our results confirm those by Risler that during the first instar the mitoses of worker larvae are diploid while the majority of mitoses of drone larvae are haploid. Our results show that the ploidy in tissues of organisms originating by haploid parthenogenesis cannot be assessed by counting the chromosomes in dividing cells.

The contrast in ploidy number between dividing and non-dividing cells, which is so strikingly exhibited in honey bee larvae, occurs also, though to a lesser extent, in mammalian cells; and it has been suggested by Mittwoch *et al.*[10] on the basis of data obtained from human fibroblast-like cells in tissue culture that, whereas dividing cells have a strong tendency to retain the diploid chromosome number, a substantial proportion of cells become polyploid in interphase.

It is customary to distinguish between the germ line and the somatic cells. It may be useful to add a further category by subdividing the somatic cells into those which are likely to divide again and those which are not. We thus have three categories, namely (1) the meiotic line, (2) the mitotic line and (3) non-dividing or differentiating cells. Cells in the mitotic line have a strong tendency to retain their basic ploidy number, whereas differentiating cells may become polyploid to an extent which differs in different organisms and in different tissues.

We thank Dr. C. G. Butler, Head of the Bee Department of Rothamsted Experimental Station, for allowing us to use his colonies and Miss Elaine Fairey for her generous co-operation in providing male and female bees and larvae. The integrating microdensitometer was provided by the Central Research Fund, University of London.

RAPID UPTAKE OF TRITIATED ANTIGEN BY MOUSE EOSINOPHILS

By PROF. AUDREY N. ROBERTS
Department of Preventive Medicine, University of Tennessee College of Medicine, Memphis, Tennessee

THE association of eosinophils with a variety of immune reactions was summarized in a recent review by Litt[1]. Numerous studies have emphasized that eosinophils do not incorporate soluble antigen directly. An indirect function of eosinophils in mechanisms of antibody synthesis was suggested by autoradiographic investigations on the cellular localization of tritiated tetanus toxin in inflammatory peritoneal exudates of mice[2–4]. Eosinophils appeared to transfer tritiated material from disintegrating inflammatory cells to macrophages, which subsequently transformed into immature plasmacytes[2].

A significant eosinophilia was demonstrated in regional lymph nodes within 24 h after a single injection of heterologous protein antigen into the footpads of guinea-pigs[1,5,6]. Repeated injections of haemocyanin into the footpads stimulated a massive accumulation of eosinophils in the nearest draining lymph nodes[5]. Following footpad injections of fluorescein-labelled antigen, Litt[6] demonstrated the accumulation of eosinophils in regional nodes at the sites of antigen localization. The direct incorporation of antigen-antibody complexes by eosinophils has been shown with immunofluorescent techniques[7], electron microscopy[8] and phase microscopy[9]. Fluorescent techniques have failed to detect the uptake of soluble protein antigen by eosinophils in the absence of specific antibody[7]. These results indicated that immune complexes stimulate the eosinophil response.

Autoradiographic investigations of antigen localization revealed numerous tritium (^{3}H)-labelled eosinophils in draining lymph nodes 24 h after injections of a soluble ^{3}H-antigen into the footpads of mice. These observations initiated an investigation of the incorporation of antigen by eosinophils during the first 24 h of a primary immune response, and the results are presented in this article.

Sulphanilic acid was tritiated by the catalytic exchange method (New England Nuclear Corp., Boston) to a final activity of 2 mc./mg. A soluble, ^{3}H-labelled, heavily substituted azoprotein antigen (^{3}H-*S*-PγG) was prepared by coupling 12·5 mg sulphanilic acid-^{3}H to 80 mg of porcine gamma globulin (PγG, Pentex, Inc., Kankakee, Illinois)[10]. The final protein concentration of the ^{3}H-*S*-PγG was 8 mg/ml., and the total radioactivity content was 14 mc./80 mg PγG. Radioactivity determinations were performed in a liquid scintillation spectrometer[11]. An unlabelled, heavily-substituted azoprotein antigen (*S*-PγG) was prepared by coupling 12·5 mg sulphanilic acid to 80 mg PγG and was dialysed to a final protein concentration of 8 mg/ml. Mice injected with the *S*-PγG provided tissues for control autoradiograph preparations.

Mouse serum antibodies specific for the sulphanilazo determinant were titrated by the passive haemagglutination reaction using sheep erythrocytes coupled with diazotized sulphanilic acid[12]. Tests for serum antibodies against the PγG carrier utilized the passive tannic acid haemagglutination technique[10]. Serum from each experimental mouse was tested by the two haemagglutination methods.

Adult albino mice (*NLW-CFW*-Webster Swiss origin) were investigated in three groups. In groups 1 and 2, each mouse received a subcutaneous injection of 80 μg

^{3}H-*S*-PγG (14 μc./0·01 ml.) into the right hind footpad. In group 1, four mice were studied at each of ten time intervals following injection: 1, 2, 3, 4, 5, 6, 7, 8, 16 and 24 h. Eight right and left lymph nodes (popliteal, inguinal, ventral and dorsal axillary) were removed from each mouse and prepared for autoradiography. Lymph node sections were prepared from two of the four mice, using one mouse for each of two staining techniques: neutral formalin fixation for the haematoxylin and eosin stain and Bouin-Hollande fixation for the Dominici stain[13]. Lymph node imprints were prepared from the other two mice and observed with the haematoxylin and eosin stain and Dominici stain. All tissue preparations were stained following development of the autoradiographs. Details of the histological and autoradiographic techniques have been described[10].

Twenty-one mice in group 2 were investigated for serum antibody formation on days 1–7 after the footpad injections. Sera were collected from 3 mice/day and were tested by the haemagglutination techniques described earlier.

In group 3, each of ten control mice received a subcutaneous injection of 80 μg *S*-PγG (0·01 ml.) into the right hind footpad. One mouse was killed at each of the ten time intervals scheduled in the group 1 investigation, and the lymph nodes were sectioned for autoradiographic background determinations[10].

The quantitation of tritium-labelled eosinophils and observations on the concentrations of tritium-exposed emulsion grains over the labelled cells were performed on autoradiographs of lymph node sections after a 6-week exposure period. The intracellular tritium concentrations were graded as light (3–10 grains/cell), moderate (10–20 grains) and heavy (>20 grains). The average number of background grains over unlabelled control tissue sections (mouse group 3) and emulsion-coated, non-tissue areas of experimental slides was 1 grain/1,000 μ² (ref. 10).

Autoradiographs revealed no tritium-labelled cells in the left popliteal, inguinal and axillary nodes of group 1 mice through the first 24 h following ^{3}H-*S*-PγG injections into the right hind footpads. The basal level of eosinophils in these lymph nodes was determined by counting the total number of eosinophils in 1,920 sections of eighty nodes. The mean of the eosinophil counts per section was thirteen, with a range of 0–61. Only eighteen of the 1,920 sections contained more than nineteen eosinophils, and many of the left popliteal node sections contained no eosinophils. The right dorsal axillary lymph nodes also remained unlabelled throughout the interval investigated. Counts of unlabelled eosinophils in 980 sections of twenty right dorsal axillary nodes revealed a mean of thirteen eosinophils to each section (range 1–47).

Autoradiographic observations detected ^{3}H-labelled eosinophils in the right popliteal, inguinal and right ventral axillary lymph nodes of group 1 mice following injections of ^{3}H-*S*-PγG into the right hind footpads. The total number of ^{3}H-labelled and unlabelled eosinophils, and the concentration of ^{3}H-exposed grains over the labelled cells, were determined in a minimum of twenty-four sections of each node, and the results are presented in Table 1. Labelled eosinophils were scattered in the regional popliteal nodes 1 h after footpad injections, but no significant increases were evident in the eosinophil counts of each section. An increase in eosinophil counts between 1 and 4 h was accompanied by a 40-fold increase in the percentage of labelled eosinophils. The highest eosinophil counts in the draining popliteal nodes occurred between 4 and 8 h, during which time over 90 per cent of the eosinophils had incorporated ^{3}H-antigen. Although the eosinophil counts decreased to normal means by 16 and 24 h, the proportion of labelled cells remained above 90 per cent.

Autoradiographs of the right inguinal and right ventral axillary lymph nodes of group 1 mice showed many heavily tritiated eosinophils 1 h after the footpad injections (Table 1). As in the regional popliteal nodes, the appearance of ^{3}H-labelled eosinophils in the inguinal and axillary nodes preceded significant increases in the number of eosinophils per section. Eosinophil counts in these lymph nodes attained very high levels at 4, 6 and 7 h, and the autoradiographs revealed a high percentage of heavily labelled eosinophils at 1, 6, 7, 8 and 24 h. The inguinal and axillary nodes which contained tritiated eosinophils usually had eosinophil counts significantly above the normal means derived from the contralateral nodes. Exceptions to this relationship occurred at 1 and 24 h. Individual mouse variation was noted in the incorporation of ^{3}H-antigen by cells of the inguinal and axillary nodes[14]. Autoradiographs failed to detect radioactivity in the right ventral axillary node sections examined at 2 h and in the inguinal and axillary node sections studied at 5 and 16 h (Table 1). Autoradiographs of lymph node imprints from other group 1 mice, however, demonstrated ^{3}H-labelled eosinophils in the right inguinal and right ventral axillary nodes at 2, 5 and 16 h. The uneven distribution and irregular depth of the cells in these tissue imprints prevented any quantitative evaluation of the eosinophil responses. Of the 40 group 1 mice which received footpad injections of ^{3}H-*S*-PγG, all responded with antigen incorporation by cells of the draining popliteal nodes, but six failed to show any ^{3}H-antigen in the right inguinal and right ventral axillary nodes. The results from the latter six mice indicated variation in the distribution of antigen from the injection site.

The appearance and distribution of labelled eosinophils in the popliteal, inguinal and axillary nodes were similar. The efficient incorporation of ^{3}H-antigen by eosinophils was emphasized by the high percentage of heavily labelled cells which persisted [illegible] 24 h of the investigation (Table 1). The ^{3}H-grains were densely packed over the cytoplasm of the labelled eosinophils, closely surrounding the nuclear lobes, but no intranuclear localization was observed (Fig. 1). More than 90 per cent of the eosinophils were mature cells with

* 80 μg (14 μc.) of ^{3}H-sulphanilazo porcine γ-globulin was injected subcutaneously into each right hind footpad of twenty mice.

† Cells of the right popliteal, right inguinal and right ventral axillary lymph nodes incorporated ^{3}H-antigen.

‡ Mean of the total eosinophil counts per section in a minimum of twenty-four sections per lymph node from each of two mice.

§ Intracellular ^{3}H concentrations were scored as: heavy = >20 ^{3}H-exposed emulsion grains/cell; moderate = 10–20 grains; light = 3–10 grains.

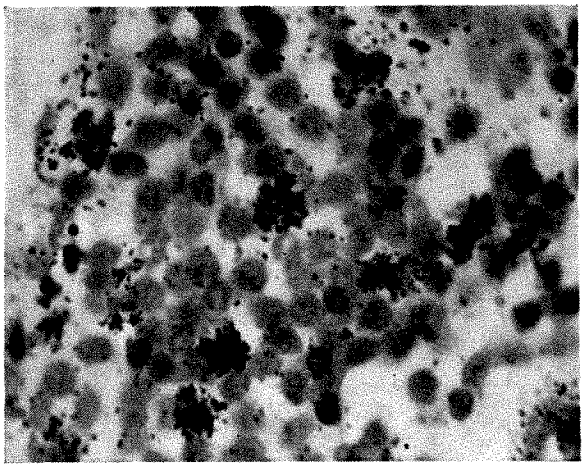

Fig. 1. Autoradiograph of right ventral axillary node section 1 h after ^{3}H-antigen injection into right hind footpad. Note the concentration and intra-cytoplasmic localization of tritium in the eight heavily and moderately labelled eosinophils. (×c. 667)

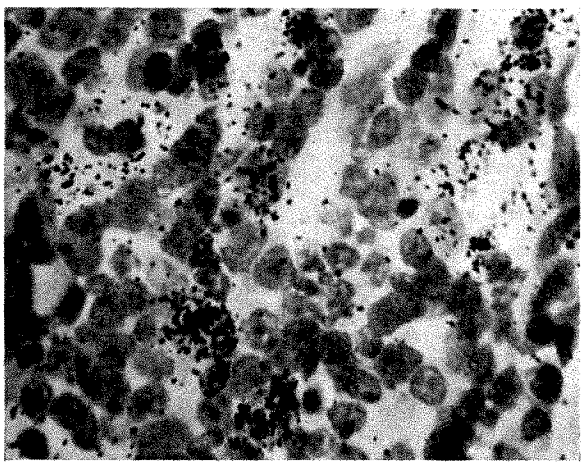

Fig. 2. Autoradiograph of right inguinal node section 3 h after ^{3}H-antigen injection into right hind footpad. This shows the distribution of eight heavily tritiated eosinophils in areas of unlabelled lymphoid cells (×c. 667)

^{3}H-labelled mononuclear eosinophils were observed in the lymph nodes, but these immature cell forms were never prevalent.

From 1–3 h after injection, the labelled eosinophils were scattered in the medullary regions, interfollicular cortex and polar regions of the nodes. At 3 h, labelled eosinophils were distributed in areas of heavily labelled macrophages. No distinct association was observed, however, between the two cell types[14]. Many heavily labelled eosinophils were also scattered generously in areas of unlabelled lymphoid cells (Fig. 2). At 4, 6 and 7 h, large clusters of heavily labelled eosinophils were demonstrated in the right inguinal and right ventral [illegible]llary nodes. These clusters of thirty to fifty cells [illegible]od in the interfollicular medullary areas, inter-[illegible]ortex and polar regions of the nodes. The 8-h [illegible]ode sections presented a similar appearance, [illegible]ers of heavily tritiated eosinophils localized [illegible]follicular medullary areas (Fig. 3). Although [illegible]counts in the three nodes had returned to [illegible] 16 and 24 h, the tissue localization of the [illegible]was unchanged.

[illegible]nice in groups 1 and 3 contained no [illegible]s specific for the sulphanilazo deter-[illegible]arrier protein when tested by the [illegible]tination methods. Sera from group 2 mice yielded negative haemagglutination results on days 1–6 after antigenic stimulation. The three mouse sera studied on day 7 demonstrated low antibody titres of 1 : 8 to 1 : 16 against the sulphanilazo determinant and remained negative (< 1 : 2) for the carrier protein. These serological results indicated a primary immune response.

The present investigations combined the specificity of a heavily tritiated antigen (175 μc./mg) labelled only in the determinant group, the autoradiographic sensitivity of ^{3}H localization and a regional primary response stimulation. This allowed us to quantitate early antigen incorporation by lymph node eosinophils. The demonstration of ^{3}H-antigen in eosinophils contrasts with the results of other investigations on antigen localization[2–4,10,15] and experimental eosinophilia[1,5–7]. Previous investigations did not reveal antigen incorporation by eosinophils following the intravenous injection of ^{3}H-aniline-azoprotein into mice[10]. The absence of ^{3}H-labelled eosinophils in sites of antigen deposition could have resulted from the low radioactivity of the antigen (64 μc./mg), the route of injection and the lack of observations within the first 24 h. Studies on the localization of tritiated tetanus toxin in mouse peritoneal exudate cells failed to detect the direct incorporation of ^{3}H-toxin or ^{3}H-toxin-antitoxin complexes by eosinophils[2–4]. However, this lightly labelled toxin (2 μc./mg) provided very low sensitivity for autoradiographic observations. Nossal *et al.*[15,16] observed the cellular localization of iodine-125 and iodine-131 labelled antigens following a primary response stimulation in the footpads of rats. Although autoradiographs of draining lymph nodes did not reveal antigen incorporation by eosinophils, the use of the methyl green-pyronin stain for all histological preparations could have hindered recognition of these cells.

In this investigation, the appearance of eosinophilia in lymph nodes draining the sites of antigen injection correlates with the results of Litt[1,5,6]. Previous observations on experimental eosinophilia indicated, however, that antigen-antibody complexes were the prominent mediators of the eosinophil response[1,5–7]. *In vivo* and *in vitro* investigations of the interaction of cells with fluorescent-tagged antigen, antibody and antigen-antibody complexes detected the intracytoplasmic localization of only the fluorescent immune complexes in eosinophils[7]. From these results, Litt[1,6,7] proposed that following a primary antigenic stimulus, the draining lymph node responds with the very early formation of antibody which complexes with antigen and subsequently stimulates eosinophilia. Recent indirect evidence has suggested that antibody formation begins within 24 h following a primary

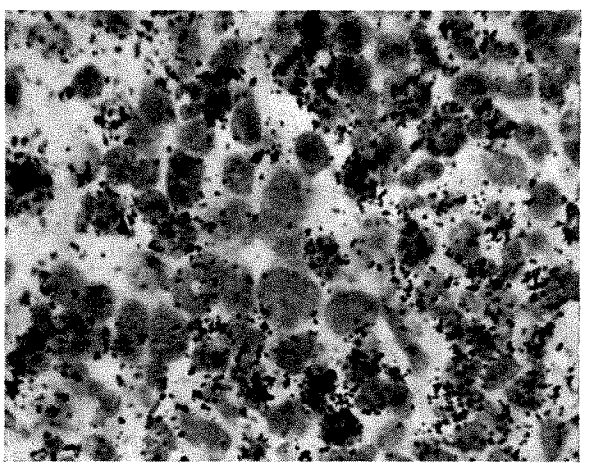

Fig. 3. Autoradiograph of right popliteal node section 8 h after ^{3}H-antigen injection into right hind footpad. A large cluster of heavily labelled eosinophils in the interfollicular medullary area. (× c. 667)

response stimulation[17]. However, previous observations by Nossal *et al.*[18] did not detect significant antibody formation prior to day 3 with the highly sensitive immune adherence phenomenon.

The present investigations have demonstrated the rapid uptake of ^{3}H-antigen (or antigen fragments containing the ^{3}H-sulphanilazo determinant groups) by eosinophils and the subsequent eosinophilia in draining lymph nodes within 4 h of primary antigenic stimulation. The early, heavy accumulation of ^{3}H in eosinophils indicates that the soluble, heterologous protein induced the eosinophil responses in the absence of specific antibody. It is unlikely that antibodies were synthesized and released from lymph node cells in quantities sufficient to complex with the ^{3}H-antigen prior to its incorporation by eosinophils. These results suggest, therefore, an important function of eosinophils in mechanisms of the primary immune response.

NEURONAL MODELS FOR CONDITIONED REFLEXES

By PROF. W. BURKE
Department of Physiology, University of Sydney, Sydney, New South Wales, Australia

THE large number of neural models of learning[1–9] is a reflexion of our lack of understanding of the learning process at the cellular level. Nevertheless, model-building may be of value, particularly if the model is sufficiently precise to be tested experimentally. The argument for making it precise rests on the assumption that learning involves a change in the quality of synaptic transmission at specific synapses. In this discussion attention will be directed mainly to the classical conditioned reflex[10].

The essential change occurring in the formation of a classical conditioned reflex is that a given stimulus now produces a certain response whereas previously it did not do so. In neuronal terms, somewhere along the chain of neurones connecting stimulus receptor to effector facilitation has occurred. The facilitation arises because of a temporal association between the unconditioned stimulus (UCS) and the test stimulus (CS). Although the conditioned response (CR) eventually obtained to CS is usually not identical with that resulting from the UCS (UCR), it is clear that at least some of the effector pathways must be common to the two reflexes. In other words, there must be convergence of the CS and UCS at some point in the chain.

Because of the extremely large number of conditioned reflexes which can be formed, in the primate at least, it is improbable that there is a growth of nerve terminals under specific chemotactic influences. Because of the speed with which conditioned reflexes can be established it is unlikely that there is any extensive growth of nerve terminals. The assumption is made here that all pathways are laid down by early life and that learning consists in selective facilitation of certain synapses already present.

Fig. 1*a* summarizes the situation described here. However, this model is inadequate and in conflict with accepted concepts. It is inadequate because a prediction from the model is that learning should occur by simple contiguity of CS and UCS (in the absence of reinforcement), but it is doubtful if this ever occurs. The model also conflicts with our concept of the independence of afferent terminals on a cell. Phenomena such as post-tetanic potentiation, once considered to provide a basis for learning, seem to be confined to the pathway being tetanized.

A model which overcomes the second objection is shown in Fig. 1*b*. For the purpose of these diagrams the convention is adopted that any cell is discharged by simultaneous activity in two terminal knobs but activity in one is not enough, unless it is 'facilitated'. Thus B is discharged only by concurrent action of CS and UCS. B synapses with a CS terminal on A and discharge in B produces presynaptic facilitation of the terminal so that after a certain number of CS/UCS pairings CS alone will fire A. However, this model is also unsatisfactory as an explanation of permanent learning. If CS is given without UCS, B does not fire, facilitation gradually disappears and CS becomes ineffective.

The model in Fig. 1*c* includes the element of reinforcement which seems to be necessary for successful conditioning. The model functions as follows. Neurone C, discharged only by concurrent action of CS and UCS, is capable of activating A, leading to the response. Neurone B is discharged by concurrent activity in C and in some reinforcement pathway. B feeds back on to a CS terminal to produce presynaptic facilitation. After an appropriate number of CS/UCS pairings, the degree of facilitation is adequate to allow CS alone to discharge neurone C and thus neurone A and so to elicit the response. If reinforcement is withdrawn, neurone B is not discharged and there is no further facilitation, so that eventually CS fails and the conditioned reflex is extinguished. Differences between CR and UCR can be accounted for by assuming different degrees of facilitation at individual synapses.

The diagram is for positive reinforcement (reward or avoidance of injury) but could be the same for negative reinforcement (injury) if the action of B on the CS terminal is inhibitory. The model is the simplest which incorporates reinforcement. The axon of B is shown forming an axo-axonal contact with the CS terminal on C. It does not synapse with the cell-body of the CS terminal because this would not give facilitation at specific nerve terminals. Axo-axonal synapses have been reported in various parts of the central nervous system[11] and so far it has been assumed that they subserve a process of presynaptic inhibition[11]. This assumption should be re-examined. Presynaptic hyperpolarization has been demonstrated in the mammalian spinal cord[12] and a process of presynaptic facilitation has been postulated at the giant cell of the abdominal ganglion of the sea slug[13,14].

In the process of presynaptic inhibition a depolarization of afferent terminals occurs[11]. One might imagine that pre-

synaptic facilitation would involve a hyperpolarization of the terminals; however, an action potential falling during the active phase of such a hyperpolarization would tend to be inhibited rather than enhanced. Since a conditioned reflex, once established, may persist for years in the absence of CS, the process of facilitation must involve more than a mere change of membrane potential. It therefore seems probable that the action of neurone *B* on the CS terminal concerns not only membrane potential changes but also the synthesis and storage of transmitter by that terminal.

We may suppose that facilitation involves both stimulation of synthesizing processes and an increased store of transmitter. If no presentation of CS is made the store remains unchanged. If CS is presented without reinforcement the store is depleted, but the facilitated synthesizing processes partially restore the level so giving 'spontaneous recovery'. Eventually the absence of reinforcement will lead to a depression of the synthesizing process.

Experimentally, CS must be given slightly before UCS or overlapping in time. Therefore it must be assumed that the CS pathway to *C* involves a longer and more complex route than UCS so that there will be synchronous bombardment of neurones *C* and *B*. 'Orientation' may provide a background depolarization of all *C* neurones non-specifically but decrementing (habituation) unless facilitated.

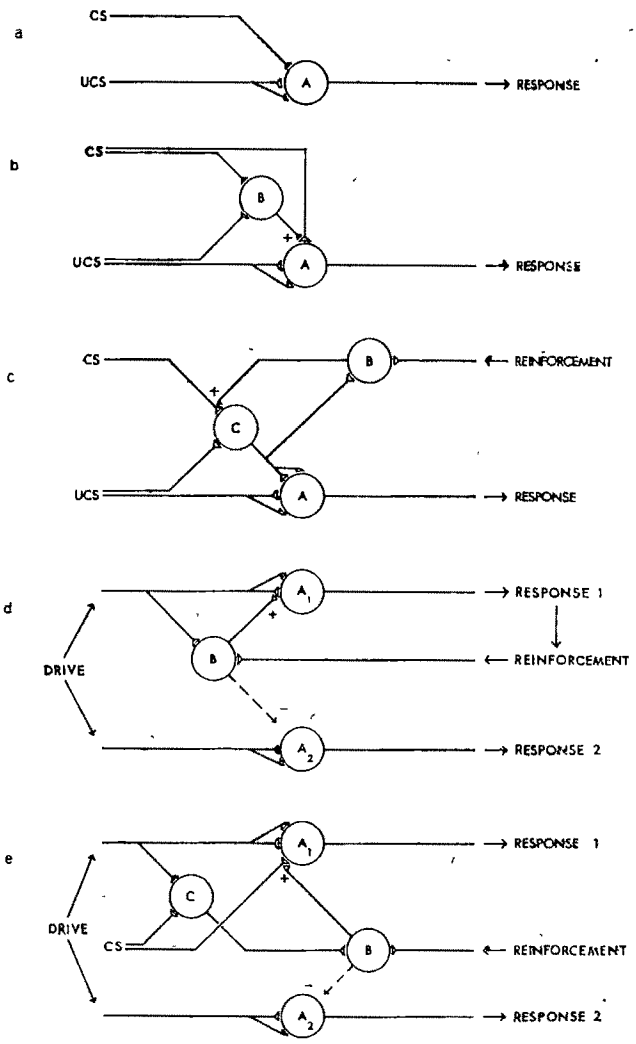

Fig. 1 Possible models for conditioned reflexes In all cases the convention is that the cell-body (represented as a circle) is discharged only by concomitant activity in two terminals; a single terminal is ineffective unless 'facilitated'. CS, Conditioned stimulus. UCS, Unconditioned stimulus +, Facilitation. −, Inhibition. *a*, *b*, *c*, Models for classical conditioning. *d*, *e*, Models for instrumental conditioning. Further explanation in text

'Backwards conditioning' in which UCS precedes CS is much less effective because UCS activity is finished by the time CS arrives at *C*. It may be necessary, however, to suppose that UCS or UCR prevents CS reaching *C*. It is also necessary to suppose that *C* cells, once they discharge, continue to fire for some time, at least seconds, without further activation by CS and UCS. 'Disinhibition' (a strengthening of the response during extinction as a result of applying a new stimulus) may operate in a similar way to orientation, that is by a generalized depolarization of *C* neurones.

An important inference from the model is that neurones *B* and *C* are private to the particular reflex set up. In other words, these neurones might never function in the entire life of the individual. They may be allowed only low-frequency 'spontaneous' activity. This idea may not be so improbable. Learning ability in different species seems to be a function of the number of neurones available; at least in the mammalian central nervous system the numbers involved are extremely large. Furthermore, because of higher-order conditioning and stimulus generalization, *B* and *C* neurones may participate in many different reflexes. It would also seem to be necessary that any given *B* neurone be reciprocally connected with a *C* neurone in the manner shown, and that *A* and *C* neurones lie close together so that there will be a high probability of UCS innervating *C* neurones which project to *A* neurones also innervated by UCS. Any departure from strict correspondence of innervation will permit a stimulus generalization, assuming that there is an orderly topographical projection within any given modality. Conversely, the more precise the correspondence of innervation the finer will be the discrimination. Thus, parts of the central nervous system may consist of aggregates of *A*, *B* and *C* neurones; in vertebrates the reticular formation[15–18] and parts of the cerebral cortex are possible sites although axo-axonal contacts seem to be absent in the cerebral cortex[19].

Figs. 1*d* and 1*e* show models for instrumental conditioned reflexes[10], for the free-responding and signalled situations respectively. For the establishment of any conditioned reflex, classical or instrumental, 'drive' ('motivation') seems to be necessary. 'Drive' includes already established unconditioned and conditioned reflexes, for example, hunger and fear. In any given situation 'drive' leads to a limited number of responses. In Figs. 1*d* and 1*e* only two possibilities are shown. In the free-responding situation the 'correct' response produces facilitation of synapses in the neuronal pathway leading to that response and inhibition of other responses. The mechanism for inhibition is not shown but might be a form of presynaptic inhibition. Fig. 1*e* shows a possible circuit for a situation in which a particular stimulus (CS) is the signal for a certain response, only the combination of CS and correct response being reinforced.

For 'stimulus–stimulus' learning it must be supposed that, although there is no overt response, the combination of two stimuli leads to a reinforcement, for example, intellectual satisfaction, which feeds back and facilitates certain synapses coupling the two stimuli together in some way.

There is not space here to discuss all the features of conditioned reflexes in terms of the models. For many of these features, for example, external inhibition, additional circuitry is necessary. It may be objected that the models contain no inhibitory pathways whereas the evidence for these is strong; the models, however, provide a core around which accessory features can be built. It is a reasonable assumption that the basic mechanism for learning will be the same for all organisms possessing nervous system. If this is so, it may be most rewarding to study the simplest organisms. The recent demonstration[20] in *Aplysia* of heterosynaptic facilitation at the cellular level produced by a classical conditioning procedure is most encouraging.

I thank Sir John Eccles, Prof. P. O. Bishop, Mr. W. R. Webster and Mr. I. S. C. Bruce for their advice.

FUNCTION OF NEUROSECRETION IN ENDOCRINE REGULATION

By SIR FRANCIS KNOWLES
Department of Anatomy, University of Birmingham
AND
PROF. HOWARD A. BERN
Department of Zoology and Cancer Research, Genetics Laboratory, University of California, Berkeley

THE theory of neurosecretion has undergone modification during the past decade, and it is perhaps now time to restate the original postulate in slightly different terms[1]. In his last major paper, the late Ernst Scharrer[2] began a reconsideration of the contribution of the nervous system to endocrine regulation. In extending the re-estimation of the role of neurosecretion, we wish to continue the distinction between the endocrine role characteristic of neurosecretory neurones and the secretory activity characteristic of neurones generally[3,4]. Although secretion is a general property of neurones at the cellular level, at the level of the organism neurosecretion occupies a specific and central position in the developing field of neuroendocrinology.

At the beginning, the neurosecretion theory was based on the selective staining of secretory materials within some neurones of the central nervous system. The quantity of secretory material thus demonstrated was large, and changes in the amount and nature of the stainable inclusions often suggested the existence of secretory cycles as in gland cells. Later these neurones were associated with the production of hormones (for example, antidiuretic hormone in vertebrates, chromactivating hormones in crustaceans, prothoracotropic brain hormone in insects). Later, the neurohaemal concept[5] provided a useful criterion for assessing whether a neurone was truly neurosecretory. According to the neurohaemal concept, neurosecretory neurones are engaged in hormonogenesis and liberate their products into the blood stream at a neurohaemal organ.

They are thus distinguishable from neurones engaged in transmitter activity. This definition of neurosecretion has been widely accepted[6]. Recent investigations with the electron microscope, however, indicate that an autochthonous endocrine activity may not be the sole function of neurosecretion, and that the concept of neurosecretion should be extended to include other aspects of neuroendocrine regulation besides the production of blood-borne hormones. The present communication attempts to develop the concept of neurosecretion in the light of recent discoveries.

The neurohaemal concept implied the absence of transmitter activity of neurosecretory neurones and thus of synaptic termination. Some neurosecretory axons, however, would seem to make contacts with endocrine cells, notably in the corpora allata of insects[7] and in the pars intermedia of the vertebrate pituitary[8–10]. The physiology of these junctions has not yet been studied, but morphologically many of the contacts described resemble ordinary secretomotor junctions between nerve fibres and gland cells. A close association between neurosecretory fibres and ependymal cells has also been demonstrated[11], and junctions between neurosecretory fibres and ependyma-like pituicytes, with the morphological features of synapses, have been seen[12]. Contacts such as have been observed raise the possibility that some ependymal cells, functionally related to neurosecretory systems, might have a humoral function concerned with communication within the central nervous system[13]. It is evident that discharge of hormones into the blood stream can no longer be considered as the sole function of neurosecretory neurones.

During the past decade certain staining techniques, notably the Gomori chrome-alum-haematoxylin (CAH) method, the Gabe paraldehyde fuchsin method and the Adams-Sloper alcian blue technique, have proved useful for the recognition of neurosecretory systems. Indeed the term 'Gomori-positive' has often been used to denote material stained blue by the basic component of the CAH method, and 'Gomori-negative' to specify material coloured red by the acid component. Although these terms have a certain convenience and persist in the literature it should be recognized that the foregoing staining methods are not sufficiently specific to be diagnostic of neurosecretory systems, and especially that the term Gomori-negative is confusing since it could be interpreted as a failure to stain with either component of the Gomori CAH method.

A brief survey of the findings by workers who have used the Gomori CAH method to identify neurosecretory systems will show how varied is the staining reaction of neurosecretory neurones. Among those which stain with the basic stain are: (1) the pars intercerebralis–corpus cardiacum–corpus allatum system of insects; (2) the eyestalk and other neurosecretory systems in crustaceans; (3) the principal hypothalamus–pars nervosa system of higher vertebrates; (4) elements in the innervation of the pars intermedia of lower vertebrates.

Some other neurosecretory systems, however, are stained by the acid component of the Gomori technique, notably: (i) the hypothalamic nucleus lateralis tuberis innervating the pars distalis of teleost fishes[14]; (ii) some elements in the pars intermedia of elasmobranch fishes[8,9]; (iii) neurosecretory cells in the brains of many inverte-

brates. Yet other neurosecretory systems are relatively unreactive to the Gomori CAH technique, notably: (*a*) the caudal neurosecretory system of some fishes[15]; (*b*) neurosecretory neurones in the median eminence of tetrapods[16].

Most but not all of the foregoing neurosecretory systems are equipped with elementary granules on the ultrastructural level. The typical elementary neurosecretory granule, electron-dense and measuring 1000–3000 Å in diameter, originally described by Bargmann and by Palay[17], is characteristic of most established neurosecretory systems where hormonogenesis is unquestionably involved. However, these granules are apparently not diagnostic of every neurosecretory system.

The median eminence of the amniote neuro-hypophysis, for example, shows vesicles and granules which more frequently resemble those associated with cholinergic and adrenergic nerve endings[16]. It has been suggested that two biochemically distinct groups of neurosecretory products—peptide and non-peptide respectively—may be represented in neurosecretory systems[18]. It appears evident that more than one kind of neurosecretory system may be concerned in the regulation of other endocrine activity. Whereas the '*A*' fibres in contact with pars intermedia cells in elasmobranchs contain typical elementary neurosecretory granules of diameter of about 1800 Å, the '*B*' fibres (with vesicles of diameter of about 700 Å) resemble adrenergic fibres[8]. '*B*' type fibres also form the major part of the innervation of the pars distalis of some teleosts[13].

Neurosecretory fibres, then, may influence endocrine gland cells, either by blood-borne hormones, or through neurosecretomotor junctions morphologically not unlike typical synaptic connexions, but possibly involving 'transmitters' with special biochemical and physiological features. Another possibility can also be envisaged, namely, the release of chemical agents from what might be termed a neurosecretory neuropile[19]. Such agents would reach adjacent glandular tissue by diffusion and exert control in a manner indistinguishable from that of blood-borne hormones. The concept of 'chemical addressing'[20], which in this case means the development of specific tissue sensitivity to a diffusing neurohormone, can thus be extended to this direct neurosecretory influence.

The present evidence indicates, therefore, a diversity in neurosecretory form and function, in the spatial relations between neurosecretory neurones and other tissues, and in the biochemical nature of the neurosecretory hormones. Yet it is possible to recognize one unifying feature of neurosecretion, namely that all the neurosecretory neurones specified above participate either directly or indirectly in endocrine control and form all or part of an endocrine organ. They may directly control bodily function by releasing hormones into blood vessels or into a haemocoel (or even into the cerebrospinal fluid[11,13,21]) to regulate particular activities (for example, water balance in vertebrates, colour change in crustaceans, tanning in insects). In other instances the action of the neurosecretory neurones is indirect and involves control of other endocrine tissues. This control may be exerted through the systemic circulation at some distance from the point of liberation of the neurosecretory hormone (for example, the prothoracotropic 'brain hormone' of insects, the moult-inhibiting hormone of crustaceans), through a short special circulatory pathway (for example, the portal transport of adenohypophysial releasers and inhibitors), through diffusion from a neurosecretory neuropile, or through direct neurosecretory contact (for example, with the pars intermedia of lower vertebrates, with the corpus allatum and the intrinsic cells of the corpus cardiacum in insects).

One striking feature of neurosecretory systems is their ability to sustain an inhibition or excitation of endocrine tissue or other effector organs. The pars intermedia of fishes and amphibians and the corpora allata of insects appear to be under a sustained inhibitory control; the control of colour change and water balance requires a regulatory system which can maintain a steady stimulus without fatigue. This temporal distinction between neurosecretory and non-neurosecretory neurones would seem to be fundamental; neurosecretory control can be viewed as 'tonic', depending on a slow continous release of a slowly degraded product. In analysing the nature of the physiological contacts between neurosecretory fibres and endocrine cells, this special temporal feature needs to be considered; it has been suggested, moreover, that different forms of neurosecretory control of endocrine function might be distinguishable on a temporal basis[8].

It must be admitted that there are still problematical areas in the delineation of neurosecretion. For example, the adrenal medulla (chromaffin) cells receive cholinergic innervation from preganglionic fibres of the sympathetic nervous system, which are therefore indirectly engaged in endocrine control. The frequently reported occurrence of stainable 'neurosecretory' fibres extending to non-neurohaemal and non-endocrine tissues also requires further investigation. However, controversies as to the possible neurosecretory nature of neurones do become simplified for the time being by our suggested definition that neurosecretory neurones are engaged directly or indirectly in endocrine control and may form all or part of an endocrine organ.

According to this concept, nerve fibres which innervate muscles or exocrine glands would not be classified as neurosecretory, even if they possess special staining properties or contain granules resembling those of neurosecretory cells. In our opinion the finding, by itself, of electron-dense granules at the level of ultrastructure cannot at the present time be more diagnostic of neurosecretion than is the presence of droplets staining by the Gomori or other 'neurosecretory' stains.

Morphologically, neurosecretory neurones combine neuronal and glandular characteristics. Physiologically also they provide an essential link between the nervous and endocrine systems. As such they provide the final common pathway for neuroendocrine regulation[2].

This work was aided by a grant from the U.S. Science Foundation.

EFFLUX OF PROSTAGLANDIN FROM ADRENAL GLANDS STIMULATED WITH ACETYLCHOLINE

By P. W. RAMWELL and JANE E. SHAW

Worcester Foundation for Experimental Biology, Shrewsbury, Massachusetts

AND

PROF. W. W. DOUGLAS and A. M. POISNER

Department of Pharmacology, Albert Einstein College of Medicine, New York

THE prostaglandins, a group of pharmacologically active, unsaturated hydroxy-carboxylic acids, have been found in a variety of tissues in many different species, but their physiological significance is uncertain[1,2]. The fact that these acids have been observed to escape from various tissues on nervous stimulation[3–5] led us to suspect that their discharge could be related to the release of neurohumours. This conjecture prompted us to test whether prostaglandin might escape during release of catecholamines from the chromaffin cells of the adrenal medulla which are developmentally related to sympathetic nerves and offer the experimental advantage of a more massive secretory activity. Our results show that prostaglandin $F_{1\alpha}$ appears in the venous effluent from perfused cats' adrenal glands when catecholamine secretion is evoked by acetylcholine (ACh).

Cats' adrenal glands, acutely denervated, were perfused *in situ* with Locke's solution by the method previously described[6]. Venous effluents were collected from one or both glands. Acetylcholine (10^{-5} g/ml.) was introduced for 20–40 sec five to ten times at 6-min intervals and the effluents collected during the stimulation periods were pooled. Effluents collected during the 5–10 min period preceding the first exposure to acetylcholine in each experiment served as controls. Catecholamines were measured fluorimetrically[7]. The prostaglandin content of control glands was determined after brief perfusion with Locke's solution, and that of stimulated glands after the aforementioned treatment with ACh. The prostaglandin content of effluents and glands was determined as follows: the effluents were acidified to *p*H 2 and extracted with petroleum ether followed with diethyl ether and the diethyl extracts were dried and biossayed on the rat uterus[3]. The glands were homogenized in saline and the homogenates extracted and assayed as above except that extraction was preceded by three washes each with equal volumes of petroleum ether and diethyl ether at *p*H 7·0 to remove substances likely to interfere with the bioassay. Control experiments with prostaglandin E_1 (PGE_1) or prostaglandin $F_{1\alpha}$ (PG$F_{1\alpha}$) showed that 80–90 per cent of these substances were recovered in the acid–diethyl ether extracts. Acetylcholine, catecholamines and other polar substances are not extracted by the procedure used and thus did not interfere with the bioassay; interference from spasmogenic unsubstituted C_{18} and C_{20} carboxylic acids and phospholipids was eliminated due to their solubility in acid–petroleum ether. When acid–diethyl ether extracts contained oxytocic activity equivalent to 100 ng or more of PG$F_{1\alpha}$, thin-layer chromatography in the *A*I and *A*II systems of Gréen and Samuelsson[8] was performed as described previously[4]. In all experiments the R_F of the oxytocic activity obtained from the adrenal glands and effluents after stimulation of the glands with acetylcholine coincided with the R_F of the PGF compounds in the *A*I system and PG$F_{1\alpha}$ in the *A*II system; PGE_1, PGE_2, PG$F_{1\alpha}$, and PG$F_{2\alpha}$ were used as standards. No evidence for the presence of prostaglandins other than PG$F_{1\alpha}$ was obtained. PG$F_{1\alpha}$ was therefore used as the standard in all assays, and results are expressed in terms of PG$F_{1\alpha}$ equivalents. Since the number of glands used in different experiments varied, all values for prostaglandin or catecholamines in perfusates or homogenates are expressed in units per gland used.

In the absence of stimulation, prostaglandin was detected in only two of seventeen samples of venous effluent collected from eleven different adrenal preparations. These two samples contained the equivalent of 12·5 and 18·8 ng PG$F_{1\alpha}$/gland perfused. The corresponding values for catecholamine output, 0·075 and 0·25 μg/gland perfused, were within the normal range found in effluents from unstimulated glands. In six preparations ACh (10^{-5} g/ml.) was added to the perfusion medium for periods from 100 sec to 7 min and increased catecholamine secretion to high levels (37·7–175 μg/gland perfused). In each instance prostaglandin was detected in the effluent: the range was 18·8–250 ng PG$F_{1\alpha}$/gland perfused (Table 1).

Table 1. STIMULANT EFFECT OF ACETYLCHOLINE ON EFFLUX OF CATECHOLAMINES AND PROSTAGLANDIN FROM PERFUSED ADRENAL GLANDS

Experiment No.	Spontaneous release: Catecholamines (μg/gland)	Spontaneous release: PG$F_{1\alpha}$ equivalents (ng/gland)	ACh-evoked release: Catecholamines (μg/gland)	ACh-evoked release: PG$F_{1\alpha}$ equivalents (ng/gland)
(1)	0·58	< 5	37·7	30
(2)	0·39	< 10	67·9	250
(3)	0·25	< 5	148	100
(4)	0·80	< 2·5	175	18·8
(5)	0·25	18·8	97	33
(6)	0·17	< 10	140	250

Since catecholamines have been found to release prostaglandins from some tissues[3], experiments were performed to determine whether the efflux of PG$F_{1\alpha}$ from the adrenal gland during exposure to ACh was the result of some action of the catecholamines that were released. Six preparations were perfused with epinephrine, norepinephrine, or mixtures of equal parts of the two, in a concentration (50 μg/ml.) which exceeded that found in the venous effluents from adrenal glands stimulated with ACh. No prostaglandin was detected in the effluents except in the one experiment where prostaglandin was present in the effluent obtained during the preceding control period.

Prostaglandin was found in adrenal glands in each of eleven experiments: The mean content was 15·5 ng PG$F_{1\alpha}$/gland. This is a much smaller amount of prostaglandin than was found in the venous effluents (mean = 114 ng PG$F_{1\alpha}$/gland perfused). The prostaglandin content of ACh-stimulated glands did not differ significantly from that of unstimulated glands (Table 2). In four experiments cortices and medullae were assayed

Table 2. PROSTAGLANDIN CONTENT OF ADRENAL GLANDS

Experimental treatment	PG$F_{1\alpha}$ equivalents (ng): Medulla	Cortex	Total	Total/gland
Control	15	100	115	28·8
Control	< 20	50	50–70	12·4–17·5
Control	—	—	12·5	6·25
Control	—	—	15	7·5
ACh†	< 10	50	50–60	25–30
ACh	10	30	40	20
ACh	—	—	25	12·5
ACh	—	—	12·5	6·25
ACh	—	—	12·5	6·25
ACh*	—	—	60	30
ACh	—	—	30	15

Two glands were used for each measurement except in each of the first two (control) experiments where four glands were used. The glands designated by the symbols † and * were obtained from the animals used in experiments 5 and 6, respectively, of Table 1.

separately: the bulk of the prostaglandin was present in the cortex, where its concentration ranged from 115 to 197 ng $PGF_{1\alpha}$/g. The concentration of prostaglandin in the medulla in the two experiments where values were obtained was higher: 370 and 430 ng $PGF_{1\alpha}$/g.

Previous experiments have shown that analysis of the venous effluent from the adrenal gland for substances other than the released catecholamines is a useful means of analysing cellular events involved in catecholamine extrusion. Thus the finding that the catecholamines in the effluent are accompanied by equivalent amounts of ATP metabolites indicates that the immediate source of these amines is the nucleotide-rich chromaffin granules[9,10]; and the demonstration that massive amounts of ATP may escape unhydrolysed in appropriate conditions shows that hydrolysis of the ATP within the chromaffin granules is not a critical step in catecholamine release[11]. Furthermore, these results, as well as the detection in the adrenal effluent of protein characteristic of the chromaffin granules[12], lend support on chemical lines to the view advanced on electron-microscopical grounds that the chromaffin granules empty directly to the cell exterior by reverse pinocytosis or some related process[13,14].

The present finding that prostaglandin escapes from the adrenal gland during exposure to ACh—but not when catecholamines are perfused through the gland—suggests that the efflux of these lipid acids may offer an additional clue to the mechanism of medullary secretion. Since the mechanism of catecholamine secretion described here must involve momentary disruption of the membranes of the chromaffin granule and the chromaffin cell, it is conceivable that prostaglandin could be formed from breakdown of these lipid membranes. That prostaglandin is indeed formed during the action of ACh is indicated by the fact that the amount of prostaglandin escaping on stimulation greatly exceeded the amount endogenous to the adrenal glands.

It seems pertinent that the formation and escape of a group of spasmogenic acid lipids (SRS; slow reacting substance) closely related to prostaglandins[15] also occurs during the release of another biogenic amine, histamine; and, moreover, that this effect has been attributed to phospholipase *A* activity[16,17]. Possibly ACh activates an endogenous phospholipase *A* in the adrenal gland which splits off prostaglandin from membranes and thus allows catecholamines to escape. Although there is, as yet, no evidence that prostaglandins are incorporated in phospholipids and can be split off by the activity of such an enzyme, the postulate that stimulation with ACh involves activation of an endogenous phospholipase *A* is consistent with the following facts: first, that phospholipase *A* activity is reportedly present in adrenal glands[18]; second, that most preparations of phospholipase *A* are activated by calcium which is believed to mediate the stimulant effect of acetylcholine on catecholamine secretion[6,19,20]; and third, that a possible end-product of phospholipase *A* activity, lysolecithin, has been detected in the adrenal medullae of cattle[21] and cats and dogs[22]. This line of speculation is, of course, based on the assumption that it is from the medulla, the classical site of action of ACh, that the prostaglandin escaped. However, our results do not exclude the possibility that some other action of ACh within the gland is responsible, for example an action on cortical cells[23].

Finally, our conjecture that prostaglandin release may be an accompaniment of secretory activity in the adrenal gland offers a possible explanation for the occurrence of prostaglandin in other systems. Thus nerves, the stimulation of which also results in prostaglandin release, are cells modified to 'secrete' in a specialized way; furthermore, the classical source of prostaglandin, the prostate, is an exocrine gland. Perhaps prostaglandin formation is a common accompaniment of secretory activity.

We thank Dr. J. Pike, Upjohn Co., Kalamazoo, for prostaglandin standards. We also thank Mr. R. Jessup, Miss A. Palazzolo and Mrs. M. Perlstein for assistance in this work, which was supported by grants from the U.S. Public Health Service and the National Association for Mental Health.

AUTORADIOGRAPHY *IN VIVO* OF HUMAN CANCERS

By PROF. P. KISSEL, DR. A. DUPREZ, DR. M. BESSOT, PROF. J. SCHMITT and PROF. A. DOLLANDER
Faculté de Médecine, Nancy, France

AUTORADIOGRAPHY in the human *in vivo* has only rarely been carried out[1,2], because the doses necessary for satisfactory results are dangerous to the patient. We have found an effective isolated isotopic perfusion technique[3] which allows us to decrease the quantity of circulating radioactivity so that the investigation becomes innocuous to the patient. We have applied this method of autoradiography *in vivo* to patients with a variety of cancers in order to investigate the precise kinetics of malignant human cells.

The life of a cell can be divided into four periods: (1) Cell division by mitosis or amitosis over a period of 30–60 min. (2) First resting phase (G_1) which varies between several hours and several years depending on the type of cell. The cell matures and its physiology is characterized. (3) A 6–10-h phase of synthesis (S), during which the cell doubles its DNA reserve. (4) Second resting phase (G_2) of 2–6 h, at the end of which the cell division begins and the cycle begins anew[4].

We introduced a radioactive DNA precursor during the synthesis phase in order to study this period and the second resting phase (S and G_2). The DNA molecule is composed of two purine bases (adenine and guanine), two pyrimidine bases (cytosine and thymine), a pentose (desoxyribose), and inorganic phosphates. If the synthetizing cells are tagged with tritiated thymidine or ^{32}P, the newly formed DNA will incorporate the isotope. The autoradiographic technique will then identify the labelled cells.

We studied five cancers of the colon, one of which had metastasized to the liver and the periaortic lymph nodes; five gastric cancers, two of which had metastases; one uterine paramalpighian carcinoma; one metastatic adrenal gland from a primary digestive cancer; and three osteosarcomata, two of which were from patients with Paget's disease.

This procedure was incorporated into the surgery of the cancer and did not cause the patient any additional ordeal. The vascularizing artery of the pedicle of the tumour is isolated and then denuded and cannulated with a No. 1 or 2 cannula which is tied in place. The normal arterial flow and venous drainage are not disturbed. A 1-h perfusion of 100 c.c. of isotonic saline containing 0·5–1 mc. of tritiated thymidine or ^{32}P (specific activity 2·7 c./mmole) is begun. Sometimes at the beginning of the perfusion a slightly increased perfusion pressure is necessary. This procedure varies with the type of tumour. In carcinomata of the digestive tract, the tumour is completely isolated except for the vascular pedicle (vein and artery) to be perfused. The pyloric pedicle is chosen for the stomach, the inferior mesenteric pedicle for the descending colon and rectum. The tumour is resected and the continuity re-established. Perfusion through the vascular pedicle in bone tumours is followed by resection, amputation, or disarticulation as the case may be. In this case arteriographic verification is sometimes necessary.

Six to ten samples are taken from different zones (with two control pieces from normal tissue) for histological examination. The pieces are fixed in Bouin's solution, passed through alcohols, and embedded in paraffin. For best results the sections must be as thin as possible; sections 2·5–5μ in thickness give best results. The sections are deparaffined and placed in running tap water. After this, all subsequent operations are carried out in darkness.

An emulsion of Ilford '*NRE* K_2' is diluted in the proportion of one part emulsion to 10 parts distilled water. This is kept in a water-bath at 40° C. The slides are 'dipped' in this emulsion for 5 sec, then drained in the vertical position for 1 min. They are then placed in a black box, which is in turn placed into a second black box. The boxes are refrigerated at 4° C for 14 days when ^{32}P is the isotope; and for a period of 40 days when the tissues were prepared with tritiated thymidine. At the end of the cold-storage period the slides are developed in Kodak '*D* 76' during an 8-min period. They are fixed in a 10 per cent hyposulphite bath for 15 min. Finally, they are washed in running water for a minimum of 20 min.

The primary interest of this procedure lies in the possibility of combining the standard histological staining methods with autoradiography, thereby permitting a precise study of the pathological microstructure of a malignant tumour including changes in the points of reference normally found in non-cancerous tissue.

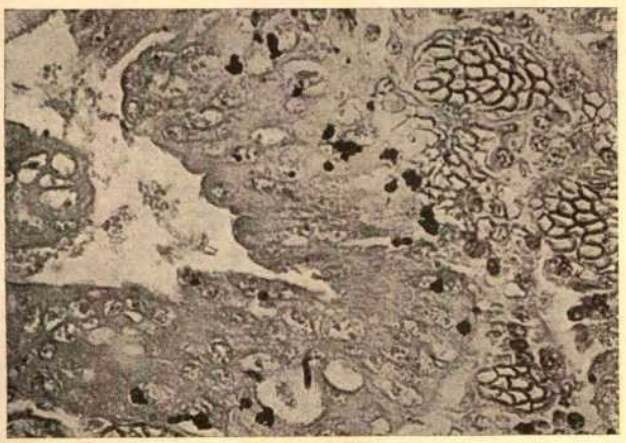

Fig. 1. Gastric carcinoma, basal and axial labelled cells. Blood vessels on the right. (×300)

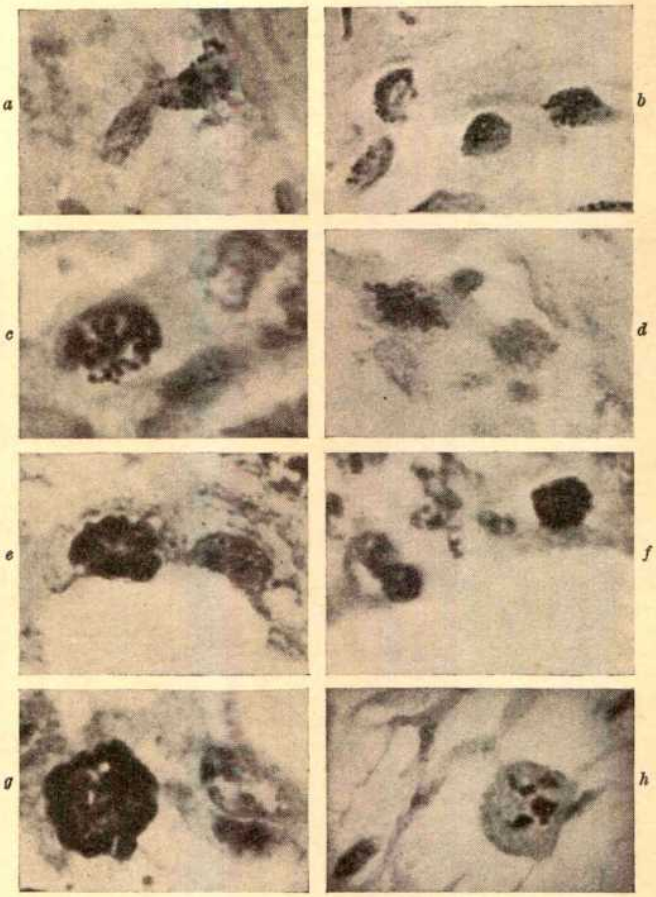

Fig. 2. (*a*) Gastric carcinoma (stroma); (*b*) osteosarcoma (elegant argyrophilic granulations) (×550); (*c*) cancer of colon, confluent silver granules (×700); (*d*) osteosarcoma, confluent silver granules (×700); (*e*) gastric carcinoma, a 'diamond-studded ring' nucleus (×700); (*f*) cancer of colon, flecked labelling in two nuclei (×700); (*g*) cancer of colon, a confluent labelling giving the impression of a 'fleck' (×800); (*h*) osteosarcoma, 'irregular moats' in a nucleus (×800)

Feulgen's method (with or without Lumière green) and Masson's trichrome stains are excellent, but we have found it an advantage to decrease the staining time. We prefer a staining technique without haematoxylin because of the blue-black spotted artefacts which sometimes appear. For this reason we used carmine alum 1 per cent, eosin 1 per cent, and safran 1/300.

The labelled cells are clustered, suggesting the division of the tumour into active and resting zones. The labelled zones are usually found to be in close proximity to, or surrounding, a blood vessel (Fig. 1) in the form of a rosette. Sub-groups in which DNA synthesis is synchronous can be seen in the actively dividing zones. Low-power examination of these sub-groups or moats is often misleading, because of their resemblance to artefacts (Fig. 1). This type of zone-distribution is characteristic of the malignant process, and can be explained by loss of the 'normal structure synthesis model'. In glandular epitheliomata, the labelled cells are numerous adjacent to the basement membrane and in the zones peripheral to the polystratified lining (Fig. 1). This last finding emphasizes the loss of homoeostasis at the cellular level. In addition to the perivascular region, marked cells can be plainly seen in the extensive dedifferentiated areas. The perivascular labelling is not observed in infiltrating tumours; the tagged cells are found in groups of two or three cells situated close to the limit of the normal tissue.

The stroma and monocytes are labelled with varying intensities and the conjunctivo-vascular tissue is sometimes labelled, whereas the sclerotic zones are never tagged with the isotopes. Normal muscular, connective, or epithelial tissues were almost never labelled under our

experimental conditions. We have found on rare occasions a lightly labelled cell in the region of the fundus of a crypt of Lieberkühn, but there was no confusion between the frankly labelled tumour cells and the rare cells found in normal tissue which showed a very slight affinity for the isotope.

Cytological examination revealed several types of labelling (Fig. 2, *a–h*). Nuclei of the stromal cells (Fig. 2*a*) and some well-differentiated malignant cells (Fig. 2*b*, *c*) had an elegant argyrophilic granulation which was often distributed in a homogenous manner. The least typical of the differentiated malignant cells were labelled in irregular moats (Fig. 2*h*), almost always found under the nuclear membrane, giving the impression of a diamond-studded ring (Fig. 2*e*).

Massive zones containing few or no differentiated cells, the basal cells of the tubules, and the atypical sarcoma cells have a flecked labelling (Fig. 2*f*, *g*) due to the confluence of numerous silver granules (Fig. 2*c*, *d*). Some nuclei were partly labelled by the isotope as though only a part of the nuclear DNA had been synthesized (Fig. 2*h*). This was observed with greatest frequency in the osteosarcomata. In very proliferative osteosarcomata and in metastasized epitheliomata we observed some labelled mitotic figures. Sometimes, two contiguous nuclei in the same chondroplast or osteoplast are intensely labelled, suggesting that one nucleus had divided into two.

This technique gives excellent autoradiographic labelling and is innocuous to the patient. The weak dose of isotope (0·5–1 mc.), the rapid transformation of the tritiated thymidine to heavy water[2], and the short half-life of ^{32}P are evidence that the method is not more dangerous than thyroid cartography or other routine *in vivo* isotopic studies. Moreover, its application in patients whose treatment requires much higher follow-up doses of radiotherapy justifies our isotopic explorations.

Up to now it has been difficult to draw prognostic conclusions from the usual histopathological study. On the other hand, knowledge of the rates of cell division makes possible a decisive prognosis[5]. The presence of numerous labelled elements shows that cellular divisions are frequent. The fact that healthy tissues are not labelled proves that the malignant cells have a turnover which is clearly superior to that of normal cells[6,7]. The presence of numerous nuclear flecks attests to the rapid uptake of the isotope, which in turn is responsible for the over-exposure of the photographic emulsion. The fact that many marked molecules were incorporated in a relatively short period of time shows that the duplication of DNA is more rapid in these cells.

Finally, one can conclude from the presence of the labelled mitotic figures that in some malignant cells a part of the S phase, all the G_2 phase, and a part of the cell division period took place in a 1-h period (perfusion time), whereas this normally requires 6–12 h. We think it possible that this method could be used to calculate the rate of tumour growth, and with this information an accurate prognosis could be arrived at.

When surgical exploration is not complicated it is possible to carry out several successive autoradiographic studies with ^{32}P. Well-chosen intervals between studies would eliminate a cumulative radioactivity at the level of the tumour. One could then evaluate the therapeutic effect of various drugs and even of radiotherapy. It is feasible in certain cases to use ^{32}P as the therapeutic agent. Since the least differentiated cells take up more of the isotope, such action might have the effect of redifferentiating tumours about to become anaplastic (dedifferentiated).

IN VITRO CELL TRANSFORMATION BY X-IRRADIATION

By CARMIA BOREK and PROF. LEO SACHS

Section of Genetics, Weizmann Institute of Science, Rehovoth, Israel

CARCINOGENESIS can be induced by viral, non-viral chemical, and physical agents. In order to elucidate the mechanism of carcinogenesis, it would be of value to be able to induce by these different agents transformation of the same normal cells to tumour cells in tissue culture. It has previously been shown that normal hamster cells can be transformed to tumour cells *in vitro* by a virus such as polyoma[1], and by carcinogenic hydrocarbons[2]. The present experiments were undertaken to determine whether *in vitro* transformation of normal hamster cells can be directly induced by X-irradiation, and if so, to characterize some of the conditions required for this transformation to occur.

Short-term cultures from golden hamster embryos were used as a source of normal cells. The cells were grown in plastic Petri dishes (Falcon Co.) with Eagle's medium containing a four-fold concentration of amino-acids and vitamins plus 10 per cent calf serum, in a humified incubator with a constant flow of 10 per cent carbon dioxide in air. Primary cultures were seeded at 1×10^7 cells per 100 mm Petri dish, and subsequent passages were usually seeded at 1×10^6 cells per 50 mm Petri dish. Cells were plated for cloning at 5 or 7×10^2 cells per 50 mm plate. The cells were cloned on X-irradiated (4,000 r.) rat embryo feeder cells, and for the assay of transformed clones the plates were fixed, and stained with May–Grünwald–Giemsa, after 10 days of incubation[3].

Two types of X-ray machines were used. One type, which gave hard X-rays, was from a Picker Vanguard X-ray machine operating at 250 kV and 15 m.amp, filtered with 1·0 mm of aluminium and 0·5 mm of copper. This was used at a dose rate of 60 r./min. The second type, which gave soft X-rays, was from an R. Seifert Derm ovolt X-ray machine operating at 56 kV and 15 m.amp, filtered with 1·5 mm of aluminium. This was used at a dose rate of 280 r./min. The dose was measured with a Philips standard dosimeter, and for the dose measurement the meter was covered with a plastic Petri dish lid. The cells were irradiated in covered plastic Petri dishes in 4 ml. of medium per 50 mm and 10 ml. of medium per 100 mm plate. The medium in the cultures was changed before irradiation.

The first experiments were carried out with mass cultures. One-day-old primary cultures were irradiated with 300 r. Three days after irradiation the cells were seeded at 1×10^5 cells per plate on rat feeder layers, and they were then passaged when confluent, without a feeder layer, at 1×10^6 cells per plate. The growth rate of the controls decreased with further passaging,

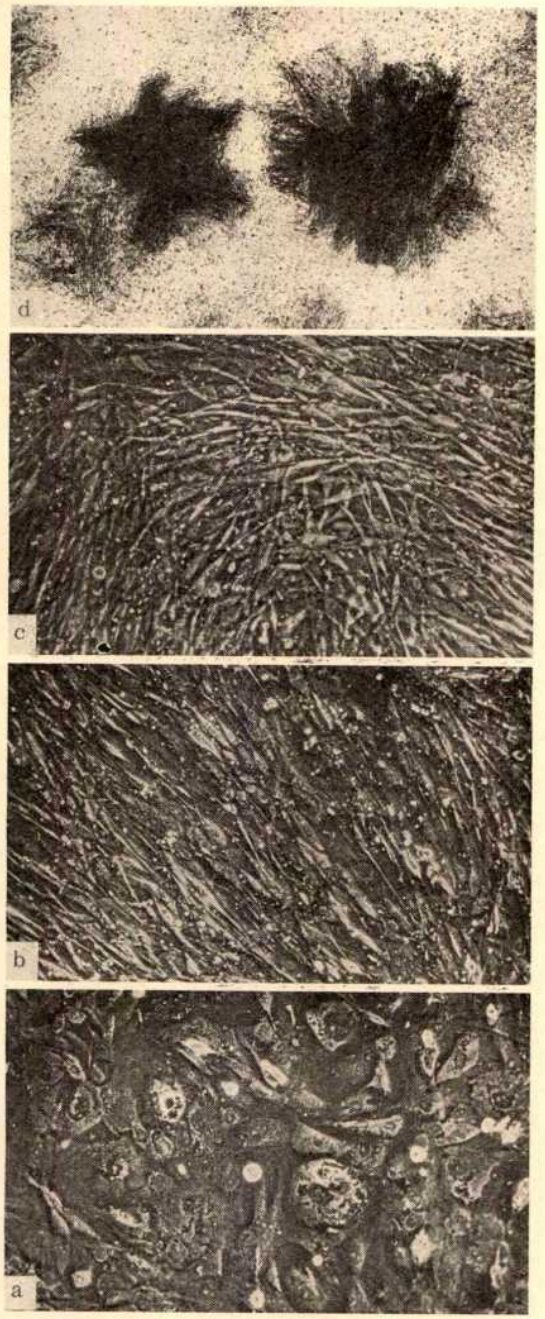

Fig. 1. Photographs of cells derived from hamster embryos. Control mass culture after 28 days (*a*), transformed cells in X-irradiated mass cultures after 25 days (*b*) and 58 days (*c*), and clones of transformed cells from mass culture 59 days after X-irradiation (*d*). *a–c*, Living cultures, phase contrast (× 72). *d*, Fixed and stained 10 days after seeding (× 4)

until at about 40–80 days after seeding there was no further growth and the cultures consisted only of giant cells. In contrast to this degeneration of the controls, in seven experiments a considerable increase in mitoses was found in the irradiated mass cultures at 17–41 days (average = 34 days) after irradiation, and at 23–54 days (average = 44 days) piled-up fusiform cells were observed on the background of flat cells. These piled-up fusiform cells had a selective advantage in the mass cultures, and on continuing passages they outgrew the other cells. The hereditary multi-layering shown by these cells indicated that transformed cells with a decrease in contact inhibition[4] had been obtained in the X-irradiated cultures (Fig. 1). The transformed cells could be continuously cultured *in vitro*, and some of the cell lines have now been cultured for 15 months. Owing to their rapid rate of growth, the cultures with transformed cells were passaged at $2{\cdot}5 \times 10^5$ cells per 50 mm plate at 35–76 days (average = 62 days) after irradiation. An examination of the clones indicated that although the X-ray transformed cells were piled up on one another (Fig. 1), they were less randomly arranged than hamster cells transformed *in vitro* by polyoma or carcinogenic hydrocarbons.

Transformed cells were found in seven out of seven experiments after irradiation of mass cultures of one-day-old primaries and further passaging as already described. Similar results were obtained in three experiments with, and four without, a medium change immediately after irradiation, and with irradiation at either 250 kV or 56 kV.

In addition to their ability for multi-layering and continuous cultivation *in vitro*, the X-ray-transformed cells possessed some other properties that have also been observed in cells transformed by polyoma or carcinogenic hydrocarbons[1,2]. Thus the X-ray-transformed cells made the medium more acid than normal cells, they could not be as easily removed from the surface of the Petri dish by trypsin, and were more resistant to nutritional conditions unfavourable for normal cells and to the toxic action of benzo(*a*)pyrene[2,5]. The transformed cells continued to grow well on passage when cells were maintained without a medium change for 20 days, and when tested after 9 months *in vitro* gave no decreased cloning efficiency after the addition of 25γ per ml. of benzo(*a*)pyrene.

In contrast to cells transformed by other agents[6], the X-ray transformed cells after 1 year in culture did not form colonies in 0·30–0·34 per cent agar when seeded at $1{-}5 \times 10^5$ cells per 50 mm Petri dish and observed for 60 days. Although they did not grow in the agar, cells isolated after 14–40 days in agar again grew well in fluid medium.

The ability for tumour formation *in vivo* was tested by subcutaneous inoculation of $6{\cdot}5 \times 10^6$ cells per animal into 2–6-week-old hamsters. Thirty-five hamsters were inoculated with transformed cells taken at about 2 or 8 months after X-irradiation. In all animals growths were formed after several days at the site of inoculation; these reached a maximum size of about 7–10 mm in diameter, and then regressed beginning at about 10–30 days (average = 20 days) after inoculation. No such growths were formed after inoculation of the same number of cells from normal hamster embryo cultures. Histologically these growths, before regression, were classified as fibrosarcomata. Cells taken from such growths before regression, and transplanted into adult hamsters either without or with a further growth *in vitro* for 1 month, again gave growths after several days that reached a maximum size of about 8–10 mm diameter and then regressed. When animals in which growth had regressed were inoculated a second time with the same transformed cells, the second inoculation gave a smaller growth that regressed more rapidly than after the first inoculation. These results indicate that, although the transformed cells had a better growth potential *in vivo* than normal cells and formed small growths—these did not grow progressively—and that the regression was presumably partly or wholly due to an immune reaction owing to the acquisition of a new antigen by the transformed cells.

After the foregoing results had shown *in vitro* cell transformation by X-irradiation and some properties of the transformed cells, the following experiments were carried out to determine some of the conditions required for the transformation to occur, and the percentage of transformed clones. In these experiments the percentage of transformed clones was determined after 300 r. irradiation of confluent mass cultures, sparse mass cultures, and cells plated for cloning, by scoring the percentage of piled-up transformed clones (Table 1). Irradiation of confluent cultures gave 0·7–0·8 per cent transformed clones in three out of three experiments when the cells were cloned immediately after irradiation, but no trans-

* Confluent primary cultures were irradiated 3–4 days after seeding 1 × 10^7 cells per 100 mm Petri dish, and sparse primary cultures 1 day after seeding the same number of cells. Cells plated for cloning were secondary cultures seeded 1 day before irradiation.

† Plates were fixed and stained 10 days after cells were plated for cloning.

‡ Transformed cells were also obtained in seven out of seven experiments in which sparse cultures were irradiated with either 250 or 56 kV and passaged 3 days later as mass cultures (see text).

§ 10 per cent foetal calf serum. All other experiments with non-foetal calf serum.

formed clones were observed in six experiments when the cells were cloned at 3–5 days after irradiation. In these six experiments further passaging of the cultures resulted in cell degeneration at about 40–60 days in the same way as in the controls. About the same frequency of transformed clones was found, with 250 kV or 56 kV, after irradiating confluent primary cultures cloned immediately after irradiation, sparse primary cultures irradiated 1 day after seeding and cloned 3 days later, and secondary culture cells 1 day after they were plated for cloning. The results suggest that the recovery of transformed cells requires the irradiation either of cells that are actively growing or of those able to do so soon after irradiation. In all experiments the transformed clones were on the average larger than the normal, indicating that they had acquired an increased rate of cell multiplication.

The small decrease in cloning efficiency in the irradiated cultures, and the absence of transformed clones in the controls, indicate that the transformation was directly induced by the X-irradiation and not merely the result of a selection of spontaneously occurring transformed cells. The existence of transformed clones at 10 days after irradiation of cells plated for cloning indicates, as with polyoma and carcinogenic hydrocarbons[2,3,6], that the expression of X-ray induced transformation is a rapid event, presumably within the time required for one cell generation. The frequency of transformation, as with these other two agents[2,3,6], is also much higher than that expected from a randomly occurring mutation. Further experiments are required on the properties after passage of apparently normal-looking clones in the X-irradiated cultures, to show whether there may also be X-ray induced transformation other than the type scored in the present experiments.

The foregoing results showing that transformation can be induced by X-irradiation in culture now make it possible to transform hamster cells *in vitro* by a virus such as polyoma, non-viral chemical carcinogens, and a physical agent such as X-rays. This allows a comparison *in vitro* of the molecular mechanism of transformation by these three different agents. The decrease in contact inhibition in X-ray induced transformation suggests that, as in the case of transformation by polyoma and carcinogenic hydrocarbons, the change of cell surface may be responsible for the change in the regulatory mechanism of the cell[7]. The lack of growth in agar by the X-ray transformed cells could be interpreted to suggest that the change induced in normal cells need not necessarily lead to the same final results with all three agents. In order to analyse possible similarities in mechanism at the molecular level, further investigations are aimed at determining to what extent transformation by X-irradiation and non-viral chemicals can result in a change in the regulation of normal cellular DNA synthesis of the same type as that induced by polyoma[8]. It is of interest in this connexion that, in addition to the chromosome abnormalities and reversible mitotic lag[9] observed after treatment with X-rays, there is also a report of an increase in the number of cells synthesizing DNA soon after X-irradiation[10].

We thank Mrs. Nava Shtacher for her assistance, and Mr. Aaron Yerushalmi and his staff for the X-irradiation. This investigation was supported by a research grant from the National Cancer Institute, U.S. Public Health Service.

HETEROGENEITY OF ENDOTOXIC BACTERIAL LIPOPOLYSACCHARIDES REVEALED BY ION-EXCHANGE COLUMN CHROMATOGRAPHY

By PROF. A. NOWOTNY
Department of Microbiology, Temple University School of Medicine, Philadelphia, Pennsylvania

FREE boundary electrophoretic analysis and sedimentation in the ultracentrifuge or by the density gradient technique are most commonly used for the detection of heterogeneity in bacterial lipopolysaccharides. Gel-diffusion or immunoelectrophoretic patterns also reveal heterogeneity if the antiserum used contains precipitating antibodies against all components of the preparation. These procedures usually do not detect all substances

present in such materials. Paper chromatography or paper electrophoretic analysis, other important methods used in exposing heterogeneity, could not be applied satisfactorily in this laboratory. No sensitive and specific method could be found which would detect lipopolysaccharides on paper sheets. In addition, the very large molecular weight of the components to be separated prevents the application of such procedures.

Column chromatographic procedures were applied in our laboratories using highly porous tertiary amine anion exchangers. Best results were obtained with 'Amberlite *XE* 220' resin (generously supplied by Rohm and Haas Co., Philadelphia, Pennsylvania).

First, an analytical procedure was developed. A column 12 mm in diameter by 180 mm in height was prepared from a slurry of resin in the HCO_3^- form. 5 mg bacterial lipopolysaccharide, dissolved in 0·5 ml. water, and then adjusted to *p*H 7·5, was applied on the column. Approximately 5 ml. of the resin slurry was then carefully layered on top of the sample, followed by elution with 20 ml. water. Thereafter, linear gradient elution was carried out by mixing 100 ml. water and 100 ml. saturated sodium hydrocarbonate in a gradient device, and was continued by mixing 50 ml. saturated sodium hydrocarbonate and 50 ml. 2 N sodium hydroxide, producing a 0–2 N sodium hydroxide gradient.

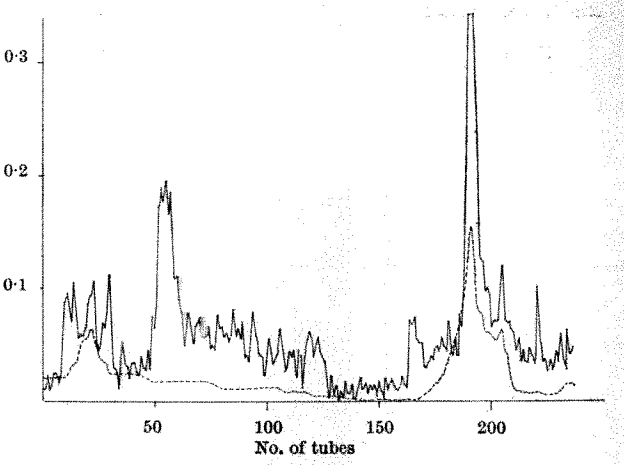

Fig. 3. Preparation obtained from *Serratia marcescens* by the aqueous ether procedure (ref. 2). The dialysed product was precipitated with methanol. LD_{50} is approximately 1,000 μg/mouse. Solid line shows the optical density of the phenol-sulphuric acid carbohydrate determination. Broken line indicates the automatic monitoring of the effluent at 260 mμ

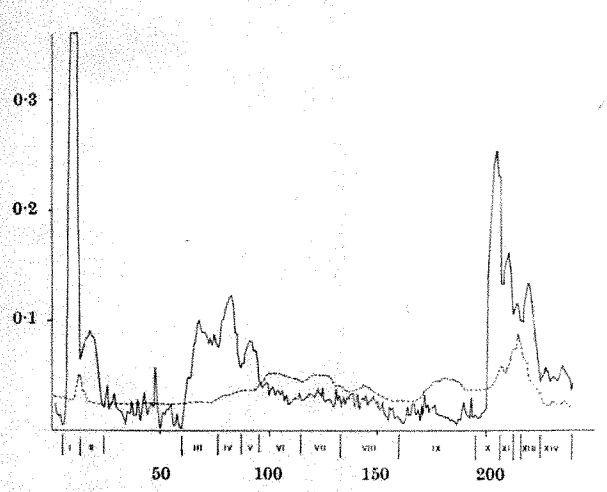

Fig. 1. Lipopolysaccharide isolated from *Serratia marcescens* by cold trichloroacetic acid. Crude product was purified by repeated methanol extraction and sedimentation at *p*H 10 at 5,000*g*. The LD_{50} of the preparation is 420 μg/mouse. Roman numerals designate the isolated fractions obtained by pooling the collected tubes as marked on the baseline of the figure. Solid line shows the phenol-sulphuric acid carbohydrate determination. Broken line indicates automatic monitoring of the effluent at 260 mμ

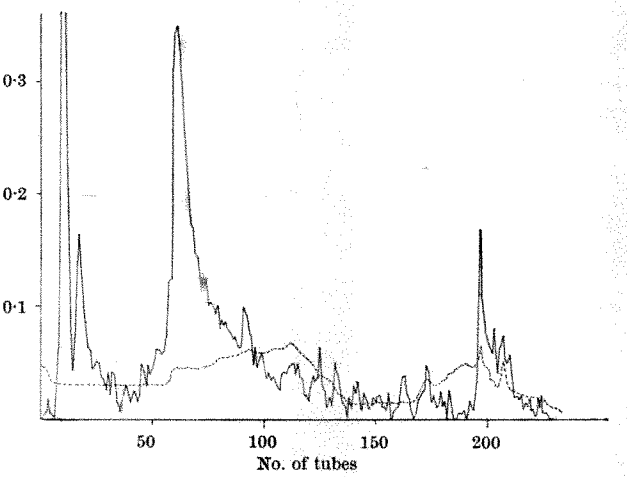

Fig. 4. The same preparation as in Fig. 1, but after detoxification with CH_3OK (ref. 5). The LD_{50} of this preparation is 4,000 μg/mouse. Solid line shows the optical density of the phenol-sulphuric acid carbohydrate determination. Broken line indicates the automatic monitoring of the effluent at 260 mμ

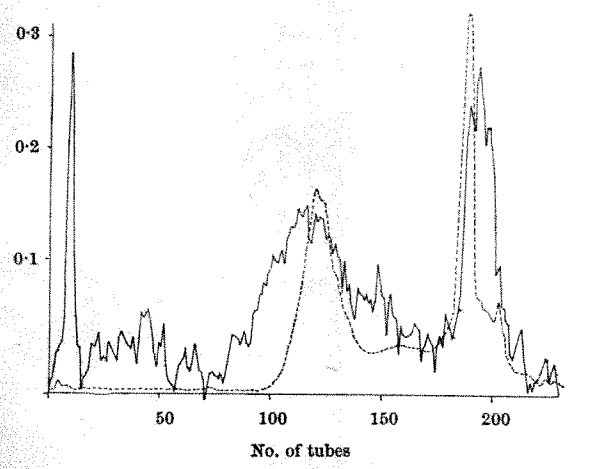

Fig. 2. Lipopolysaccharide isolated from *Serratia marcescens* by the phenol-water method at 68° C (ref. 2). The LD_{50} of this material is 670 μg/mouse. Solid line shows the optical density of the phenol-sulphuric acid carbohydrate determination. Broken line indicates automatic monitoring of the effluent at 260 mμ

Effluent was channelled through a micro-flow cell of a spectrophotometer and the optical density was automatically recorded at 260 mμ. 1·5 ml. samples were collected from the effluent of the flow cell in chromic acid washed and pre-calibrated test-tubes. The collected samples, approximately 250 tubes in each run, were used for the determination of carbohydrate content. 1·5 ml. 5 per cent phenol in water was added to each tube, followed by 7·5 ml. concentrated sulphuric acid (all chemicals were reagent grade). Reagents were dispensed from all-glass, automatic pipettes. After 60 min at room temperature the developed colour was read at 490 mμ in a spectrophotometer supplied with the proper test-tube adapters.

The following figures show the results obtained by analysing different bacterial lipopolysaccharides. Brief descriptions of the preparations are given under each figure.

By using merely two parameters for chemical analysis, that is, ultra-violet monitoring and carbohydrate analysis by the phenol–sulphuric acid procedure, it became obvious that endotoxic lipopolysaccharide preparations consist

* The figures represent the extent of haemorrhagic necrosis. They are the products of two diameters (in centimeters) taken at right angles.

† Lethality was measured in 10-day-old chick embryos by chorioallantoic inoculation. > 200 or > 100 means that none or less than 50 per cent died from this dose.

‡ The intensity of the formed precipitation lines was compared in Ouchterlony agar gel-diffusion. The antiserum used was hyperimmune rabbit O-antiserum.

of several components. Amino-acid, hexosamine, or carboxylic acid analysis of the collected tubes most probably will reveal additional components.

Enlarged operation on a preparative scale for the separation of components of a partially purified and trichloroacetic acid extracted endotoxin from *Serratia marcescens* cells was also elaborated (the supply of freeze-dried *Serratia marcescens* cells was obtained through the courtesy of Merck, Sharp and Dohme Co., Rahway, N.J.). The profiles obtained in preparative scale were similar to those obtained in analytical operations.

The isolated fractions showed similar inhomogeneity in their biological activities. Serological reactivity with the homologous O-antiserum of some of the fractions was investigated by micro-gel diffusion. It could be shown that not all fourteen isolated components formed precipitin lines with O-antiserum. Shwartzman skin tests on rabbits and chick embryos were used to check the toxic effects of the fractions. It was observed that several fractions which exhibited reactivity with O-antiserum were non-reactive in the skin test, and some fractions showed no reactivity in either system. The serological and biological activity of the isolated components is indicated in Table 1. The skin reactivity and lethality of fractions XII–XIV could be destroyed by the strong alkaline eluting agent. The preparations are being subjected to further chemical and biological analysis[4].

During these experiments some major endotoxin fractions manifested an extremely high affinity to anion exchangers. This adhesion to the resin is so strong that it could not be displaced with 2 N ammonia or similar less degradative eluting agents. This remarkable property is a common feature of serologically unrelated but similarly toxic bacterial lipopolysaccharide preparations. As shown in Fig. 4, endotoxoid[5] obtained through chemical detoxification of endotoxin does not show the same affinity to ion exchangers.

An especially noteworthy result of the analysis of the curves shows that phenol–water extraction isolates a very large amount of polysaccharides from the bacteria (see Fig. 2, tubes 80–180), which are almost absent from similarly toxic preparations obtained by trichloroacetic acid. Aqueous ether procedure, in addition to dissolving very large amounts of proteins, also elutes some polysaccharides from the whole cell (see Fig. 3, tubes 15–35 or 160–170), which are not present in appreciable amount in other preparations. The above results support our earlier report, which described that the different extraction methods, applied to the same strain, will yield preparations with chemically different components.

While chromatographic procedures seem to be appropriate tools in isolating endotoxins and a large number of different cell constituents, further elaboration of the method is required. Nevertheless, it should be pointed out that results of previous investigations on the endotoxic lipopolysaccharides should be re-evaluated in the light of the foregoing observations.

This work is continuously supported by the U.S. Public Health Service.

SOME RELATIONSHIPS OF FISHES TO BENTHIC ORGANISMS ON CORAL REEFS

By DR. GERALD J. BAKUS
Allan Hancock Foundation, University of Southern California

RECENTLY, certain tropical fishes have been suspected of influencing the sedentary biota. Stephenson and Searles[1], through experimentation in the field, showed that grazing by reef fishes accounts for the scarcity of intertidal algae at Heron Island, Queensland, Australia. Further work on the feeding habits of tropical fishes was reported by Newman[2], Hiatt and Strasburg[3], Stephenson[4], Bardach[5], Randall[6,7] and Bakus[8].

Perhaps one of the most common characteristics of a number of tropical coral reefs is the lack of exposed organisms (that is, those organisms living on the surface of a coral substratum where they can readily be consumed by predators and grazers), with the major exceptions of corals, organisms with skeletal protection (for example, shelled gastropods and calcareous algae), and organisms that are poisonous, venomous or distasteful to predators or grazers (for example, sea cucumbers). Tropical coral reefs may be unique in that more species are concealed within the reef complex than are usually observed in substrata of non-coral-dominated tropical, temperate, and boreal shallow waters[3,9–13]. Even subtropical coral reefs may harbour a rich and varied infauna[14]. Quantitative data to support this are extremely difficult to obtain. All but about six of approximately forty species of Porifera collected by me at Fanning Island, Line Islands, central equatorial Pacific, were concealed within reefs (only two of the six exposed species were common to abundant) whereas in the San Juan Islands, Washington, it would be safe to state that at least half the species of sponges were exposed in sublittoral waters. From a collection of intertidal sponges made on April 14–15, 1965, at Punta Peñasco, upper Gulf of California, it was found that representatives of ten out of a total of fourteen species were growing exposed. Moreover, numerous

tunicates were also growing exposed on the firm sandstone substratum. Glynn[10] indicated the species composition of *Porites furcata* reefs in Puerto Rico, but quantitative data were not available at that time. Garth concluded that the overwhelming representation in the atoll fauna of the family Xanthidae, which alone constituted 45 per cent of the genera and 56 per cent of the species of Brachyura collected at Eniwetok, is believed in large part due to the protection afforded its smaller members by the branching corals[15].

Fishes appear to be faced with numerous modes of concealment and protection on the part of coral reef invertebrates that serve as a potential food source. For example, there are boring sponges, barnacles, bivalved molluscs, polychaetes and sipunculids. Some organisms are concealed by means of their biological associations (for example, haplocarcinid crabs within protective 'coral galls', numerous invertebrates are inquilines in certain tropical sponges, etc.[12,16,17]). Pearse[16] found that specimens of the loggerhead sponge (*Spheciospongia vesparia* (Lamarck)) collected in the Dry Tortugas, off southern Florida, contained from 6,282 to 17,128 animals (the latter number represented by 22 species). During my investigations on biological associates within Porifera of Washington[18], the most capacious sponges seldom contained more than about a hundred metazoan inquilines represented by several species. Certain marine organisms are poisonous or venomous[19,20]; the incidence of this characteristic may be higher in the tropics, according to Dr. Bruce W. Halstead (personal communication). If one quantifies Southcott's and Halstead and Mitchell's information (in ref. 20) it is found that at least 74 per cent of the coelenterates (out of a total of 34 species) and 68 per cent of the fishes (out of a total of 101 species) of medical importance to man live in tropical and subtropical waters. However, it should be emphasized that many marine organisms are immune to ciguatera- and tetraodon-type toxins that afflict man[21]. With the large number of species of carnivores and omnivores associated with coral reefs one would assume that numerous protective devices (for example, venomous spines) would have evolved over a long geological time period (see following).

Perhaps the most significant method of concealment occurs in the numerous organisms that live in fissures and crevices of corals, on the undersides of coral slabs, and under the bases and among the branches of corals. This concealed fauna includes such a large number of organisms that it may be preferable to consider the animals a more or less ecologically distinct fauna. Gerlach[11] called this the 'phytalfauna'; I prefer to use the term 'cryptofauna', because it is more descriptive. In certain regions of the Indian Ocean the lack of exposed organisms may be in part the result of the destructive annual scouring due to subtidal surge which is caused by the action of winds (monsoon) on shallow waters (Dr. John S. Garth, personal communication). The shortage of organisms was noted earlier by Gardiner (in ref. 22), who stated: "The reefs of the Chagos are in no way peculiar, save in their extraordinary paucity of animal life", but Kohn[23] discovered that on the Isle du Coin organisms such as cup sponges (*Phyllospongia foliascens*) and cone snails (*Conus*) were abundant on the exposed seaward reef flat. He found that the density of *Conus* on a reef at Peros Nahos was considerably higher than in most populations he studied in Hawaii (Dr. Alan J. Kohn, personal communication).

There are very few reports of direct observations on feeding behaviour of fishes in extra-tropical latitudes. Information from Elegvad[24] in Denmark, Suyehiro[25] in Japan, and Limbaugh[26] in southern California suggests that fish predation and fish-grazing on shallow-water benthic invertebrates are widespread. However, direct observations made by Limbaugh[26] during a 5½ year investigation on feeding fishes in southern California suggest to me that the intensity of fish-rasping is considerably less in temperate latitudes than in the tropics. This conclusion appears to be supported by Neushul and Haxo[27]. Although they report the effects of grazing on *Macrocystis* and mention three species of kelp-eating fishes, there seem to be no direct observations on intense fish-rasping activities at La Jolla, California. In contrast, the effects of fish-grazing and rasping on algae, sponges and didemnid tunicates at Fanning Island, central Pacific, during July and August 1963[8] are presented in Figs. 1 and 2.

The previous statements lead to the suggestion that there has been an accentuation towards protective mechanisms and habits in certain coral reef invertebrates and that this may be in part an evolutionary response to the predatory and grazing habits of the diverse tropical reef fishes over a long geological period. Scleractinian reefs have persisted since the Mesozoic[28,29], and coral reef fishes apparently have had a long geological history[30]. That the influence on invertebrates by fishes perhaps is significant may be inferred from the numbers of genera and species of tropical fishes that are grazers and raspers

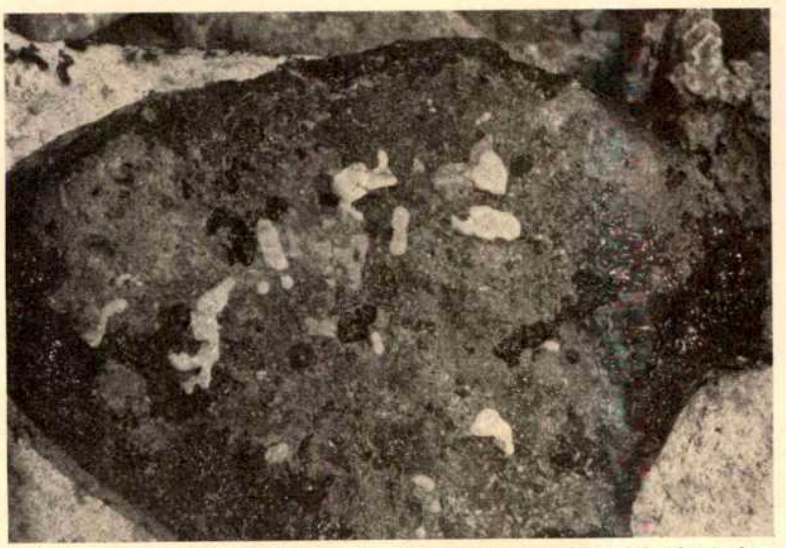

Fig. 1. View of the underside of a coral slab; the slab was collected from 3 ft. of water in English Harbor Channel, Fanning Island, Line Islands, central Pacific. Note the dark sponges, white didemnid tunicates and peripheral brown algae (see ref. 8)

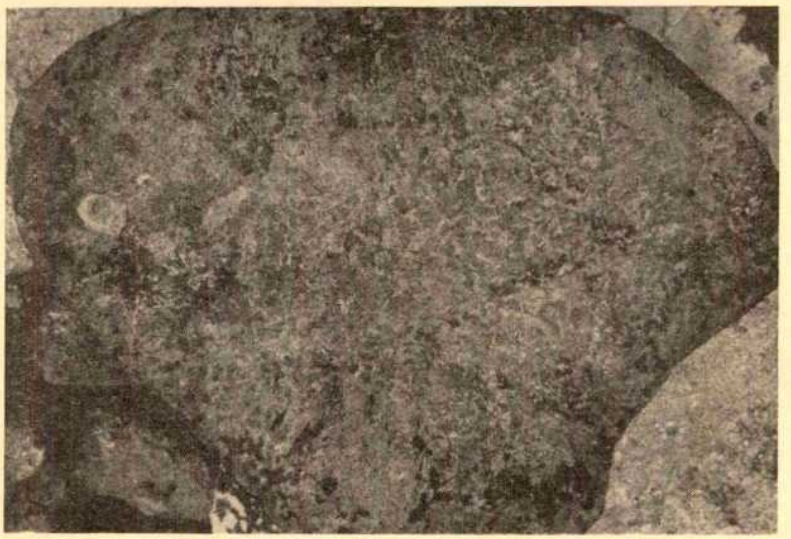

Fig. 2. View of the underside of the coral slab shown in Fig. 1, after placing it in 2 ft. of water in English Harbor Channel with the underside exposed to rasping fishes for only 1 h. Note the numerous tooth marks (see ref. 8)

and the high overall percentage of carnivores[3,30–34] (see also following refs.).

It appears that the standing crop of exposed foliaceous shallow-water marine algae in the tropics is often considerably less than that of similar benthic algae at comparable depths in temperate and boreal latitudes[28,35–37]. This may be true of Fanning Island and perhaps Christmas Island, central equatorial Pacific, but much additional work is needed to verify this general impression. Odum, McConnell and Abbott[38] and McFarland and Prescott[39] indicated that the standing crops of a *Macrocystis* bed, coral reef, and littoral algal community at Woods Hole, Massachusetts, based on the number of grams of chlorophyll *A* per m² of surface, are of the same order of magnitude, but it should be emphasized that much of the chlorophyll of coral reef communities is buried within the living and dead coral substratum. There is a difference in the composition of the algae. There is a predominance of red algae (especially calcareous algae) and a reduction in brown algae in the tropics when compared with coastal algae at higher latitudes[22,28,35,36,40–43]. In fact, certain reefs may consist almost entirely of calcareous algae[12,22,44]. Certain reefs in the Caribbean and in the Cocos-Keeling Islands are reportedly exceptions since reef-building algae of the *Porolithon*-type are poorly represented in comparison with that of Pacific reefs[45,46]. Odum and Odum[47] found *Porolithon* only in small patches beneath the other algae or down in crevices on Japtan reef, Eniwetok, but it should be noted that zonation of this inter-island reef is very different from zonation on other island reefs described in the literature. It is of interest to note that Smith[48] reported twenty-seven species of Corallinaceae from the Monterey Peninsula, California, whereas Taylor[35] listed only thirteen species of Corallinaceae from Bikini and Rongerik atolls, Marshall Islands. This emphasizes the point that only a small number of algal species (*Porolithon*-type) play a major role as cementing agents on tropical coral reefs.

There have been reports of low species diversity in tropical Pacific benthic reef algae. Taylor[35] attributed the lack of species diversity in places such as Bikini and Rongerik atolls to intense isolation (154 species of benthic marine algae were reported from the two atolls), but Dawson[49] reported some 220 species of benthic algae from Eniwetok Atoll, Marshall Islands (12° N. Lat.). In contrast, Smith[48] described 490 species of benthic marine algae from the Monterey Peninsula, California (36° N. Lat.). Wilse[50] indicated that there are fewer species of benthic marine algae in the Arctic than in cool temperate latitudes. It would appear that where algae may be less available or less desirable as fish food (that is, tropical calcareous algae) fishes may have specialized in the direction of predation and grazing on invertebrates. Table 1 gives comparative data on the feeding habits of marine fishes living at different latitudes. There is general agreement in that tropical coral reef fishes consist of roughly 25 per cent herbivores and 65 per cent carnivores. I had thought that the percentage of carnivorous-omnivorous fishes in waters of tropical coral reefs was greater than that of fishes in temperate or boreal shallow waters. The data in Table 1 suggest the opposite, but it should be emphasized that so far as is known no truly comprehensive investigations have been published on the feeding habits of nearshore fishes in temperate and boreal latitudes and even the information offered here is unsuitable for an adequate comparison.

If the assumption is made that the percentages of carnivorous-omnivorous nearshore fishes are approximately the same throughout the world it is still likely that the effects of predatory and grazing fishes on benthic invertebrates are more marked in tropical reefs. Le Danois[30] listed forty-one families of reef fishes; seven families are grazers. Table 2 indicates the diversity of nearshore fishes in different latitudes. Although the number of fishes given for southern California may appear great, this is somewhat misleading in that rock-fishes (Family Scorpaenidae) are atypical since they are represented by about forty-five species. Moreover, the total number includes peripheral representatives from cool temperate and sub-tropical waters. Therefore, not only are there a large number of species of carnivorous-omnivorous fishes in waters of tropical reefs, but Randall[7] indicated that the Scaridae (rasping parrot fishes) is the largest family by weight at St. John's reef, Virgin Islands, and that this dominance may be the rule throughout the West Indies. This may also be characteristic of the Indo-Pacific region (Dr. Philip Helfrich, personal communication).

The question now arises: Are there major exceptions in regard to the lack of exposed fleshy algae and animals on tropical coral reefs? Two large equatorial regions that have a diverse and moderately abundant algal flora are south-east Asia[12,36,51] and the Caribbean[28,52,53]. However, neither certain Vietnamese nor Caribbean reefs appear to harbour a standing crop of exposed fleshy algae comparable to that of coastal regions in temperate and boreal latitudes (Dr. E. Yale Dawson, personal communication) although they may approach that of the Arctic. It should

Table 1. FEEDING HABITS OF NEARSHORE MARINE FISHES IN DIFFERENT LATITUDES

Investigator	Region	Method of estimation	Herbivores (per cent)	Omnivores (per cent)	Carnivores (per cent)
Randall (ref. 7)	St. John, Virgin Islands	Percentage by weight from natural reefs	24	16	60
Hiatt and Strasburg (ref. 3)	Marshall Islands	Percentage by No. of species, 212 species considered	25	8	67
Bardach (ref. 60)	Bermuda	Percentage by weight	—	32 (mostly herbivorous)	68
Al-Hussaini (ref. 61)	Ghardaqa, Red Sea	Percentage by No. of species, 56 species considered	23	23	54
* Suyehiro (ref. 25)	Japan	Percentage by No. of species, 85 species considered	5?	21?	74?
† Limbaugh (ref. 26)	Southern California	Percentage by No. of species, 49 species considered	0?	6?	94?

* Certain species were not collected from nearshore waters.

† Food habits were incompletely investigated, especially in regard to algae consumed.

Incidental hervibores and omnivores, detritus and plankton feeders, and scavengers are excluded. Percentages are approximate values. Question marks are placed after the data taken from Suyehiro and Limbaugh, because the investigations were incomplete.

Table 2. DIVERSITY OF MARINE FISHES IN DIFFERENT LATITUDES

* The total No. of species of fishes in the Fiji Islands is estimated to be roughly twice this figure.

† The total No. of species of fishes in the Marshall and in the Hawaiian Islands is estimated to be about 600 each.

be emphasized that the gross primary productivity of coral reefs is very high compared with other habitats on the Earth's surface and that a low standing crop is not indicative of the level of primary production[54]. However, Odum and Odum[47] indicated that a large amount of green plant material on Japtan reef, Eniwetok, is sub-surface. This suggests that much energy from primary producers may be available only to those fishes that are raspers or to carnivores and omnivores that consume animals containing zooxanthellae. However, Hairston, Smith and Slobodkin[55] report that herbivores are seldom food-limited, at least in terrestrial environments. Hayne and Ball[56], who worked with freshwater fishes in southern Michigan, found that in the presence of fish, the standing crop of benthic fish food was depressed and the rate of production increased. Whether or not this phenomenon is characteristic of tropical reefs is unknown. The lack of exposed fleshy algae and certain animals coupled with high primary production on certain tropical coral reefs may be associated with low nutrient concentrations and rapid local recycling of available nutrients. If the coastal Caribbean and south-east Asian regions are compared it is evident that they share the following characteristics: (*a*) They have partially land-locked waters and (*b*) they receive an appreciable quantity of nutrients during the year from land run-off[57]. This nutrient reservoir could support a greater standing crop of productive fleshy algae and presumably make more plant food available for animals ('island' or 'land effect'). Odum, McConnell and Abbott[58] found a strong relationship between nutrient concentration and the standing crop of benthic primary producers in shallow-water communities at different latitudes. Dr. Alan J. Kohn (personal communication) observed that a large proportion of the area of some reef flats in the Seychelles and Ponape (high islands with considerably more land run-off than that of atolls) is covered with plants (for example, *Cymodocea* in the Seychelles). In conclusion, the predatory, grazing and rasping behaviour of tropical coral reef fishes may be reflected in the protective mechanisms and habits of certain invertebrates associated with these reefs (for example, certain sponges, didemnid tunicates, brachyuran crabs, etc.).

The information offered here immediately evokes many questions, some of which may be answered in part during the next decade:

(*A*) Have the feeding habits of carnivorous, grazing and rasping tropical fishes led to the evolution of protective behaviour in certain reef invertebrates? If so, in which ways?

(*B*) Is the intensity of fish grazing at Fanning Island related to the apparent low diversity and low standing crop of certain invertebrate taxa (for example, bivalved molluscs, thoracican barnacles) coupled with an apparent diversity and abundance of fishes (see refs. 8 and 58)?

(*C*) What are the factors that restrict the standing crop of exposed fleshy benthic algae in shallow waters of the tropics?

(*D*) Have the encrusting coralline red algae (for example, *Porolithon*) evolved their habitus in part as a response to the grazing and rasping habits of reef fishes?

(*E*) How significant are algae (for example, *Ostreobium*) living within coral in regard to the food requirements of certain rasping fishes (for example, parrot-fishes) that consume them?

(*F*) Which factors have led certain tropical fishes to specialize in grazing and rasping behaviour in order to exploit the sessile benthic biota as a food source?

These and numerous other problems await solution.

Dr. E. Yale Dawson (personal communication), while in the Galapagos Islands during early February 1964, observed intense grazing on shallow-water fleshy benthic

algae by crabs, fishes and marine iguanas. Mr. Andrew A. Pilmanis investigated the grazing habits of shallow-water fishes in the region of Los Angeles, California, during the first half of 1964 and found no evidence of intense rasping such as that described for certain tropical reefs. Squires[59] presented evidence that certain fishes may feed on corals at depths of from 35 fm to 90 fm off Mayor Island, New Zealand. These observations again suggest that fish-grazing may influence marine invertebrates more than formerly thought.

There is little reason to suspect that fish predation and fish-grazing have been solely responsible for what may prove to be rather widespread protective mechanisms and habits in certain coral reef invertebrates. Larval settling behaviour and the possible effects of surge on the survival of reef invertebrates must also be considered. Experiments I performed at Fanning Island indicate that sedimentation (that is, specifically siltation) is another environmental factor of major significance in regard to the distribution and survival of certain sponges and tunicates[8]. Invertebrate predators (for example, *Conus*) may be found to exert a strong influence on the habits of certain of their invertebrate prey on coral reefs, but very little seems to be known about this (Dr. Alan J. Kohn, personal communication). Further work is needed to determine how significant is each of these factors in regard to the biology of reef invertebrates.

I thank the British Government for permission to investigate the marine biota at Fanning Island, the U.S. National Science and Cocos Foundations and Dr. Robert W. Hiatt and the University of Hawaii for jointly sponsoring the Fanning Island Expedition, Drs. Stephen Wainwright, Charles Stasek, William Newman, Mr. Francois Mautin and many others for their help during the Fanning Island Expedition, Mr. Robert Lavenberg for compiling data on the fishes of southern California and Drs. John S. Garth, E. Yale Dawson, Philip Helfrich, and Alan J. Kohn for reading the manuscript. This work was supported by a research grant from the U.S. National Science Foundation.

Addendum. An exception to the statement that benthic red algae predominate in tropical waters is offered by Knox[69], who indicated that the majority of genera and species of benthic algae in southern Australia and New Zealand are Rhodophyta. Andriashev[70] reported that there are about seventeen species of fishes in the upper 100 metres of eastern Antarctic waters. The greatest diversity of fishes (thirty-one species) apparently occurs at a depth of about 400 metres.

Randall[71] found that bands of bare sand separating reefs and beds of sea grasses (*Thalassia* and *Cymodocea*) in the Caribbean appear to be the result of heavy grazing by parrot fishes (*Scarus* and *Sparisoma*) and surgeonfishes (*Acanthurus*). Talbot[72] reported that the fishes of Tutia Reef, Tanganyika, East Africa, consist of about 20 per cent herbivores and 80 per cent carnivores by weight and 16 per cent herbivores and 84 per cent carnivores by number of species. Approximately 20 per cent of the fishes (by weight) are coral feeders and 49 per cent consume invertebrates. These data are based on 96 species of fishes, excluding plankton feeders. The category 'herbivores' includes a few facultative omnivores. Stasek[73] concluded that behavioural responses of the giant bivalve *Tridacna*, such as the aiming of the excurrent siphon and spurting of water, are probably defensive adaptations to the presence of grazing fishes.

LETTERS TO THE EDITOR

RADIO ASTRONOMY

Magnetic Field within some Quasi-stellar Radio Sources

THE origin of the energy in the powerful radio sources presents one of the major problems in present-day astrophysics. It is generally accepted that the radio emission arises from the synchrotron mechanism, and Burbidge and Burbidge[1] have shown that the energy requirements are at a minimum when there is approximate equipartition between the magnetic and particle energies.

Making reasonable assumptions about the upper and lower limits in the energy spectrum of the relativistic electrons responsible for the emission, the total energy may then be computed if the volume of the source is known. In the case of the compact sources associated with quasi-stellar objects the energy needed to produce a source of given radio luminosity is considerably less than that required for the more extensive radio galaxies if equipartition occurs in both types of sources; the radio emission in the latter case will, however, persist for a longer period.

In order to establish the energy requirements it is, therefore, essential to decide whether or not the particle and magnetic field energy approximate to the condition of equipartition, for if they do not the total energy must be correspondingly increased.

In a recent paper, Hornby and Williams[2] have shown that for quasi-stellar radio sources of small angular size it is often possible to establish an upper limit for the magnetic field within the source. Many of these sources show a cut-off in the flux density at low frequencies. The most probable cause of this cut-off is self-absorption by the synchrotron mechanism itself, and in this case the magnetic field B can be related directly to the observed angular diameter θ. If the number of relativistic electrons per unit volume, with energies lying between E and $E+dE$, is represented by $N(E)\,dE = \text{const.}\ E^{-\gamma}\,dE$, it can be shown that:

$$B^{-\frac{1}{2}}\theta^2 = \frac{S_h}{\nu_h^{(1-\gamma)/2}} \left\{\frac{e}{2\pi m_0^3}\right\}^{\frac{1}{2}} \frac{(1+z)^{\frac{1}{2}}}{\nu_m^{(\gamma+4)/2}}\, G(\gamma)$$

where S_h is the observed flux density of the source at frequency ν_h higher than the frequency at which the cut-off begins; ν_m is the frequency at which the observed flux density is a maximum; z is the red-shift of the source; and $G(\gamma)$ is a numerical factor derived from Le Roux[3] and is approximately equal to 5 for $1{\cdot}6 < \gamma < 3$ (using MKS units throughout, and measuring θ in radians).

ν_m can be determined directly from the observations of the spectrum so that the measured angular diameter, θ, or an upper limit to θ, allows an upper limit to B to be found.

It is, of course, possible that some other mechanism may be responsible for the observed low-frequency cut-off in the spectrum; in these circumstances the frequency at which synchrotron self-absorption would occur must be even smaller than the value of ν_m observed. The calculated upper limit for B is, therefore, still valid. A similar argument can be used for sources which show no sign of a cut-off over the range of frequencies observed.

It is important, however, to consider the possibility that in sources such as 3C 273 a compact component showing strong self-absorption even at high frequencies may be associated with a more extensive component with a normal spectrum. In such circumstances information on the angular size obtained at high frequencies where the compact source may contribute most of the total intensity might erroneously be associated with a normal low-frequency spectrum associated with the more extensive component. Ideally, the angular structure should be determined at comparatively low frequencies.

In the present communication, six sources are considered for which interferometric (Int) measurements at long baselines have revealed values of $\theta < 0{\cdot}6$ sec arc. The measurements were made at 408 Mc/s with a baseline of 180,000 wave-lengths[4] and at 1,420 Mc/s with a baseline of 600,000 wave-lengths[5]. Evidence of the angular diameter at low frequencies was obtained by observing interplanetary scintillations (IPS) at a frequency of 178 Mc/s[6], and from such evidence the source 3C 208 was also included for consideration. The value of the angular diameter actually used in the calculation is indicated by an asterisk. The spectra of these sources were also determined and the value or limiting value of ν_m measured. These values together with the derived values of B are listed in Table 1.

On the assumption that the observed red-shifts are cosmological, the distance of each source can be determined and hence the volume. From this the value of the magnetic field, $B_{eq.}$, which would correspond to equipartition between magnetic field and particle energy may be computed. The values of $B_{eq.}$ are given in Table 1. If it is supposed that the total particle energy is 100 times that of the electrons[7] then the lower limits of $B_{eq.}$ should be increased by a factor of 3·7; the increased values are given in brackets.

It may be seen that for three of the sources listed (3C 48, 286 and 287) the derived upper limit of B is considerably lower than $B_{eq.}$, and for these sources the total energy of the relativistic electrons is far greater than the energy of the magnetic field. The minimum values of the total energy, U, needed for each source are included in Table 1; in brackets are given the corresponding values of the total energy if it is assumed that the total particle energy is 100 times that of the electrons. Finally, for comparison, the minimum total energies for equipartition are listed.

Table 1

3C	z	θ_{178} (IPS)	θ_{408} (Int)	θ_{1420} (Int)	ν_m (Mc/s)	B (gauss)	B_{eq} (gauss)	U (erg)	U_{eq} (erg)
48	0·37	$<0{\cdot}7''$	$0{\cdot}4'' \times *$ $\leqslant 0{\cdot}3''$	—	70	$\leqslant 1{\cdot}8\ 10^{-4}$	$\geqslant 4{\cdot}5\ 10^{-4}$ $(1{\cdot}7\ 10^{-3})$	$\geqslant 1{\cdot}2\ 10^{57}$ $(1{\cdot}1\ 10^{59})$	$\leqslant 6{\cdot}10^{56}$ $(8\ 10^{57})$
119	—	$<0{\cdot}5''$	—	$0{\cdot}16'' \times *$ $\leqslant 0{\cdot}1''$	70	$\leqslant 4\ 10^{-5}$	—	—	—
138	—	$\leqslant 0{\cdot}15''*$	$\sim 0{\cdot}5''$	—	80	$\leqslant 1{\cdot}7\ 10^{-4}$	—	—	—
147	0·55	$<0{\cdot}7''$	$0{\cdot}6'' \times *$ $\leqslant 0{\cdot}4''$	—	105	$\leqslant 5{\cdot}10^{-3}$	$\geqslant 3{\cdot}6\ 10^{-4}$ $(1{\cdot}3\ 10^{-3})$	—	$\leqslant 2{\cdot}0\ 10^{57}$ $(2{\cdot}8\ 10^{58})$
208	1·11	$\sim 1''*$	$>4''$	—	$\leqslant 30$	$\leqslant 1{\cdot}1\ 10^{-4}$	$\geqslant 1{\cdot}8\ 10^{-4}$ $(6{\cdot}7\ 10^{-4})$	$\geqslant 1{\cdot}1\ 10^{58}$ $(1{\cdot}0\ 10^{60})$	$\sim 9\ 0\ 10^{57}$ $(1{\cdot}3\ 10^{59})$
286	0·85	$<1''$	$\leqslant 0{\cdot}4''$	$0{\cdot}12'' \times *$ $\leqslant 0{\cdot}1''$	$\leqslant 80$	$\leqslant 1{\cdot}0\ 10^{-5}$	$\geqslant 6{\cdot}0\ 10^{-4}$ $(2{\cdot}2\ 10^{-3})$	$\geqslant 2{\cdot}5\ 10^{59}$ $(2{\cdot}5\ 10^{61})$	$\leqslant 1{\cdot}0\ 10^{57}$ $(1{\cdot}4\ 10^{58})$
287	1·06	$<1''$	$\leqslant 0{\cdot}4''$	$0{\cdot}14'' \times *$ $\leqslant 0{\cdot}1''$	$\leqslant 80$	$\leqslant 5\ 10^{-5}$	$\geqslant 6{\cdot}0\ 10^{-4}$ $(2{\cdot}2\ 10^{-3})$	$\geqslant 1{\cdot}7\ 10^{58}$ $(1{\cdot}7\ 10^{60})$	$\leqslant 8\ 0\ 10^{56}$ $(1{\cdot}1\ 10^{58})$

The most striking of these sources is 3C 286, and for this source especially further evidence is needed to determine the angular diameter at low frequencies and so eliminate the possibility of a structure similar to 3C 273. Some evidence has been obtained by observations of interplanetary scintillations which show that at 178 Mc/s the source has a diameter which is certainly less than 1 sec arc[6].

The uncertainty in the value of ν_m for 3C 287 is due to confusion by the neighbouring source 4C 25·44; ν_m could indeed be considerably less than 80 Mc/s, in which case the magnetic field would be even weaker and the total energy even greater than the values quoted.

These results suggest that very compact sources contain an intense flux of relativistic electrons in a comparatively weak magnetic field; the total energies involved are then comparable with those of the extensive radio galaxies. The magnetic field is of course too weak to contain the electrons. The association between quasi-stellar sources and radio galaxies has already been suggested by the observations of 3C 47 (ref. 8), which showed that a source with large total energy requirements was associated with a compact optical object showing strong ultra-violet excess.

I thank Prof. M. Ryle for his advice.

GEOPHYSICS

Breakdown of the Biennial Variation of Ozone and of Lower Stratospheric Temperatures in the Middle Latitudes of the Southern Hemisphere

A BIENNIAL variation in atmospheric ozone has recently been reported at Australian, Indian, Japanese and Italian stations[1,2]. This phenomenon was tentatively connected with the biennial variation of zonal winds in the stratosphere of low latitudes[2,3], which was elucidated by several other workers[4–6]. Evidence was also put forward to show that there existed at Laverton (37·9° S., 144 8° E.) and Macquarie Island (54·5° S., 159·0° E.) in middle latitudes of the southern hemisphere a biennial variation of temperature at 60 mbar with higher temperatures in even years when the spring level of ozone was high[3].

An examination of the recent ozone data at Brisbane (27·5° S., 153·0° E.), Aspendale (38·0° S., 145·1° E.) and Macquarie Island (Fig. 1) brings out the following: (1) since the beginning of the ozone observations at Aspendale and Brisbane in 1955 and 1956 respectively up to 1963, the spring maximum (July–October) was higher in even years. However, in 1964 the level of ozone in July–October was more or less the same as in 1963 and 1965. (2) At Macquarie Island the level of ozone was slightly higher in 1958 than in 1957 and also was higher in 1964 than in 1963. But in 1965 the level seems to be the same as in 1964.

By taking 12-month running means the breakdown of the biennial cycle is clearly shown after the years 1962–1963 (Fig. 2). Although the total ozone amount in 1964 was not higher than in 1963 the ozone content between 24–36 km as calculated from 'umkehr' observations made at Aspendale continued to be in agreement with the biennial oscillation with the ozone in 24–36 km greater in 1964 than in 1963 (ref. 7).

It is interesting to note that the earliest ozone observations made with the old type of Dobson's spectrograph in the years 1929–32 at Mt. Stromlo, Canberra (35·3° S., 149·0° E.), also showed no biennial variation in the spring level of ozone of the type observed from 1955 to 1965. 1929–32 was a period of low sunspot activity.

Fig. 3 gives the mean monthly temperatures at 100 mbar at Laverton, Hobart (42·8° S., 147·5° E), and Macquarie Island from 1951 to 1964. These data were kindly supplied by the Commonwealth Bureau of Meteorology, Melbourne. The following points are interesting: (1) the level of maximum temperature in July–October at Laverton and Hobart seems to vary in alternate years from 1954 to 1962 with higher temperatures in even years. However, in the years preceding 1954 and after 1962 there is no such oscillation. (2) At Macquarie Island the level of minimum temperature in June–September seems to oscillate with a 2-year cycle from 1954 to 1963, whereas the cycle is somewhat uncertain prior to 1954.

These facts are brought out more clearly in Fig. 4, which gives the average 100 mbar temperature for the months July, August and September (Fig. 4). As can be seen from the diagram, between 1954 and 1962 there existed a biennial oscillation in the 100 mbar temperatures at Laverton, Hobart and Macquarie Island. The maximum temperatures at Laverton and Hobart and the minimum temperatures at Macquarie Island were higher in even years. Prior to 1954 and after 1963 there appears to be no oscillation (excepting Macquarie Island where the oscillation continued even after 1963). It should be remembered that the years 1954 and 1963 are years of low solar activity. It can also be seen that there is a suggestion of a gradual cooling at 100 mbar from 1955 to 1961.

Almost all the work done on the biennial oscillation of zonal winds over low latitudes and similar temperature and ozone oscillations is based on observations made since 1953.

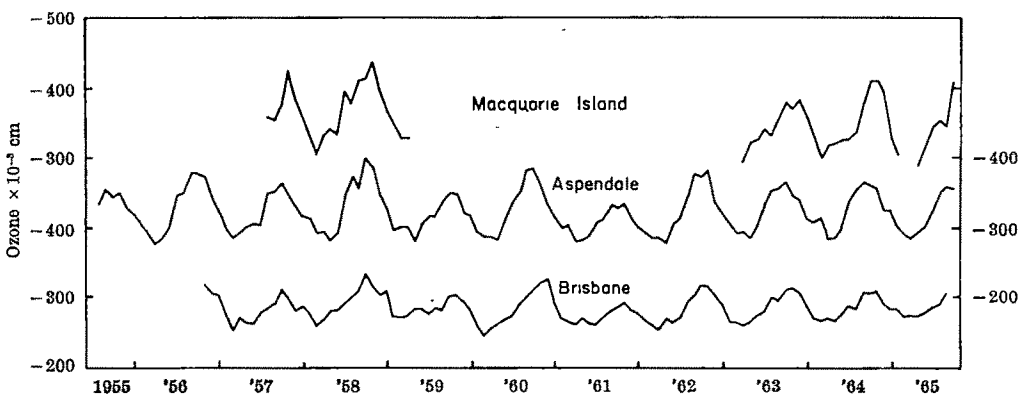

Fig. 1. Monthly mean ozone values at Brisbane, Aspendale and Macquarie Island

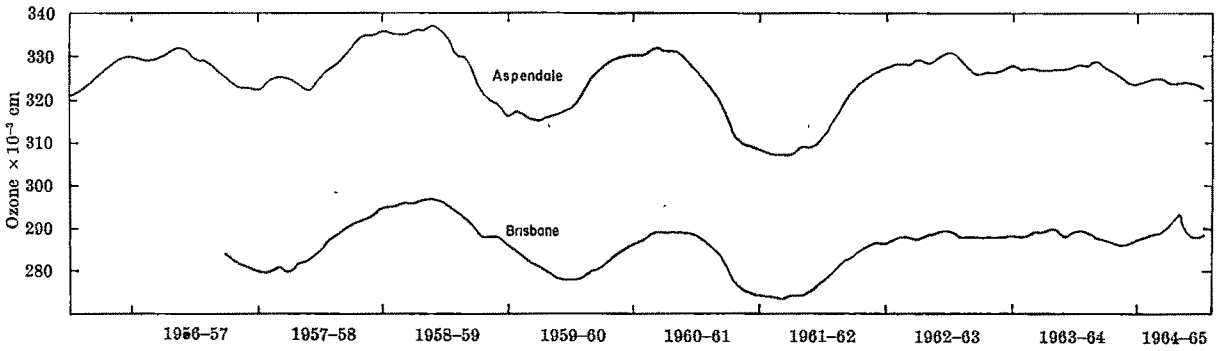

Fig. 2. Running 12-month means of ozone for Aspendale and Brisbane

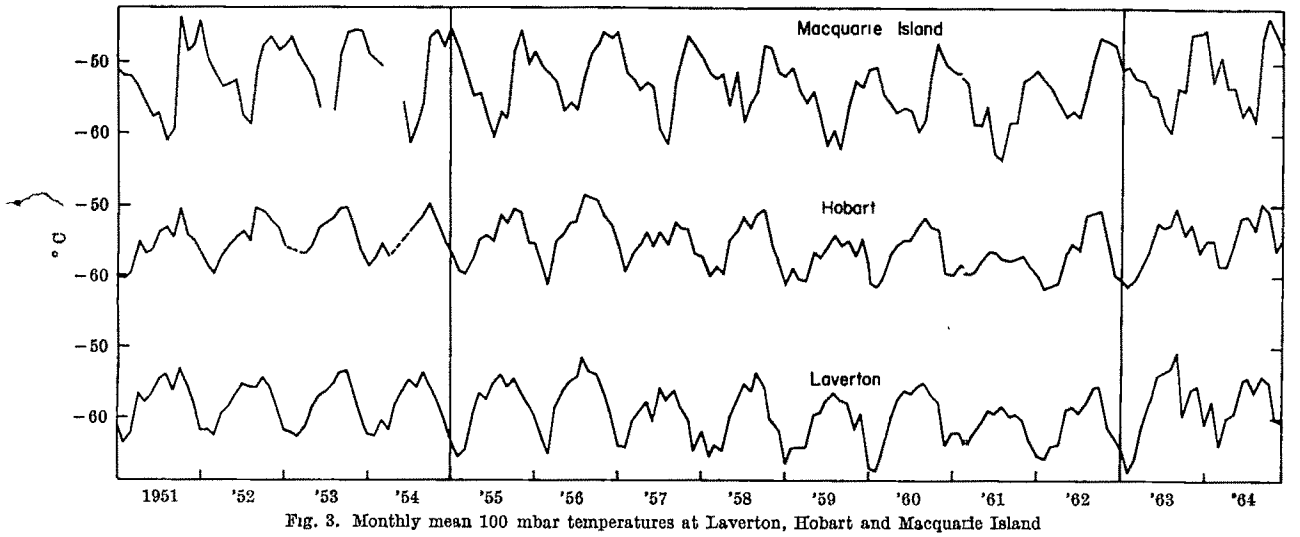

Fig. 3. Monthly mean 100 mbar temperatures at Laverton, Hobart and Macquarie Island

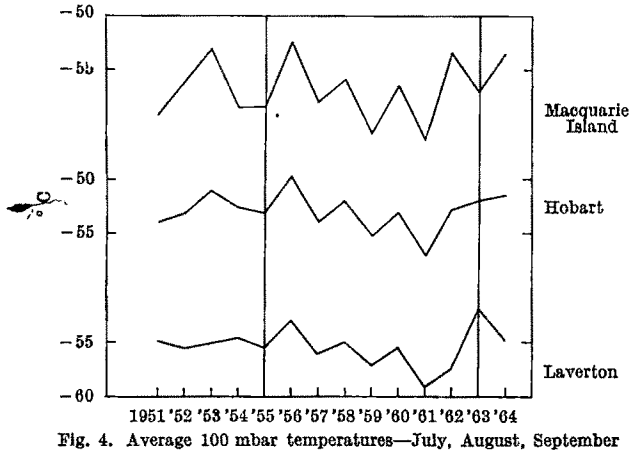

Fig. 4. Average 100 mbar temperatures—July, August, September

The above analysis tends to show that a biennial oscillation existed between 1954 and 1963 and not prior to 1954 and after 1963. It is interesting that the cycle should have been observed between periods of low sunspot activity, though with such a limited amount of observations any suggested connexion can only be tentative. The other possible explanation that the period of the cycle is not exactly 24 months, with its consequent disappearance after some time, gains little support from the fact that the occurrence of the breakdown is rather abrupt. It is, however, possible that the process responsible for the biennial oscillation could have descended to lower levels during 1954–63 to effect a temperature oscillation at the 100-mbar level. The observations that ozone above 24 km was higher in 1964 than in 1963, but not the total ozone, and that there was a breakdown of the cycle in 100-mbar temperature in 1963 imply that the influence of the process did not extend down to lower levels after 1963.

PHYSICS

Application of the Principle of Extremum to a Submerged Discharge

IN hydraulic problems the use of the principle of extremum has produced results in good agreement with the results of experiments for some cases in which streamlines are nearly rectilinear and the flow passes from subcritical to supercritical flow. This type of flow occurs in hydraulics when water flows over a broad-crested weir, in a drop structure, or in a channel with side constriction. Flow over a sharp-edged weir, however, or over a curved spillway crest, involves curved streamlines which have the effect of increasing the flow considerably. It has been shown that the principle of extremum can be applied to curved streamlines[1] and this method has also been used for the calculation of discharge over a sharp-edged weir, giving values which agree very well with experiment[2]. In all the foregoing cases the principle of extremum has been applied to free surface flow, in which the boundary

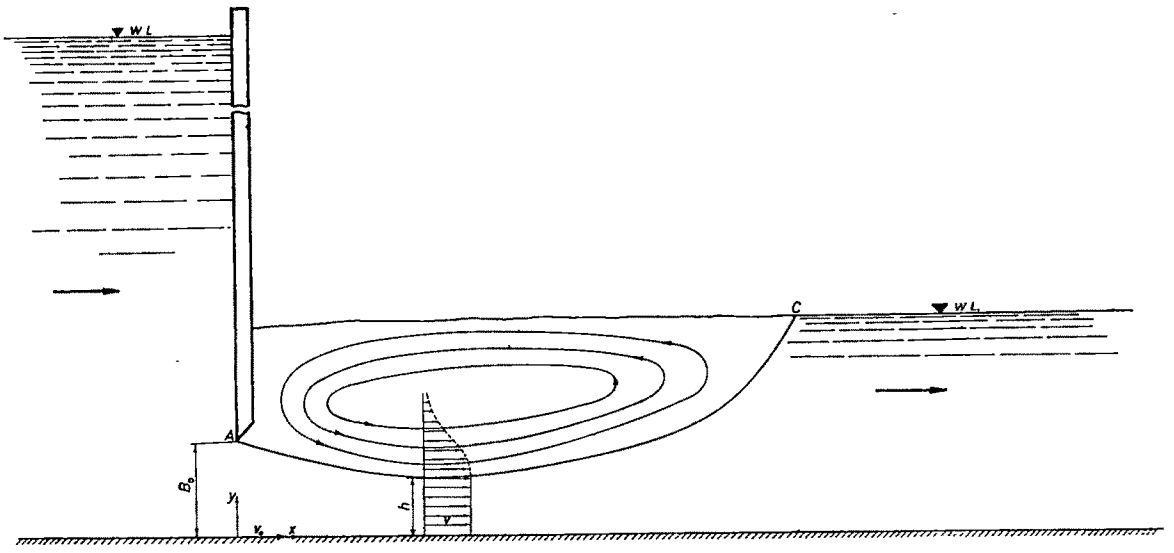

Fig. 1. Jet from a sluice gate with velocity distribution at critical section

streamlines are free to adjust for the condition of a minimum of energy head. However, the principle can also be used for the determination of the contraction coefficient when the boundary streamline is submerged, as in the case of submerged jet issuing from a sluice gate; in this case there is a separation-line (defined later) which also adjusts to a minimum of energy head.

It is not necessary to know the exact velocity distribution in a section for the application of the principle of extremum. The true distribution will be determined by its use when the velocity is given at known boundaries. The two following conditions can be derived from the principle of extremum for its application to hydraulics: (1) Discharge through a critical section is a maximum when the energy head upstream of the critical section is not influenced by the change of depth downstream from the section. (2) Discharge through a critical section requires the minimum energy with which it is possible to fulfil the theorem of Bernoulli. Conditions 1 and 2, which indicate Q_{max} and H_{min}, respectively, must simultaneously be fulfilled in the critical section[2,3].

A submerged jet issuing from a vertical opening of a sluice gate does not immediately spread in the upward direction but forms a compact stream for some distance, which is bounded by the floor and to the curved boundary defined by line AC in Fig. 1. Furthermore, the water is supplied from a large reservoir of high head. It is assumed for this analysis that the floor is a smooth rigid boundary and does not exert any resistance on the flow. Moreover, the rigid boundary will be considered as a streamline with velocity V_0 (Fig. 1). The assumption of a frictionless rigid boundary is justified, because the section under consideration, where the compact stream reaches its minimum depth, lies at a distance from the gate of about twice the height of the gate opening, as has been demonstrated by model tests[3], and consequently for large-scale flows frictional forces over this length are negligible. The upper boundary of the compact stream is separated from the rest of fluid by the line AC, which is defined as the separation-line. The fluid in the region above this line does not take part in the motion of the jet. It is either at rest, or it has a strong closed circulation which does not affect the main motion of the jet.

According to Strscheletzky[4], the separation-line AC can be identified as a separation-line with a second-order discontinuity, in which velocities, accelerations and pressure of fluid particles in an incompressible and inviscid fluid are equal on both sides of the separation-line. It can further be shown that the derivative of velocity along the streamlines, and all components of acceleration and pressure, are continuous across the separation-line. But the derivative of the velocity in a normal direction indicates a discontinuity (Fig. 2). The fluid particles of an inviscid fluid which are separated by the line AC do not slide on each other, but the first-order partial derivatives of velocity components across the separation-line are related to each other. Viscosity in a real fluid introduces an additional limiting condition to the foregoing partial derivative, but which does not nullify the existence of a distinct separation-line.

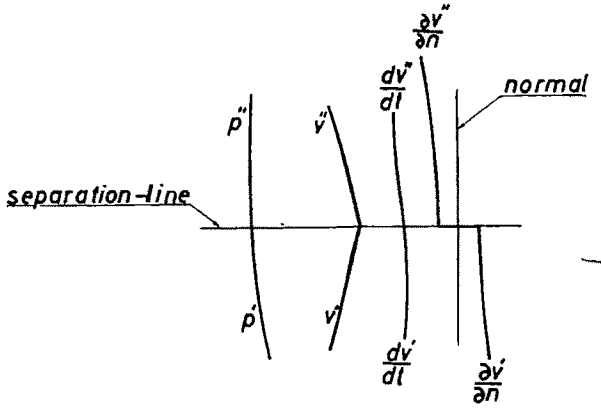

Fig 2. Second-order discontinuity in an incompressible fluid (according to Strscheletzky)

The form of the separation-line can be seen in practice by injecting dye to one side or the other, but the separation-line cannot easily be distinguished because of the turbulent diffusion of the flow across it. There is, however, a separation-line in a real fluid which forms in almost the same manner as in an incompressible inviscid fluid. A submerged jet issuing from a sluice gate, therefore, taking into account all forces acting on it, can be considered as a conservative system in which the principle of extremum is applicable for determining the contraction coefficient.

A submerged jet issuing from a sluice gate can be represented by substituting a rigid boundary for the plane of symmetry of a completely submerged jet (free turbulent flow). This has been studied by Tollmien[5] and other investigators. The velocity distribution of such flow is expressed as a term of the error function, but the use of the error function in this analysis introduces unnecessary complications. Moreover, as already mentioned, the principle of extremum does not require an

exact velocity distribution. For simplicity, we take an approximate equation for the velocity distribution:

$$\frac{V}{V_0} = \frac{a^2}{\left(\frac{y}{h}\right)^2 + a^2} \quad (1)$$

where h is the height of the submerged jet (Fig. 1), a being a constant which will be determined from the boundary condition

$$\frac{V}{V_0} = \alpha \text{ when } y = h$$

in which α is given by Albertson and others[6]:

$$\alpha = \exp\left(-\frac{(h + \sqrt{\pi}\, c_1 x - B_0)^2}{2(c_1 x)^2}\right)$$

where B_0 is the gate opening and x is the distance of the critical section from the gate. The value of c_1 has been taken as 0·109 since it has been assumed that the vena contracta lies in the 'zone of flow establishment' in which the core of the issuing jet of constant velocity, V_0, steadily decreases with distance from the gate. Further, since the contraction is gradual, the transverse components of velocity and acceleration may be neglected near the vena contracta. As shown by Henry[7], this assumption is justified, because the jet issuing from a sluice gate is similar to that of a free jet discharging from a nozzle or slot. It follows that:

$$a = \sqrt{\frac{\exp(-X)}{1 - \exp(-X)}}$$

where

$$X = \frac{(h + \sqrt{\pi}\, c_1 x - B_0)^2}{2(c_1 x)^2}$$

Hence, equation (1) can be written:

$$\frac{V}{V_0} = \frac{1}{\left(\sqrt{\frac{1 - \exp(-X)}{\exp(-X)}} \cdot \frac{y}{h}\right)^2 + 1} \quad (2)$$

and discharge per unit width can be obtained from equation (2) as follows:

$$q = \int_0^h v\, dy$$

$$= V_0 \sqrt{\frac{\exp(-X)}{1-\exp(-X)}}\, h \text{ arc tan} \sqrt{\frac{1-\exp(-X)}{\exp(-X)}} \quad (3)$$

According to condition 1, already defined:

$$\frac{\partial q}{\partial h} = 0$$

and by its application in equation (3) the following equation is obtained:

$$\left(1 - \frac{2\sqrt{X}\, h}{2c_1 x\,(1-\exp(-X))}\right) \text{arc tan} \sqrt{\frac{1-\exp(-X)}{\exp(-X)}} + h\, \frac{\sqrt{2X}\, \exp(-0{\cdot}5\, X)}{2c_1 x \sqrt{1-\exp(-X)}} = 0 \quad (4)$$

Equation (4) has been solved graphically to determine the value of h, when x, the distance of the vena contracta downstream of the gate, has been taken as twice[3] the gate opening. When there is a large head upstream of the gate, calculation gives the value for the contraction coefficient C as 0·61 for all gate openings. Hsin-Kuan Liu's measurements in a small-scale model gave C constant for all gate openings but with a mean value of approximately 0·67. The discrepancy is probably due to the low Reynolds number of his tests. The velocity distributions obtained from equation (2) have similar forms (Fig. 1) to some of those given by the measurements of Henry[7].

Thus the use of the principle of extremum allows the calculation of the contraction coefficient, which is in reasonable agreement with measured values for a case of submerged flow.

I thank my colleagues at the Station for several useful discussions and for their encouragement in writing this communication. I also thank Dr. T. Brook Benjamin for his helpful comments on the original manuscript.

Study of Correlation of the Three Basic Indices of Ionospheric Propagation: R_{12}, I_{F2} and Φ

SOON after the introduction of regular ionospheric measurements in 1938, it was found that the critical frequency of the $F2$ layer is closely correlated with the relative sunspot-number R. Further investigation has led to the introduction of the 12-months' running average of this number, R_{12}, as a basic index of ionospheric propagation[1].

About 1947, Medd and Covington[2] began regular measurements of the solar noise flux at 10·7 cm, Φ, which was also found to be correlated with ionospheric characteristics.

Later, about 1955, Minnis and Bazzard[3] introduced the index I_{F2}, now based on measurements at nine long-established ionospheric observatories, and monthly values of I_{F2} are now available from 1938 onwards.

In 1963, the International Radio Consultative Committee introduced these three indices, R_{12}, I_{F2} and Φ, as basic indices for ionospheric propagation, which are at present regularly published in the *Telecommunication Journal* of the *International Telecommunication Union*.

While the values of Φ and of I_{F2} are known and published the month following the month in question, the value of R_{12} is known only after a delay of 7 months.

The existing series of values of R_{12}, I_{F2} and Φ permits the establishment of correlation curves of these three indices and the use of these curves for the prediction of the other two indices, using the prediction of one index as a base. The form of these curves, their approximate analytical formulae and numerical values can be found in Figs. 1 and 2 and Table 1. The points in the figures show averages of the respective values taken in intervals of 5.

Table 1

190	+182	236
200	+187	246
210	+192	256

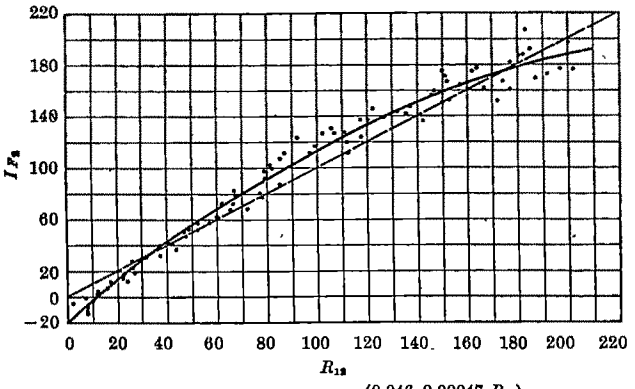

Fig. 1. $I_{F_2}=(2{\cdot}05+0{\cdot}001\ R_{12})R_{12}^{\ (0{\cdot}946-0\ 00047\ R_{12})}-20$

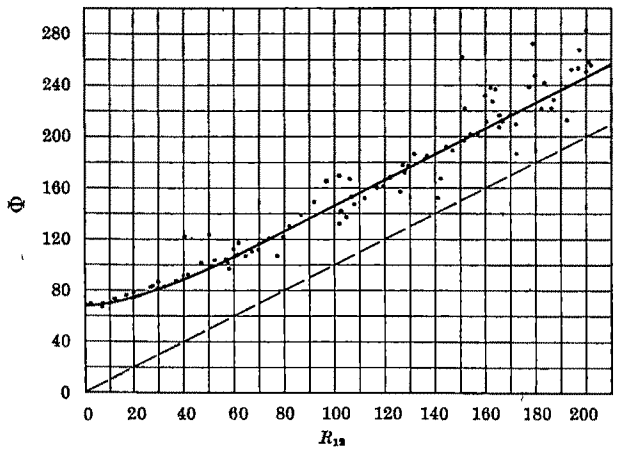

Fig. 2. $\Phi=R_{12}+46+23^{-0\ 05\ R_{12}}$

Since the index I_{F2} can be calculated with only a short delay and since, at the same time, it is possible to evaluate the preceding prediction up to 6 months ahead, this index is used as a basis for predicting R_{12} and Φ. The prediction of R_{12}, according to that procedure, can be considered only as an additional attempt, as predictions of R_{12} by other means are already well established. For the values of Φ, this method presents the first attempt at prediction and can be used in the evaluation of the 'planetary' F_2-layer ionization, quite recently proposed by Chaman Lal[4], to constitute another basic index of ionospheric propagation.

GEOLOGY

Strontium Isotopes and Trace Elements in Carbonatites and Limestones from Ice River, British Columbia

HIGH in the westerly ranges of the Canadian Rockies the Ice River alkaline complex, described in a classic memoir by J. A. Allan[1], intrudes the Ottertail Limestones (of Cambrian age) forming an extensive metamorphic aureole of contact skarns and hornfels. In the heart of the complex, on Aquilla Ridge, is a large mass of carbonate rocks which Allan described as an "abnormally large xenolith" of metamorphosed Ottertail Limestone "at least ¾ mile long", but which J. E. Rapson[2,3] has recently shown to be even more extensive and to consist of intrusive carbonatites. This locality is therefore a particularly favourable one in which to test certain isotopic and chemical criteria which are used to differentiate carbonatites from metamorphic limestones, and for this purpose we have examined a small series of specimens provided by J. E. Rapson. They comprise five carbonatites from Aquilla Ridge, three metamorphosed limestones from the contact of the nepheline syenites and ijolites with the Ottertail Limestone, and four specimens of unaltered Ottertail Limestone, one from nearby, and three from the Palliser River area 60 miles to the south-east, far from any possible effects of the intrusion. The Palliser River specimens, collected by Dr. G. B. Leach and donated by the Geological Survey of Canada, are from three well-spaced points in a stratigraphic section 1,450 ft. in thickness.

Petrographically the Ottertail Limestone specimens are fine-grained laminated rocks, predominantly calcitic, but with a variable dolomite content which is sometimes substantial. They are somewhat argillaceous, and all contain a few per cent of authigenic albite. The metamorphosed limestones, from close to the contact with the syenites, are calcite marbles containing phlogopite, tremolite and minor amounts of albite and pyrite. The carbonatites comprise both calcitic and ankeritic rocks containing minor amounts of phlogopite, chlorite, feldspar, apatite, pyrite, barite and other accessories, which in one sample (*G*.II 7) include very minor amounts of pyrochlore.

Strontium was extracted from the carbonates in dilute acid and separated as the nitrate. The isotope ratios were determined at Oxford on an A.E.I. *MS*.2 solid-source mass spectrometer (6 in. radius tube) and all $^{87}Sr/^{86}Sr$ ratios were normalized to an $^{86}Sr/^{88}Sr$ ratio of 0·1194. Calibration of this machine against the *MS*.5 mass spectrometer (12 in. radius tube) on which earlier determinations by Hamilton and Deans[4] were made has not yet been completed, but so far determinations of the $^{86}Sr/^{88}Sr$ ratio on 48 different samples (limestones, carbonatites, granites, micas and feldspars) have given an average of 0·1198. Selected trace elements were determined spectrographically by Miss D. Hosking in the laboratories of the Mineral Resources Division, London. The results, shown in Table 1, confirm the validity of these criteria for distinguishing carbonatites from limestones, and merit some brief comments.

Powell[5] has tabulated the $^{87}Sr/^{86}Sr$ ratios of thirty-two carbonatite samples, all from different complexes in America, Europe and Africa, and his results show that in this class of rocks the ratio is remarkably constant, with a mean value of 0·7032, and the standard deviation of this mean $\sigma = 0{\cdot}0002$. The Aquilla Ridge carbonatites with a mean ratio of 0·7029 ($\sigma = 0{\cdot}0006$) conform to Powell's mean, and we believe that the rather wider scatter of our

$a = <0{\cdot}002$. $b = <0\ 01$. $c = <0{\cdot}005$.

results is probably due to lack of certain experimental refinements. In contrast the limestones and metamorphosed limestones show substantially higher $^{87}Sr/^{86}Sr$ ratios, with mean values of 0·7113 (σ = 0·0013) and 0·7146 (σ = 0·0021) respectively. Applying the statistical 't' test to compare these three groups (omitting the single specimen A), we find:

Carbonatites/metamorphosed limestones, t = 6·8
Carbonatites/unaltered limestones, t = 6·7

whereas the critical value of 't' for 1 per cent probability is 3·7 with six degrees of freedom. In marked contrast, for:

Metamorphosed limestones/unaltered limestones, t = 1·3 (critical value of 't' for 25 per cent probability is 1·34 with four degrees of freedom).

These calculations substantiate our contention that the $^{87}Sr/^{86}Sr$ ratio of the carbonatites is significantly different from that of the Ottertail Limestones, whether metamorphosed or not, and demonstrate also that metamorphism has not altered this ratio.

The trace element data clearly reveal that the carbonatites are characterized by the presence of niobium and lanthanum, elements not detected in the limestones and marbles, and by a markedly greater abundance of strontium and barium. These results are completely in keeping with experience elsewhere. It may be noted that in four out of five cases the concentrations of niobium, lanthanum and strontium in the carbonatites are much below the levels associated with the appearance of distinctive minerals, such as pyrochlore, so that this characteristic might easily pass unnoticed if a mineralogical examination of a few specimens was solely relied on. The absence of niobium and lanthanum from the contact metamorphosed limestones is also noteworthy, and in keeping with general experience, for although the alkaline silicate rocks associated with carbonatites commonly carry the same suite of trace elements as the latter, no cases are recorded of these elements having diffused from the alkaline rocks into adjacent limestone skarns.

Hayatsu *et al.*[6] have recently expressed doubts regarding the significance of strontium isotope ratios in investigations of carbonatite, citing new preliminary results from eastern Canada where Grenville Marbles have $^{87}Sr/^{86}Sr$ ratios ranging from 0·7072 where no alkaline metasomatism has occurred, to 0·7030 (= average for carbonatites) where the marble has reacted with calcite-free syenite. The contact metamorphism of the Ottertail Limestones by the Ice River syenites was clearly much less intense than that in the Grenville province, so that the conflicting evidence arises in very different circumstances. More extensive and detailed studies of the Grenville rocks might lead to a better understanding of this problem.

We thank those of our colleagues who helped us in the laboratory work, and Mr. E. H. Beard and the late Prof. L. R. Wager for their support in this research.

Mechanisms of Cauldron Subsidence

WILLIAMS'S subdivision of calderas into 'Krakatoan' and 'Glen Coe' types[1] has been the subject of recent discussion[2–4]. Williams's concept of the 'Krakatoan' mechanism is that explosive eruption of pumiceous volcanic products from the vents of a central-type volcano produces a void in the underlying magma chamber; the unsupported chamber roof then collapses, producing a caldera at surface level bounded by a ring-fault escarpment. The 'Glen Coe' type, on the other hand, is said to involve the stoping of magma up ring fractures and the coeval descent of the enclosed cylindrical block.

From gravity surveys of seven Japanese calderas Yokoyama[3] claims that four of these showing negative Bouguer gravity anomalies are of 'Krakatoan' type, and one is of 'Glen Coe' type and shows a positive anomaly; the lack of any anomaly on the remaining two is not commented on. McCall[4] has revised an earlier interpretation of the Menengai caldera in Kenya[5] and describes it as "primarily of 'Glen Coe' type" and not of the 'Krakatoan' type which he previously supposed. Due to the presence of an extensive bedded pumice mantle on the western flank of the volcano, however, McCall further amends its position in the classification of calderas by claiming it has "weak 'Krakatoan' characteristics" and is of a "weakly 'Krakatoan' sub-type".

I have spent several months in the detailed field investigation of Mount Suswa, a Pleistocene phonolite-trachyte volcano which lies 90 miles south of Menengai in the Rift Valley of Kenya. These two alkaline volcanoes show clearly defined calderas in the summits of primitive shield-shaped cones, and in both cases the formation of the calderas has been accompanied by the eruption of large quantities of pumice which mantle their western flanks. Unique to Mount Suswa, however, is an extensive series of lava flows (many of them of the coulée-type) that were erupted from the fissures of a complete ring-fracture complex which lies concentric with, but encircles, the caldera escarpment. These flows outcrop on the upper outer slopes of the volcano and were erupted in alternation with the pumice that constitutes the western flank. At the caldera escarpment the pumice beds mantle the caldera rim and occur as a banking inclined against the caldera wall. The intercalated ring-fracture flows are at all times concordant with the pyroclastic deposits and at the caldera rim are therefore seen to have flowed from the vents of the ring-fracture complex down the inwardly-inclined fault escarpment to occur in alternation with the beds of the inclined pumice banking. The eruption of the lava flows and the deposition of the pumice therefore post-date the formation of the caldera escarpment.

McCall in his earlier publication[5] clearly infers the post-caldera age of the Menengai pumice mantle from his accompanying sketch map and later referred[4] to the pyroclastic material as having originated by sudden pressure release caused by the initial downward movement of the cauldron block. This pumice is therefore the eruptive expression of the "weakly 'Krakatoan' characteristics" which are "a complication of the 'Glen Coe' mechanism".

Two main criticisms can be levelled at McCall's conclusions. The first is the use of the term 'Krakatoan'. Williams's hypothesis[1] clearly states that the ejection of the pumice pre-dates the subsidence and that therefore the evacuation of the magma chamber and the subsequent collapse are direct consequences of these eruptions. The demonstrable post-subsidence age of the Mount Suswa and Menengai pumice deposits obviously rules out the possibility that their eruption was the cause of the cauldron subsidence. The two calderas have apparently originated by collapse into a void caused by magmatic withdrawal, or as MacDonald has suggested[6], for the Hawaiian calderas, by the foundering of heavier crustal rocks into an underlying less-dense liquid magma. The

pumice eruptions associated with the formation of the Kenyan calderas appear to be consequences of this cauldron collapse and therefore their mode of origin is quite distinct from the role of the pumice eruptions in Williams's 'Krakatoan' mechanism. I therefore believe that the use of the term 'Krakatoan' in the context of the Kenyan calderas is an unfortunate one.

Secondly, McCall discusses the space problem presented by calderas of the 'Krakatoan' type (*sensu strictu*). It will be recalled that the problem is that estimates of the volume of pyroclastic material erupted at the time of caldera formation are usually much less than the volume of the caldera depression itself. Since a close agreement between the two volumes would add considerable support to the theory of the 'Krakatoan' mechanism, the problem is one which the advocates of the theory attempt to solve by various means. McCall, while recognizing the post-cauldron subsidence nature of the pumice of Menengai, finds it necessary to explain the volume deficit of the 'Krakatoan' calderas, the Kenyan examples included. However, if the pumice has originated by eruptions which were initiated by the pressure release resulting from cauldron subsidence (as suggested by McCall[4]), then no 'space-problem' exists as clearly the cauldron subsidence owes its primary origin to mechanisms other than removal of support by the initial explosive ejection of pumice; in other words, the volume of the caldera depression is not a function of the volume of juvenile magma ejected at the time of cauldron collapse.

The observation that eruptions of pumice may be the consequence and not a prerequisite of caldera formation has obvious implications to the general subject of cauldron subsidence mechanisms. 'Krakatoan' type calderas are frequently referred to in the literature, notably by authors working in the Pacific orogenic belts (for example, Yokoyama and Tajima[2], and Yokoyama[3]). The term 'Krakatoan' has precise genetic and geological implications, and from a consideration of the evidence presented by the Kenyan calderas it is perhaps justifiable to call for some restraint before assigning that name to calderas which merely have extensive pumice deposits associated with them: the exact relationship of the pumice deposits to the caldera ring fault is obviously of the greatest importance.

The preservation of post-subsidence pumice beds inclined against the caldera escarpment and the mantling of the caldera rim are features that perhaps are only found in special circumstances. If, for example (as suggested by McCall), a small initial downward movement of the cauldron block is arrested as the vesiculating magma expands and erupts, and the block continues to sink only when the eruptions have terminated, then the pumice beds would be truncated by the cauldron fracture and no mantling or banking would occur. In this manner pyroclastic flows ('ash flows', 'pumice flows', etc.) may also be preserved in exposures of the caldera wall. Similarly, if the upper surface of the subsided block is at such a depth that the top of any pumice banking fails to reach the higher levels of the caldera escarpment then the inclined pumice beds may consequently be obscured from view by post-caldera infilling. Backward erosion of the steep caldera escarpments would also remove any pumice beds that once were inclined against them.

McCall's recognition of the mechanism of eruption of the Menengai pumice beds (a mechanism confirmed by the depositional features on Mount Suswa) is therefore of considerable importance to the problem of the origin of calderas. It suggests that the primary mode of origin for certain collapse depressions which resemble the so-called 'Krakatoan' calderas may be by a mechanism that does not entail the initial evisceration of a magma chamber by the explosive ejection of pumice. I would like to emphasize, however, that the application of Williams's term 'Krakatoan' to the Kenyan calderas is misleading since (as already envisaged by McCall) the pumice in these examples has probably been ejected by eruptions which were inherent on the pressure release caused by the cauldron collapse, and not by primary eruptions occurring before the collapse.

Occurrence of Pollen and Spores in the Roraima Formation of Venezuela and British Guiana

THE discovery of pollen and spores in beds considered Precambrian (Proterozoic) has received brief notice in geological journals and the press[1–3]. Individual authors will doubtless publish detailed stratigraphic and palynologic accounts of the occurrence in due course. Meanwhile it is considered desirable to give an outline of the facts of the case before distorted interpretations develop from inadequate data. The following summary statement has been prepared jointly by several members of the Asociación Venezolana de Geología, Minería y Petróleo. A single author is nominated to simplify bibliographic references.

Late in 1963 G. C. K. Dunsterville made an expedition to collect orchids around Cerro Venamo, at the westernmost point on the frontier between Venezuela and British Guiana (where this mountain is known as Wenamu Head). He noted some shale-like beds at the base of a towering cliff of Roraima sandstone and collected samples for their possible paleontological interest.

G. Fournier, palynologist of the Mene Grande Oil Company, processed the samples and recovered well-preserved pollen and spores. Subsequently, L. Nijssen and J. A. Sulek, palynologists of Compañía Shell de Venezuela and Creole Petroleum Corporation, respectively, processed other pieces and recovered identical plant microfossils.

This discovery of pollen and spores in a formation of supposed Precambrian age was so remarkable that a reconnaissance expedition of qualified geologists was organized to verify the facts of the case. During April, 1964, with the assistance of personnel and vehicles of the Ministerio de Minas e Hidrocarburos, the locality was visited by a party which included N. Benain, P. J. Bermúdez, A. Espejo, G. Fournier, A. Menéndez, J. A. Sulek and F. Wright. They confirmed the salient facts as recorded by Dunsterville. The shale-like beds, being less competent, had eroded away below the massive Roraima sandstone, leaving an undercut extending 10–12 ft. inwards at the base of the cliff. The original samples were loose, weathered fragments from the talus slope below. New samples of unweathered rock were collected from the face of the undercut.

On their return to Caracas, the three palynologists made independent investigations of the new samples. Utmost care was taken to avoid any possibility of superficial contamination. The rock cleaves along finely laminated bedding planes which are coated with limonite. Every effort was made to avoid these planes and some of the pieces processed were the central nubs left after chipping away the external parts of large blocks of the rock, which was dense enough to sound when struck with a hammer. Nevertheless, microfossils of the same type as before were recovered.

Dr. P. H. A. Martin-Kaye, director of the British Guiana Geological Survey, was told of these discoveries

Fig. 1. Hand specimen of 'shale' from Cerro Venamo locality, showing bedding plane parallel to bottom edge, and diagonal cleavage. Natural size

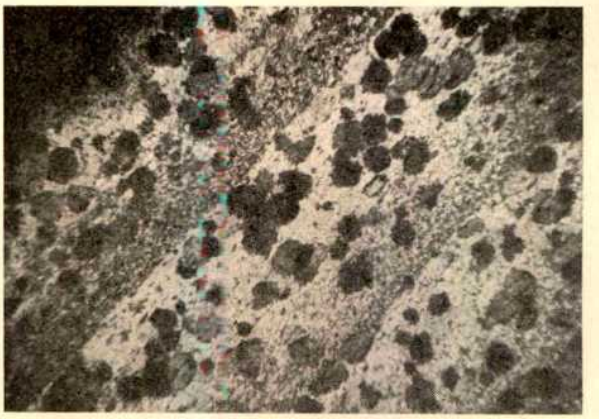

Fig. 2. Paruima hornfels (crossed nicols); large crystals are all cordierite in micaceous ground, with original fine quartz banding still preserved; biotite may be seen to right of centre of field. (×150)

in view of his group's sponsorship of radiometric dating of the Roraima Formation. He collaborated by sending samples of beds described as 'hornfelsized sediments' from a seemingly correlative level near Paruima on the Kamarang River, some 25 miles east of the original locality. As before, independent investigations were made of this material, and the same flora was recorded. Still more samples were submitted by the Survey, this time from the Kopinang area, about 110 miles south-east of Paruima. In this case, however, only indeterminate plant microfossils were obtained, not the distinctive suite recorded at Cerro Venamo and Paruima.

It needs to be stated that petrological investigation of the rocks which yielded pollen and spores showed them to be highly metamorphosed, even though in hand specimens they somewhat resembled indurated shales (Fig. 1). J. M. Bowen (Cia. Shell de Venezuela) described the samples from both Cerro Venamo and Paruima as true hornfelses in the cordierite-andalusite range, based on thin-section investigations (Fig. 2). Prof. H. H. Hess (Princeton University) confirmed this on the basis of X-ray diffraction investigations, and described the rock as a fairly typical hornfels, largely muscovite plus a little quartz, clay minerals apparently absent, and no chlorite noted. The samples from Paruima were rather more highly metamorphosed, as shown by the presence of biotite.

Fig. 3 shows a highly generalized regional cross-section based on the current geological map of British Guiana. The remarkably horizontal attitude of the Roraima Formation and the persistence of dolerite sills[4] over vast distances appear to justify the long-range correlations indicated. Relative positions are shown of the polliniferous samples and of samples dated Precambrian by radiometric techniques.

The palynological assemblage has not yet been matched conclusively against any known suite, a fact which is not surprising in view of the distance from control sections of known age and the highly endemic character of the flora of to-day, and probably the geological past, on the isolated Roraima Plateau. G. Fournier, by utilizing the herbarium of J. Steyermark, was able to compare the recent pollen of the area with the assemblage in the rocks, and has stated that they are not the same. The first opinion of Fournier was that the pollen showed Cretaceous affinities, but closer study has led to preference for a Tertiary age. L. Nijssen regards the best assemblage, from a Paruima sample, as not older than Eocene and quite possibly post-Eocene. J. W. Funkhouser (Bogotá) considers the pollen indigenous to the samples he processed but claims an age no older than Miocene, and probably younger; he notes similarities to the flora of the Mesa Formation (Pliocene-?Pleistocene) of Colombia, presence of pollen of the Compositae, and an uncompressed preservation highly unusual except in young sediments. T. van der Hammen (Leiden) recognizes a mixture of Mesozoic and Cenozoic elements, but suspects that they represent foreign material concentrated along cleavage

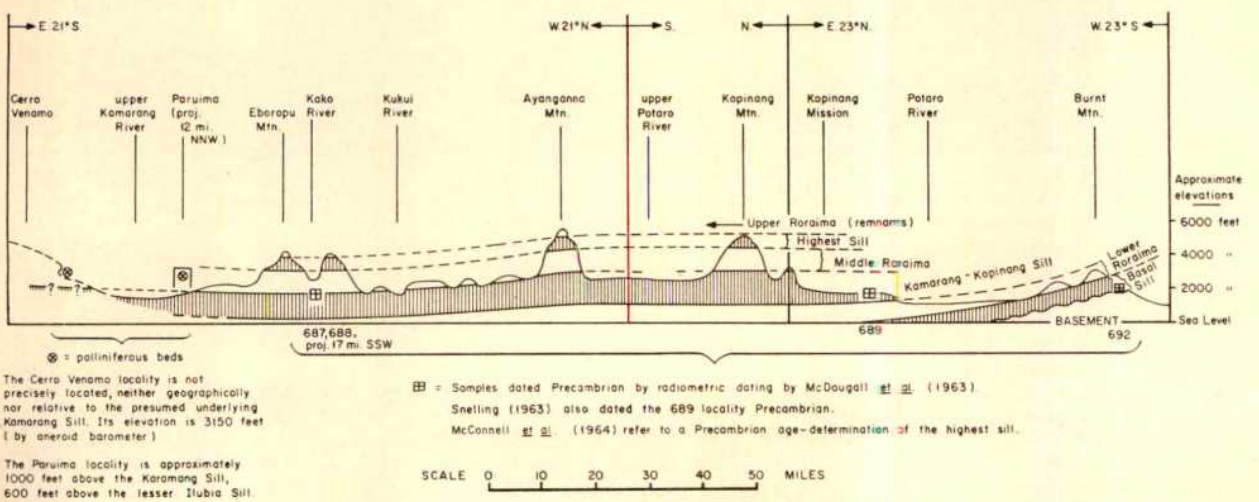

Fig. 3. Regional cross-section through the Roraima Formation in western British Guiana showing positions of polliniferous beds and of samples determined radiometrically as Precambrian

planes as, after cleaning fragments ultrasonically, he found the matrix practically barren.

As to interpretation of the significance of the fossil pollen and spores, two sharply divided opinions have been expressed. The writers make no attempt to adjudicate, but state the two concepts impartially.

One group adopts the attitude that the radiometric dating[5–7] of dolerites and a hornfels[6] within the Roraima Formation as Precambrian is beyond dispute, hence the pollen (and spores) must have entered as secondary contamination. The improbability that pollen could withstand the baking process, which converted shale to hornfels, is adduced as further evidence that the pollen must be allochthonous. The absence of macroscopic plant remains in the Roraima Formation is also noted, despite its assumed continental (? fluviatile) origin. It is admitted that entry of the pollen into its present site defies simple explanation, though some form of washing in by meteoric waters in the geological past via joints in the overlying sandstone seems the most probable cause.

The second group holds that by no conceivable physical means could the pollen (and spores) have entered the metamorphosed sediments from the outside. They are dense impermeable rocks compressed by an overburden of hundreds of feet of the overlying Roraima sandstones. The undercutting at Cerro Venamo suggests that the cliff has been steadily retreating, hence the face which was sampled must have been deep within the formation until quite recent times. The Roraima sandstones are quartzitic, of low permeability, hence carriage of extraneous pollen through them by percolating water seems highly improbable. Even if this process could occur, entry of such pollen and spores into the non-porous hornfels lacks an explanation. Furthermore, if plausibility of this process be granted, it would have been operative for a long period, and a mixed suite of spores and pollen should be expected.

In counter-argument against the first group, it is claimed that the assertion that pollen and spores cannot withstand anaerobic baking of their parent shales has never been tested experimentally. As regards the radiometric dating, there is a disquieting overlap between stated ages of the Roraima Formation[5,6] and the underlying basement rocks[7–9]. The latter suffered complex deformation and vulcanism, and were then deeply peneplaned before being covered by thousands of feet of Roraima sandstones, and only after these prolonged events were the dolerites intruded, on which age-determination of the Roraima has been based. If the radiometric technique is valid there should be a long and clear-cut time-gap between ages assigned to the basement rocks and to the Roraima beds. Such a gap does not exist in the experimental results published, but this discrepancy is glossed over in the latest summary of radiometric dating in British Guiana[7].

As stated, we offer no solution to the paradox. It is clear, however, that botanist Dunsterville in his hunt for rare orchids stumbled on a highly intriguing geological problem.

CRYSTALLOGRAPHY

Structure of Ferrierite

AN investigation into the rare aluminosilicate mineral ferrierite[1], $(Na, K)_4MgAl_6Si_{30}O_{72}2OH_2O$, has led to its crystal structure being proposed, which is based on the space group *Immm* and agrees reasonably with our X-ray powder data of 62 reflexions. After several cycles of least-squares refinement in which reflexions of zero intensity were included, an $R(Fo)$ factor of 16·5 per cent was obtained corresponding to the co-ordinates in Table 1.

Table 1

Atom	x	y	z	B (Å^2)
Si_1	0·174	0·290	0·279	1·3
Si_2	0·085	0·202	0	3·8
Si_3	0·270	0	0·289	7·2
Si_4	0·161	0	0	2·2
O_1	0·111	0·267	0·175	3·2
O_2	0·306	0·104	0·250	3·2
O_3	0·114	0·095	0	3·2
O_4	0·668	0·790	0	3·2
O_5	0·208	0	0·175	3·2
O_6	0·25	0·25	0·25	3·2
O_7	0	0·193	0	3·2
O_8	0·772	0·5	0	3·2

The framework, which is shown schematically in Fig. 1, is composed from rings of 10, 8, 6 and 5 linked Si/AlO_4 tetrahedra, and is closely related to the structures of mordenite[2], dachiardite[3] and epistilbite[4]. There are two systems of intersecting channels: (1) bounded by ten-membered rings; running parallel to c and approximately circular and 5·2 Å free diameter; (2) bounded by eight-membered rings; parallel to b; 4·7 by 3·7 Å in free cross-section and leading into cavities about 6·2 Å free diameter.

Although it has not been possible to position the cations and water molecules from X-ray data, sorption experiments suggest the cations may be situated in the wide channels and cause their partial blocking. It is hoped to

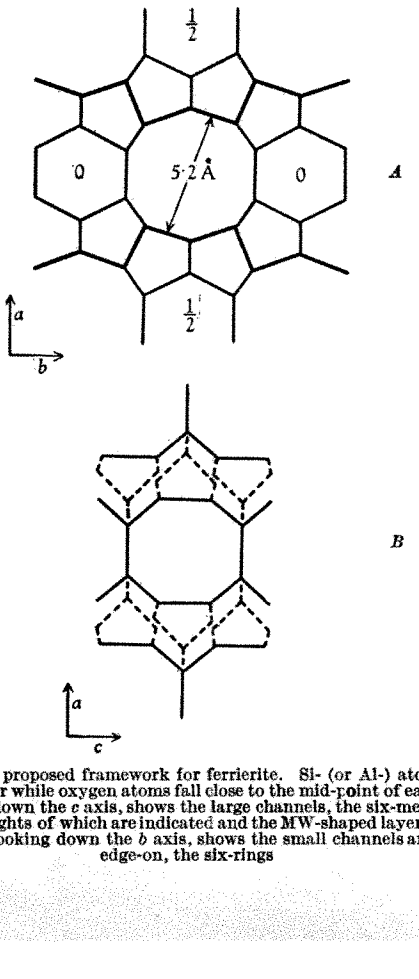

Fig. 1. The proposed framework for ferrierite. Si- (or Al-) atoms fall at each corner while oxygen atoms fall close to the mid-point of each line. *A*, Looking down the *c* axis, shows the large channels, the six-membered rings the heights of which are indicated and the MW-shaped layer (heavy lines). *B*, Looking down the *b* axis, shows the small channels and, seen edge-on, the six-rings

prepare a hydrogen-exchanged ferrierite for sorption experiments.

Since this work began, an incomplete description of a structure for ferrierite has been published[5]. While some features are similar to those described here, there are also marked differences, so that until more details of this other structure are made available, a measure of doubt will exist as to whether the two frameworks are identical or not. As part of the investigation the unit cell of our specimen was determined as orthorhombic I with $a = 19{\cdot}15$ Å, $b = 14{\cdot}12$ Å and $c = 7{\cdot}47$ Å. This differs from the heulandite cell by a small amount. It is, however, unlikely that there is a close connexion between the two structures, since the symmetry of heulandite is lower.

CHEMISTRY

Electrical Conductivity and Photoconductivity of Pure Benzene

IN addition to reporting some results of measurements of electrical conductivity and photoconductivity of benzene, we wish to direct attention to the effect of conventional out-gassing and other techniques on the purity of solutions. The effect of contamination introduced by such procedures is of considerable practical importance and has also been noted by Dubois and Wilkinson[1] in another connexion. The conductivity measurements were incidental to a study which we undertook of photoconduction in organic solutions.

Recently, Forster[2] has published results of measurements of electrical conductivity of purified benzene. Typical values after polarization for 24 h at 25° C in a cell with fields up to a few hundred V/cm were $0{\cdot}61 \times 10^{-15}$ $(\Omega\ \text{cm})^{-1}$, or $6{\cdot}9 \times 10^{-15}$ $(\Omega\ \text{cm})^{-1}$ when the benzene was saturated with dry air. He found that close to the electrodes there was a rapid fall in potential, so that the effective field in the bulk of the solution was reduced. After correcting for this, the resulting conductivity was $1{\cdot}1 \times 10^{-14}$ $(\Omega\ \text{cm})^{-1}$. Forster also quotes work by Kraus and Fuoss[3] and Kortüm and Bockris[4] in which values of about 3×10^{-15} and 5×10^{-17} $(\Omega\ \text{cm})^{-1}$ respectively are stated. A recent paper by Sano and Akamatsu[5] gives a value of $6{\cdot}4 \times 10^{-14}$ $(\Omega\ \text{cm})^{-1}$.

Among these values, those given by Kortum and Bockris, which are from experiments by Jaffé, in 1908, are outstandingly low. Our work fully supports this value as the following account will show.

At first our experiments were carried out in a cell with platinum electrodes about 1 cm² in area with a 1 cm separation. Electrical measurements were made by means of a vibrating reed electrometer (E. K. Cole, Ltd., type 1341*A*).

After vacuum distillation and transfer of the benzene under dry oxygen-free nitrogen in a closed system to the conductivity cell, and polarization for 24 h, the conductivity was found to be $0{\cdot}33 \times 10^{-14}$ $(\Omega\ \text{cm})^{-1}$ in a field of roughly 240 cm^{-1}, which agrees with Forster's values. The measurements were then repeated in a special cell with a 0·0125 cm gap between transparent conducting quartz electrodes coated with stannic oxide, so that field strengths of 15,000 V/cm were readily attainable. After polarization for 15 min, the current was steady and the conductivity was $0{\cdot}7 \times 10^{-14}$ $(\Omega\ \text{cm})^{-1}$, which agreed with the earlier determination within the variation expected from different batches of vacuum-distilled benzene. If Forster's potential variation had applied to our system we should have expected the narrow gap cell to give considerably lower conductivity values (see a discussion of Forster's results by Silver[6], who has applied the classical Thomson treatment of conductivity in gases).

We then abandoned the conventional purification techniques, and used benzene which had first been crudely distilled, then very carefully distilled by means of a 25-stage bubble-cap fractionating column, with transfer to the conductivity cell by syringe. After 15 min polarization in the cell, conductivity values for different batches varied between 2×10^{-18} and 1×10^{-17} $(\Omega\ \text{cm})^{-1}$, similar to the values found by Jaffé. The success of this distillation procedure depends on careful control of conditions in the distillation column. Starting with 4 l. of sulphur-free benzene (May and Baker, Ltd.) about 400 ml. of purified benzene were obtained after distillation for 24 h. The purified benzene was stored before use in glass containers from which moisture was excluded by means of 3/16 in. 'Hi-drite' granules (Hi-drite, Ltd.) held in the hollow glass stoppers. Other than this, no special storage precautions were taken.

These observations suggested a further investigation of the effects of vacuum distillation. This was carried out in a system constructed of glass with 'Teflon' seals and 'Teflon' vacuum taps, using a glass freeze trap and an Edwards rotary pump containing type 8*A* oil. Degassing a sample of purified benzene with solid carbon dioxide in the trap caused a three-fold increase in conductivity. A complete vacuum transfer under the same conditions caused a hundred-fold increase in conductivity, which represents a return to values similar to those reported by Forster and others. Very similar results were obtained after thorough cleaning of the apparatus and use of a liquid nitrogen trap. Evidently such contamination is of major importance in conductivity work and may also be important in any other work where degassing cycles are used.

It is of interest to note the effect of oxygen on the electrical conductivity and photoconductivity of the very pure benzene. The conductivity of a control sample in a typical experiment was 4×10^{-18} $(\Omega\ \text{cm})^{-1}$ after 15 min polarization. After 5 sec exposure to a high-pressure mercury arc (Philips 125*W*) through a Corning 0–53 filter (less than 5 per cent transmission at 290 mμ; negligible at 280 mμ) the conductivity rose to 60×10^{-18} $(\Omega\ \text{cm})^{-1}$, and fell quickly to the original value when the radiation was cut off. When the sample was saturated with dry oxygen by bubbling for 30 min the initial conductivity was 14×10^{-18} $(\Omega\ \text{cm})^{-1}$ after 15 min polarization, which after the same 5 sec exposure rose to 100×10^{-18} $(\Omega\ \text{cm})^{-1}$. In both cases, prolonging the exposure beyond 5 sec caused a reduction in the photocurrent.

The results are qualitatively similar to Forster's, except that all processes are faster, presumably because the path lengths between the electrodes are shorter and the field strengths much higher. It will be seen that the conductivities in our experiments are more than two orders of magnitude less.

Red Forms of Methylene Blue

METHYLENE blue dissolves in water and common organic solvents to give blue solutions absorbing light of wavelength near 660 mμ, for example 657 mμ in *n*-butanol (Fig. 1, curve *a*). A faint band at 480 mμ is just detectable, but can be seen more readily if the molar extinction coefficients are plotted on a logarithmic scale (ref. 1). Wine-red solutions have been obtained here when the dye is dissolved in simple aliphatic amines dried over potassium hydroxide pellets for several days and redistilled more than once if necessary. The blue colour of the dye could be restored by adding either water or ethanol; standing for several days in the amine, however, appeared to bring about some chemical change in the dye. Although the dye dissolved immediately in the hot amines the use of elevated temperatures was considered undesirable. Instead the dye was dispersed by ultrasonic vibration in the cold amine and then allowed to stand for several hours (usually overnight) to pass into solution. A typical spectrum is that in *n*-hexylamine shown in Fig. 1, curve *b*, and the special data for other systems are given in Table 1. The solutions were quite red, even when saturated; at the boiling point of the amine there was no trace of the blue form. This latter fact appears to eliminate dye–dye association (see ref. 2) and interaction with chloride counter-ions (see ref. 3) as important factors. The existence of the red form clearly depends on the strongly basic character of the amine. Thus the dye is red in primary, secondary (open-chain and cyclic), and tertiary aliphatic amines, all of which are strong bases with pK_b values in the range 2·8–3·4, and in the araliphatic amine benzylamine ($pK_b = 4·7$); aniline, pyridine, quinoline, and indeed all the other common organic solvents in which the dye is soluble are only weakly basic ($pK_b \geqslant 8·9$) and in them it is blue.

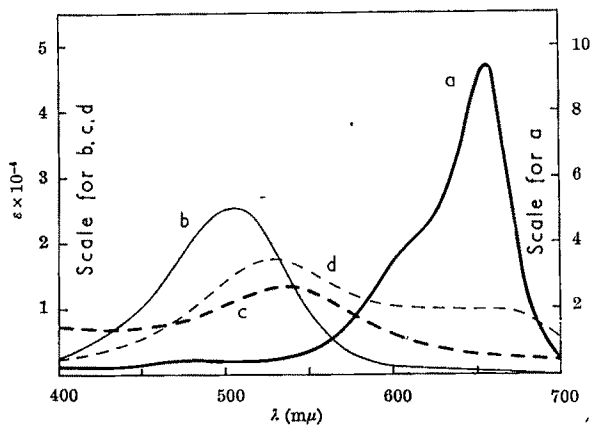

Fig. 1. Spectra of methylene blue in various solvents

It is of interest to note that in isopropanolamine, comparable in basic strength to benzylamine, yet partly an alcohol, the solution appeared blue if the light path were long and red if short. Indeed, examination of the spectrum (Fig. 1, curve *d*) shows that both forms are present.

Dahne and Stanko[4] reported a red form of the dye absorbing at 523 mμ in dilute solutions ($5 \times 10^{-4} - 10^{-6}$ M) in 'anhydrous' pyridine. Tests made here showed a similar type of effect though poorly reproducible quantitatively in pyridine dried over potassium hydroxide pellets, but not redistilled. The red form became increasingly important on dilution, but vanished in more concentrated solutions. If the dry pyridine were redistilled, however, with or without a fractionating column the effect vanished and the dye was blue even at 10^{-6} M (see Table 1).

A red solution was obtained when the dye was dissolved in an ethanolic solution of sodium (Table 1; Fig. 1, curve *c*). The red colour did not appear to be due merely to decomposition of the dye, for the blue colour could be restored by adding water.

Table 1. EXPERIMENTAL DATA FOR SOLUTIONS OF METHYLENE BLUE

Solvent	pK_b	Dye conc. (mole/l.)	λ(mμ)	ε × 10⁻⁴*
Pyridine	8·9	$0·87 \times 10^{-4}$	664	8·32
		$0·87 \times 10^{-5}$	664	8·03
		$0·87 \times 10^{-6}$	664	7·62
Quinoline	9 2	10^{-3}–10^{-4}	669	—
Aniline	9·3	0–10^{-4}	674	—

n-Hexylamine		$2·87 \times 10^{-4}$	505	2 60
n-Heptylamine		$2·92 \times 10^{-4}$	508	2 44
n-Octylamine		$3·00 \times 10^{-4}$	505	2 61
Di-*n*-butylamine	*ca.* 3 4	+	499	—
Piperidine	2 8	$2·81 \times 10^{-4}$	510	0·51
Triethylamine	3·3	+	496	—
Isopropanolamine	*ca.* 4 5	$2 95 \times 10^{-4}$	530	1·77
Sodium hydroxide in pyridine		$0·96 \times 10^{-6}$	521	< 1
1 per cent NaOEt in ethanol		$0 95 \times 10^{-3}$	538	1 32

* Note: the molar extinction coefficients, ε, are only accurate to ± 4 per cent.

+, Dye sparingly soluble.

Red forms of methylene blue have also been observed in the crystalline state[1,5], which is dichroic, and in solutions of the dye in solvent mixtures of very low dielectric constant[3,6]. In the latter case the red form was rapidly precipitated and was attributed to undissociated dye in a colloidal state.

In the blue form of the dye the positive charge is an integral part of the chromophoric system and is distributed symmetrically throughout the system by resonance[6]. If this were not so, as in the colourless non-ionic *leuco* form, then the dye would absorb at much shorter wavelengths. The close approach of an anion will repel the electrons of the chromophoric system, thereby altering the distribution of the positive charge. Interaction of the anion with a terminal position in the dye ion destroys the energetic symmetry of the dye ion; loss of energetic symmetry has been shown experimentally to shift the visible absorption of a dye to shorter wave-lengths[7–9]. Interaction of the anion with a central position in the dye ion reduces the fraction of the positive charge shared by the terminal positions and this too has been shown to shift the visible absorption of a dye to shorter wave-lengths[10]. In effect, interaction of an anion with any position in the dye ion will induce a hypsochromic spectral shift. The red forms in the undistilled anhydrous pyridine and in the ethanolic solution of sodium may therefore be attributed to the interaction of the dye ions with strongly basic anions—ethoxyl ions in the latter case. This mechanism is analogous to the formation of undissociated dye molecules and indeed these two red forms absorb at wave-lengths close to that of the undissociated dye in solvents of low dielectric constant (λ = 521, 538 mμ; compare 530 mμ in ref. 3). Furthermore, the absorption bands of the red forms all have low molar extinction coefficients. This is consistent with interaction of the anion at a terminal group in the dye ion, thereby stabilizing one resonant structure of high dipole moment at the expense of another equivalent structure[11]. Indeed, Lewis considered that with methylene blue the positive charge was almost entirely shared by the terminal $-NMe_2$ groups[12].

The mechanism by which the charge distribution within the dye ion is reduced in simple aliphatic amines cannot be ascertained from the present data. Nevertheless, since the dye is completely in the red form in these solvents one important possibility that may be worthy of further investigation is complex-formation between the dye and the amine, acting as a Lewis base (see ref. 13). Water, however, cannot be completely eliminated from the amine, and although the presence of hydroxyl ions alone is no criterion for the production of the red form because the dye is blue in aqueous alkali, the possibility that hydroxyl ions, produced by the interaction of water and the amine, may have some effect cannot be ignored altogether.

The source, purification and analysis of methylene blue have already been described[3].

Metachromasy

MANY dyes when used to colour certain tissue constituents (chromotropes) absorb light of wave-length shorter than that absorbed by the dyes in solution[1]. Similar metachromatic behaviour is exhibited in solution when the dyes interact with soluble chromotropes, for example nucleic acids[2], polyphosphates[3] and gelatine[4]. Metachromasy may also be induced in solution in the absence of chromotropic substances in three different ways[5]: by increasing the dye concentration (dye-induced), by adding salt (salt-induced) and by lowering the dielectric constant of the solvent from medium (about 20) to low (about 3) values (solvent-induced).

The phenomenon is exhibited only by dyes in which the characteristic ionic charge is an integral part of the chromopheric system and is distributed throughout the system by resonance, that is, most common basic dyes and a few acid dyes. The following discussion is therefore restricted to basic dyes, but the same arguments apply *mutatis mutandis* to dyes, such as fluorescein, with a distributed negative charge.

Metachromasy in solution has recently been attributed primarily to interaction of the dye ions and counter-ions[5], although in the past interaction of dye ions themselves was generally considered to be responsible. Usually the colour change is small and the hypsochromic ($H-$) band in the visible spectrum is removed by only about 50 mμ from the normal ($M-$) band; the interacting dye ion and counter-ion are considered to be separated by solvent molecules. In solvents of low dielectric constant[5] (and certain strongly basic solvents[6]) strong interaction occurs to form an undissociated species in which the ions are in contact and not separated by solvent molecules. In this case the colour change is large, for example, solutions of methylene blue become red and, indeed, a red form exists in crystals of the dye[7].

In organic solvents of moderate dielectric constant, for example simple alcohols, dye-induced metachromasy (at room temperature) only occurs at extremely high dye concentrations, but occurs at increasingly low concentrations as the dielectric constant is lowered (see ref. 5 and other references quoted therein). This is in keeping with electrolytic dissociation theory. In solvents of high dielectric constant, long-range electrostatic forces are smaller and solvation effects are relatively more important[8]. The marked metachromatic effects observed in water are attributed to the inability of water to solvate the large organic residues in the dye ions. The dye ions therefore tend to aggregate and the aggregation of organic ions is known to be associated with the uptake of counter-ions[9,10].

The foregoing concepts can also explain metachromasy induced by interaction with chromotropic substances either in tissues or in solution. Basic dyes exhibit metachromasy when they interact with negatively-charged substrates; the colour change is more marked the more strongly acidic the active groups (sulphate > phosphate > carboxylate)[1]. In solution, metachromasy of cyanine dyes induced by interaction with gelatine is only observed at a *p*H above the iso-ionic point of gelatine[4]. Ionic interaction of the dye ion with an ionic group in the substrate must clearly alter the charge distribution in the dye ion and, as described previously[5], this produces a hypsochromic spectral shift. We therefore believe that metachromasy induced by chromotropes should be attributed primarily to ionic interaction with the substrates, even though there is evidence[11] that basic dyes tend to aggregate when they interact with biological substrates. The aggregation requires uptake of counter-ions to reduce electrostatic repulsion between the dye ions and this will have an additional effect.

The interaction of a metachromatic dye and a chromotrope in solution often exhibits a curious phenomenon. As increasing amounts of the chromotrope, for example polyphosphate[3] and gelatine[4], are added to a solution of dye, the M-band of the dye is gradually replaced by the H-band. However, if still more chromotrope is added, until it is well in excess of the dye, the H-band gradually disappears and is replaced by a band at the same or slightly longer wave-length than the original M-band. This phenomenon is probably related to the behaviour of 1,1′-diethyl-2,2′-carbocyanine chloride in the presence of soaps, for example potassium laurate or oleate[12]. At the dye concentration used the dye absorbed light mainly in the H-band ($\lambda = 553$ mμ) and partly in the M-band ($\lambda = 610$ mμ). Both these bands diminished as soap was added and were replaced by a new band at much shorter wave-lengths ($\lambda = 480$ mμ), comparable in fact with those associated with absorption by the undissociated species of the dye insolvents of low dielectric constant[5]. When more soap was added, however, this band disappeared sharply and was replaced by a band at 610 mμ, in fact the normal M-band; the sharp spectral change occurred at the critical micelle concentration of the soap[12]. It is well known that the solubility of dyes is increased in the presence of soap micelles[13] and indeed there is evidence from diffusion data that sulphonated anthraquinone dyes form mixed micelles with surface-active agents[14]. We suggest that the basic dye ions are incorporated in the micelles of the soap and the aggregates of the chromotrope in such a way that they are effectively in a Faraday cage and are therefore subjected to a uniform electrical field. The charge distribution and thus the electronic configuration of the dye ion is therefore the same as that of the unperturbed dye ion, which absorbs in the M-band.

High-spin Five-coordinate Cobalt(II)

THE tridentate ligand 1,3-*bis*(2′-pyridyl)-2,3-diaza-1-propene, (paphy), when reacted with cobalt(II) chloride in ethanolic solution, yields several products. Two of these complexes are formulated as $Co(paphy)Cl_2$: one (designated α-) forms red plates and the other (β-) dark green needles. The β-isomer may readily be converted to the α-compound by heating in ethanolic medium.

The magnetic properties over a temperature range and the visible and near infra-red spectra have been suggested as a method of differentiating between octahedral and tetrahedral stereochemistries for Co(II) complexes. It is important to emphasize that this procedure allows a differentiation between these two stereochemistries, but may not finally establish either of them. The compounds discussed here may be used to elaborate this point.

The magnetic moment (5·04 B.M. at 293° K, $\theta = 13°$) and diffuse reflectance spectrum [absorption at 7,900 ($^4T_2$); 17,300 ($^4A_2$); 19,000, 20,500 cm^{-1} ($^4T_1$)] of the α-isomer lead us to believe that it contains Co(II) in octahedral environment, probably with chloride bridging of adjacent octahedra to attain CoN_3Cl_3 co-ordination. It is isomorphous with the corresponding compound $Ni(paphy)Cl_2$. However, the co-ordination stereochemistry for β-$Co(paphy)Cl_2$ is not clearly revealed by the spectral and magnetic data. The most intense absorptions in the reflectance spectrum occur at 4,500, 7,700 and 15,750 cm^{-1} and would most closely indicate strong field tetrahedral co-ordination (with parameters $D_q = 450$ cm^{-1}, $B' = 670$ cm^{-1}). But there are weaker bands at 12,200 and 20,000 cm^{-1} and the magnetic moment (4·84 B.M. at 294° K, falling to 4·56 B.M. at 80° K) is about 0·25 B.M. greater than that predicted for these parameters. We have therefore determined the crystal structure of this compound.

The complex, β-$Co(paphy)Cl_2$, crystallizes in the monoclinic system with cell constants: $a = 8·72$; $b = 11·93$; $c = 12·64$ Å; $\beta = 98° 2'$ and $Z = 4$. From systematic absences, the space group was uniquely determined as $P2_1/n$. Visual estimation of the intensity data collected by the Weissenberg multiple-film technique yielded 1,257 independent reflexions. The phase problem was solved by the 'heavy-atom' procedure using three-dimensional Patterson and Fourier syntheses. Isotropic least-squares refinement of the atomic parameters led to a value for R of 0·12, while the subsequent inclusion of anisotropic temperature factors has reduced this index further, to 0·095.

The stereochemistry of the molecule is illustrated in Fig. 1, from which the essentially square pyramidal geometry around the cobalt is apparent. The metal atom is 0·39 Å above the basal plane which contains all other atoms except the chlorine atom Cl(2). The average Co—N bond length is 2·12 Å and the angles N(1)CoN(2) and N(3)CoN(2) are both 74°. Angle N(2)CoCl(1) is 157°; N(2)CoCl(2) is 94°. There are no close inter-molecular interactions and the cobalt–cobalt vector is 4·62 Å.

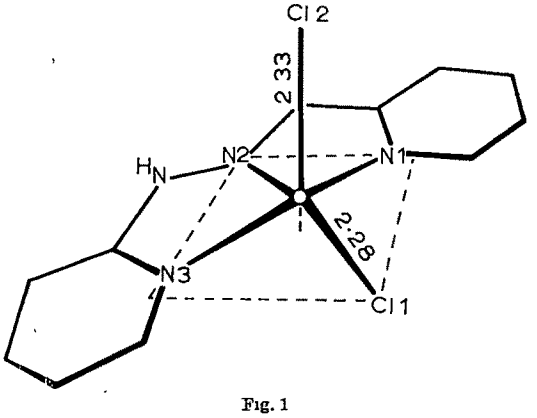

Fig. 1

Two other ML_3X_2 complexes with this stereochemistry, $Ni[CH_3As(CH_2CH_2CH_2As(CH_3)_2)_2]Br_2$ (ref. 1) and $(C_{14}H_{13}P)_3PdBr_2$ (ref. 2), have apical $M—X$ bonds considerably longer than the basal $M—X$ bonds, but in the present compound this difference is statistically just significant.

It is interesting to note that the ligand 2,2′,2″-terpyridyl, (terpy), which presents a tridentate nitrogen donor sequence closely corresponding to that of paphy, also forms a crystalline complex $Co(terpy)Cl_2$ (ref. 3). This is high-spin with a near infra-red and visible reflectance spectrum similar to that of β-$Co(paphy)Cl_2$. A comparison of the unit cell parameters and about 80 X-ray intensities from crystals of $Co(terpy)Cl_2$ and of $Zn(terpy)Cl_2$, in which there is trigonal bipyramidal stereochemistry[4], indicates that these two compounds are isostructural. A full three-dimensional refinement of both these terpy structures is in progress[5]. Trigonal bipyramidal geometry for $Co(terpy)Cl_2$ would be in contrast to the square pyramidal geometry for β-$Co(paphy)Cl_2$, but we believe that intermolecular crystal forces are a major factor influencing the co-ordination stereochemistry in these two compounds.

It is important to emphasize that a differentiation between a trigonal bipyramidal and a tetragonal pyramidal arrangement in molecules of this type is very often difficult and a reassessment of the geometry of $Zn(terpy)Cl_2$ implies a very close relationship with the paphy derivative reported here.

These complexes also provide further examples of high-spin five-co-ordinate cobalt(II), in addition to the compounds $[Co(Ph_2MeAsO)_4ClO_4]ClO_4.H_2O$ (ref. 6), *bis*(N-methylsalicylaldimato)Co(II) (ref. 7) and *bis*(N-β-diethylamineethyl-5-chlorosalicylaldimato)Co(II) (ref. 8).

Estimation of Nitrate by Nitration of 7-Hydroxy-4,8-dimethyl Coumarin

SKUJINS[1] proposed a colorimetric method of nitrate estimation using 7-hydroxy-4-methyl coumarin (I) as the reagent for nitration. The 3, 6 and 8 positions are activated for electrophilic substitution, but there is steric restriction to the entry of NO_2^+ to the 3 position.

(I) (II)

A mixture of products using Skujins's reagent and nitrate in a molar ratio of 4·5 : 1, and following the analytical procedure to be outlined later, was extracted with chloroform, and the resultant nitro derivatives subjected to paper chromatography using *n*-butanol–ammonia–water (8 : 30 : 62 v/v) as developing solvent. Three spots were observed with R_F values in agreement with 6-nitro,

* Kept for 4 h before reading. Absorbance increases slowly with time.
† Shoulder.
‡ Decomposes on melting.

8-nitro and 6,8-dinitro derivatives of the coumarin. These were synthesized by the methods of Shah and Mehta[2]. It was observed that the proportion of the dinitro compound in the mixture of products increased with reaction temperature.

7-Hydroxy-4,8-dimethyl coumarin (II) was synthesized from ethyl acetoacetate and 2-methyl resorcinol[3]. Only the 6 position of this reagent is available for nitration. Extraction and chromatography (as already outlined) of the products of nitration gave only one spot corresponding to 6-nitro-7-hydroxy-4,8-dimethyl coumarin. The formation of a dinitro derivative was avoided, thereby improving reproducibility and allowing the use of lower molar ratios of reagent to nitrate than proposed by Skujins[1]. Data from the absorption spectra of the foregoing nitro coumarins are given in Table 1.

The absorption peak at 420 mμ for the 6-nitro-7-hydroxy-4,8-dimethyl coumarin in ammonia/ammonium sulphate solution made it possible to use a simple colorimeter, equipped with a violet filter, in the analytical procedure.

The recommended procedure for estimating nitrate in soils is: (1) shake 5 g of the soil with 15 ml. of extraction solution (silver sulphate (5 g), anhydrous sodium sulphate (71 g), copper sulphate (8·3 g) and sulphuric acid (5·6 ml.) per l.) for 45 min. (2) Separate the solution by centrifugation or by standing overnight. (3) Mix supernatant (5 ml.) with 10 M sodium hydroxide (0·3 ml.) and filter. (4) Transfer cleared filtrate (0·5 ml.) to a 6 in. × 1 in. test-tube and cool in an ice bath. (5) Add 1·0 ml. reagent solution (0·03 per cent 7-hydroxy-4,8-dimethyl coumarin in sulphuric acid) and transfer to a boiling water bath for 10 min. (6) Cool again in ice and rapidly add 6 M ammonia solution (10·0 ml.). (7) Read absorption after 20 min at 420 mμ or with an Evans Electroselenium, Ltd., colorimeter equipped with an *OB*10 filter.

A linear calibration curve from 0 to 35 p.p.m. nitrate nitrogen was obtained using the aforementioned colorimeter and filter. The absorbance in ammonia/ammonium sulphate varies with ammonia concentration, and the calibration of the colorimeter should be re-determined for each batch of 6 M ammonia used.

Chloride interferes above 50 μg/ml. which necessitates the inclusion of silver sulphate in the extraction solution. The interference was found to be the chlorination of the coumarin by nitrosyl chloride. The problem of chloride interference and other chemical aspects of the estimation of nitrate by the nitration reaction will be discussed more fully elsewhere.

Elution Volume versus Reciprocal Elution Volume in the Interpretation of Gel-filtration Experiments

RECENTLY, Winzor and Nichol have suggested[1,2] that if velocities in the conventional moving boundary equation[3–5] for free electrophoresis are replaced by the reciprocals of corresponding elution volumes, the equation is then applicable to gel-filtration experiments.

At first sight this is a reasonable transformation since the velocity of a boundary within a gel-filtration column is inversely proportional to the volume of effluent that leaves the column during the time of passage of the boundary down the column. Nevertheless, further consideration leads to the different conclusion that it is not the reciprocal of the elution volume but the elution volume itself which must replace the corresponding velocity in the moving boundary equation. This can be shown as follows.

Let $\bar{V}$ be the constituent elution volume of a substance at constituent concentration w, and let $\bar{V} + d\bar{V}$ be the corresponding volume for a concentration $w + dw$. Then if a solution of concentration w is poured into a column that initially contains only solvent, the substance appears in the effluent, at a concentration w, when a volume $\bar{V}$ has passed through the column, volumes being estimated by constructing the hypothetical equivalent sharp boundary[6] on the recorded concentration profile of the substance in the effluent. At the moment when the substance first appears in the effluent, the column contains a quantity $w\bar{V}$ of substance. At this moment let the concentration of the inflowing solution be raised to $w + dw$ and the influx continued until the differential boundary so formed (estimated again as the hypothetical equivalent sharp boundary) appears in the effluent. The further volume that has been added to achieve this, say, V, represents the elution volume of the differential boundary. The whole column now contains a quantity $(w + dw)(\bar{V} + d\bar{V})$ of substance and the effluent a quantity wV. The sum of these two quantities must equal the total quantity poured into the column. Therefore:

$$(w + dw)(\bar{V} + d\bar{V}) + wV = w\bar{V} + (w + dw)V \qquad (1)$$

which simplifies to:

$$V = \bar{V} + w\frac{d\bar{V}}{dw} = \frac{d(w\bar{V})}{dw} \qquad (2)$$

when second-order differentials are neglected. A comparison of equation (2) with the conventional moving boundary equation[4,5,7]:

$$v = \frac{d(w\bar{v})}{dw} \qquad (3)$$

where v is the velocity of a differential boundary between solutions of concentration w and $w + dw$, and $\bar{v}$ is the constituent velocity of the substance, shows that elution volumes have replaced velocities, but that in other respects the equations are mathematically identical. This has

the convenient consequence that all the procedures, for example integration to determine concentration profiles[8], that have been worked out for homogeneous solutions with equation (3) can be duplicated for chromatography and gel-filtration with equation (2) simply by a change of symbol.

It is important to realize that equation (3) is not the moving boundary equation for the boundary within the column. The equation for the column must take into account the substance in the stationary as well as the mobile phase, and as is well known[9,10], can be written in the form:

$$v = \frac{\mathrm{d}(W\bar{v})}{\mathrm{d}(W)} \qquad (4)$$

where W is the total quantity of substance per unit length of column. Naturally equation (4) should transform to equation (2) since the elution record is a consequence of the flow within the column. That it actually does so follows from the fact that besides v and $\bar{v}$ being inversely proportional to V and $\bar{V}$ respectively, W is directly proportional to the product $w\bar{V}$. Substitution for v, $\bar{v}$ and W in (4) and cancellation of the coefficients of proportionality lead to:

$$\frac{1}{V} = \frac{\mathrm{d}\left(w\bar{V}\frac{1}{\bar{V}}\right)}{\mathrm{d}(w\bar{V})} = \frac{\mathrm{d}w}{\mathrm{d}(w\bar{V})} \qquad (5)$$

which is identical with (2). The paradox of velocities being replaceable by elution volumes has disappeared because both sides of the equation are inverted when the parameters for the column are replaced by their equivalents from the elution record.

Table 1. DISSOCIATION CONSTANT K FOR THE REVERSIBLE REACTION BETWEEN TRYPSIN AND SOYBEAN TRYPSIN INHIBITOR

pH	$10^7 \times K$ (mole l.$^{-1}$) From gel-filtration by equation (34), ref. 12, using (a) Reciprocal volumes	(b) Volumes	By potentiometric technique[11]
4·25	15	10·8	10·5
4·50	4·2	2·8	2·3
4·75	0·9	0·5	0 7

Finally, in Table 1, three sets of values for the equilibrium constant of the reaction between trypsin and soybean trypsin inhibitor are compared. The first set is taken from Winzor and Nichol's paper[2], and is calculated from the results of their gel-filtration experiments by substituting the reciprocals of elution volumes for velocities in a particular form of the moving boundary equation (equation (34) in ref. 12). The second set is calculated in the same way except that elution volumes themselves, instead of their reciprocals, are used to replace velocities. The third set derives from the potentiometric experiments of Lebowitz and Laskowski[11]. Clearly, the use of elution volumes rather than their reciprocals is supported by the closeness of the values of the second set to those of the third, and in fact the agreement is then to within the accuracy of measurement (0·1 ml.) of the elution volumes.

BIOPHYSICS

Properties and Structures of Lecithin Monolayers containing Potassium Ions or Acetylcholine

MANY experiments have been carried out with monolayer films of lecithin[1,2], but reports of them do not fully describe the details of phospholipid preparations. On the other hand, three-dimensional liquid crystal phases of mixtures of phospholipids and water have been studied in detail[3,4], and it has been shown that the phases are greatly influenced by the freshness of lecithin and also of the phospholipids. Aged phospholipids are not able to form liquid crystals. The electrical resistance of the fresh phospholipid bilayer at the water–water interface decreases rapidly 30 min after spreading the films in the presence of oxygen[5]. Our monolayer films of lecithin were also influenced by the degree of freshness of the lecithin.

Monolayer films of lecithin were spread on the surface of water in which salts had been dissolved. Lecithin was extracted from egg yolk[6] and dissolved in purified benzene. Water, salts and also cholesterol were purified as much as possible, particularly to eliminate the surface active substances. Surface pressures were measured with the vertical plate method and the flotation method. The curves produced by plotting surface pressures against surface areas are analogous to ones which have been produced by other workers (Fig. 1)[1,2]. If, however, the substrates on which the films are spread contain potassium ions or acetylcholine, regardless of the existence of the other ions, the surface pressure measured with the vertical plate method for fresh lecithin exhibits a plateau at large surface areas. On the other hand, plateaux were not observed in the force-area curves for substrates containing the same potassium ions or acetylcholine when the surface pressure was measured by the flotation method.

To find out whether the vertical plate was contaminated during the spreading of the samples, the surface pressure was measured by the vertical plate method, and with the lecithin spread on distilled water. The surface pressure was naturally almost zero at the larger surface

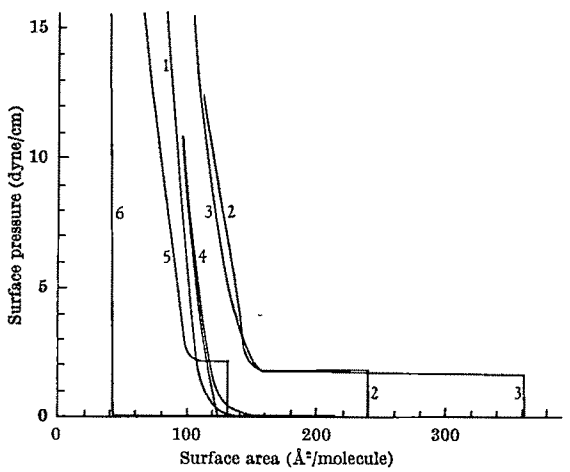

Fig. 1. Curves of surface pressure versus surface area for lecithin and other substances The abscissa unit is Å² per molecule of the substances, but for the mixture of lecithin and cholesterol, total surface area (Å²) per number of total molecules of the mixture. (1) Fresh lecithin monolayer on the distilled water. If the substrate contained sodium chloride, calcium chloride, or barium chloride, the curves were displaced over 20 Å²/molecule to the right from this curve, but they had the similar shapes to this curve. (2) Fresh lecithin monolayer on the potassium chloride aqueous solution (8 mmoles/l.). (3) Fresh lecithin monolayer on the acetylcholine aqueous solution (1 mmole/l.). (4) Fresh lecithin monolayer on the distilled water measured reversibly with the floating method. (5) Monolayer of the mixture of fresh lecithin and cholesterol (mol. ratio, 3 : 1) on the aqueous solution of potassium chloride (6 mmoles/l.). The mean molecular weight of this mixture is less than the lecithin one, then the curve displaced to the left. (6) Cholesterol monolayer on the distilled water. All curves except curve 4 were measured with vertical plate method. The plateaux were seen only on the curves 2, 3 and 5

area; however, keeping this surface area of film constant, a few ml. of aqueous potassium chloride solution (about 5 weight per cent) or aqueous acetylcholine solution (about 10 weight per cent) were gradually added to the substrate at that part of the surface kept free from lecithin by a movable barrier. The vertical plate was then raised a few mm, and there was a corresponding increase of the surface pressure of the lecithin film from zero to a few dynes per centimetre. On the other hand, with sodium chloride, calcium chloride or barium chloride (in aqueous solutions) added in this same way, the vertical plate was not raised up at all. When the surface pressure was measured with the flotation method, this phenomenon was not seen. It is therefore natural to suppose that the plateau of the force-area curves originates in contamination of the vertical plate with the benzene solution of lecithin during the initial spreading process, although this is not certain. The mixture of lecithin and cholesterol (mol. ratio, 3 : 1) produced results the same as with lecithin alone, but other mixtures of these (mol. ratio 1:3) did not show the plateaux[7].

What is the reason for the appearance of the plateaux? Supposing that the vertical plate is not contaminated, there are two possibilities. One is that the surface pressure of the lecithin film near the vertical plate, where the surface and also the monolayer film are curved, may be larger than the surface pressure of the same film at the other main flat surface. This means that the structures of the curved monolayer films are different from those of the flat monolayer[8]. If this is so, it may be thought that there are a few structures which differ from one another according to the sizes and the signs (upward or downward) of the radius of the lecithin films. Potassium ions or acetylcholine would make the lecithin film curve so that its centre of radius would exist on the hydrocarbon sides of the film under conditions similar to those in biological cells. As previously mentioned, mixtures of water and lecithin form the liquid crystal phases of three dimensions[3,4]. In the same way, lecithin may form similar two-dimensional phases with water at water surfaces, and they are easily changed into one another by ions and acetylcholine[9] and also by other surface-active substances.

The second reason for the appearance of the plateaux may lie in the two-dimensional rheological properties of the lecithin monolayer. The phases of this two-dimensional structure were usually disturbed during the measurement of surface pressure with the flotation method and the phases may have been changed into one another much as in thixotropy; but once changed, they would not be able to return to the initial phases. We have experienced similar thixotropic phenomena in the measurements of surface pressure of rhodopsin monolayers[10], although this has not been reported. Of the two possible explanations, we prefer the former.

The structures of fresh phospholipid monolayers are thus thought to be very different from those of other monolayers—for example, those of stearic acid. In the presence of K^+ or of acetylcholine, the structure would have a great many pores, each full of water molecules. We can now construct a membrane model for a biological cell. The structure of the outer side of the membrane may differ from that of the inner side, and the membrane will have a great many hydrated pores. Hydrated ions pass through a pore, but with difficulty, because of the mutual steric hindrance of the hydration of the pore and the hydration of the ions. For this reason K^+ can more easily pass through a pore than Na^+ (refs. 11–13). Water molecules can pass through the pore as easily as they travel in water or in ice in three dimensions[5,14].

It is certain that there are many types of biological membranes, but each structure would be one of the two-dimensional liquid crystal phases, some of which are easily changed by some ions or molecules and, of course, by surface-active substances. This model will make clear the other important phenomena which are related not only to the more familiar membranes but also to the surfaces of large biological molecules, especially lipoproteins, bacteriophages and so on.

Determination of the Diffusivity of Water in Biolcgical Tissue

THE problem of dehydrating vegetable tissue has been investigated for many years. We have attempted to establish a method for calculating the diffusion coefficient of water during dehydration of several systems. From the work of Carslaw and Jaeger[1], Crank[2] has developed a series of equations for diffusion with surface evaporation from porous membranes of different geometrical shapes. We have considered the cell structure of vegetables to approximate to a porous membrane and have applied Crank's equations for a plane sheet and a cylinder to vegetable dehydration.

Several attempts have been made to calculate diffusion coefficients in tissue. Sherwood[3] used a degenerate form of the equation we use, Benkar and Salkins[4] used a similar type of equation and Haque and Eubank[5] also used an equation developed from Crank's work. Fish[6] has investigated the diffusion of water through starch gel and blanched potato.

Crank[2] has developed equations for surface evaporation from (*a*) a plane sheet and (*b*) a cylinder. For a sheet the equation is:

$$\left(\frac{M_t}{M_\infty}\right) = 1 - \sum_{n=1}^{\infty} \frac{2L^2 \exp\left(-\beta_n^2\, Dt/l^2\right)}{\beta_n^2\left(\beta_n^2 + L^2 + L\right)} \qquad (1)$$

where β_n are positive roots of $\beta \tan \beta = L$, $L = l\alpha/D$ and $l = \frac{1}{2}$ sheet thickness, M_t = mass lost at time t, M_∞ = total mass lost, t = time, D = diffusion coefficient, α = evaporation constant.

For a cylinder:

$$\left(\frac{M_t}{M_\infty}\right) = 1 - \sum_{n=1}^{\infty} \frac{4L^2 \exp\left(-\beta_n^2\, Dt/a^2\right)}{\beta_n^2\left(\beta_n^2 + L^2\right)} \qquad (2)$$

where β_n are roots of $\beta J_1(\beta) - LJ_0(\beta) = 0$ and $L = a\alpha/D$, a = radius of the cylinder and other variables have been defined here.

Equations (1) and (2) are true for one-component diffusion at constant temperature. These equations were used to evaluate Dt/l^2 and Dt/a^2 in terms of a range of values of L ($0 - \infty$) for each of a series of values of M_t/M_∞ (0–1·0).

Before use could be made of the equations, the evaporation constant had to be determined. α, here defined as mass transfer per unit area per unit time per concentration difference, was determined experimentally by observing

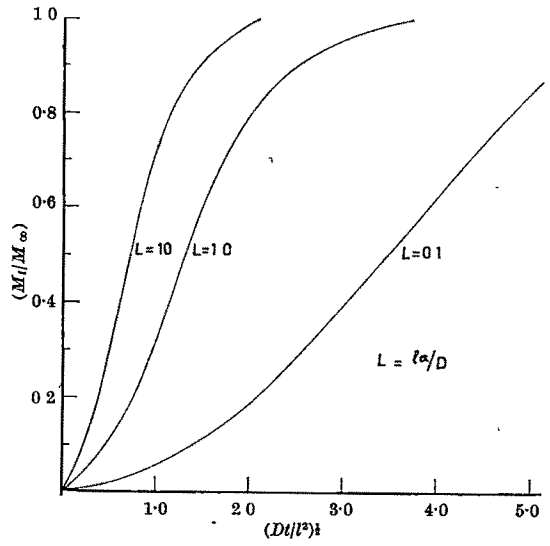

Fig. 1. The solution of equation (1) given as M_t/M_∞ against $(Dt/l^2)^{\frac{1}{2}}$ for a number of values of $L = l\alpha/D$

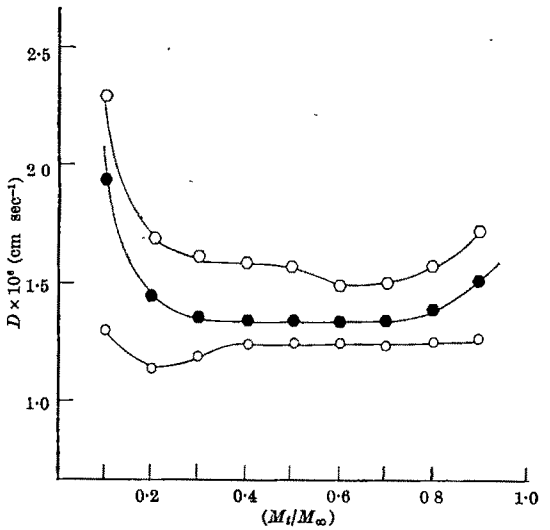

Fig. 2. The variation of D with M_t/M_∞ for a group of cylinders o Pentland Crown potato dehydrated at 31° C and zero humidity

the evaporation of water from filter paper. A value of $\alpha = 1{\cdot}80 \times 10^{-5}$ cm sec^{-1} was obtained. α was also determined from the dehydration curves by eliminating L and D from equations (1) and (2). The value thus obtained varied from $\alpha = 1{\cdot}20 \times 10^{-5}$ cm sec^{-1} to $\alpha = 2{\cdot}20 \times 10^{-5}$ cm sec^{-1} depending on the age and variety of potato.

As there is an infinite family of curves relating M_t/M_∞ to time (Fig. 1), it is important to select the curve relevant to the experimental data. To do this, the following procedure was developed: $L = \alpha R/D$ and let $X = Dt/R^2$ where $R = l$ or a; then $LX = \alpha t/R$.

The theoretical results determined allow us to plot L against LX for any value of M_t/M_∞. LX can be determined from the experimental results since α, t and R are known. We can thus, using the experimental values of LX on the theoretical L against LX curve, determine L and, from the definition of L, determine D.

Disks (0·85 cm diameter; 0·8–1·5 mm thick) and cylinders (0·4 cm diameter; 1·0–1·6 cm high) were obtained from potato using cork borers and a section razor. The cork borer 0·85 cm in diameter was fitted with a plunger on a screw thread so that known thicknesses of disks could readily be cut. The sections were suspended (in an oven at 30°–31° C and zero humidity) from a Stanton recording balance, which continually traced the weight loss. The oven fitted below the balance and could be raised and lowered to allow exchange of samples. The heating coil of the oven, composed of alternate coils of copper and manganin wire, also acted as the sensing element of the oven and was wound on an aluminium former. Inside the oven was a large gauge gauze cylinder, 2 cm in diameter, concentric with the former. Between gauze and former was placed silica gel.

The varieties of potato used were Arran Banner, Binjie, King Edward and Pentland Crown. Samples were taken from the medulla of each variety where a uniform cell structure is found.

It was found that the sample shrank in direct proportion to the amount of water lost up to 95–100 per cent loss. This was taken as 100 per cent for the purposes of calculation. The dimensions of the samples used were also such that we neglected edge effects and considered diffusion as taking place in one direction only.

The variation of D with M_t/M_∞ is shown in Fig. 2 for a group of cylindrical sections of Pentland Crown. It is obvious that there is little variation between members of a group of dehydrations carried out successively. Fig. 3 shows D against M_t/M_∞ for cylinder and disk of Arran Banner and Pentland Crown. Each curve shown is the average of a group of dehydrations. The agreement between the two cylindrical systems is exceedingly good and in the range $M_t/M_\infty = 0{\cdot}2$–$0{\cdot}9$, the agreement between cylinders and disks is within a factor of 2. Table 1 demonstrates the variation of D between varieties and within groups for a number of potatoes.

Table 1. VARIATION OF DIFFUSIVITY WITH VARIETY AND GEOMETRIC SHAPE FOR A NUMBER OF SAMPLES OF POTATO DEHYDRATED AT 31° C AND ZERO HUMIDITY

To obtain a direct comparison of theory and experiment, a correlation curve was constructed. The experimental curve of M_t/M_∞ against $(t/R^2)^{\frac{1}{2}}$ was first drawn. This has the typical sigmoid shape of the family of curves (Fig. 1). The theoretical curve of M_t/M_∞ against $(Dt/R^2)^{\frac{1}{2}}$ requires several assumptions in its construction. The major assumption is that as M_t/M_∞ increases, we can change L by an amount proportional to the change in R. Taking small intervals of M_t/M_∞, a value of L can be estimated and the increment in Dt/R^2 over the interval thus found. Combining the increments in Dt/R^2, a curve of M_t/M_∞ against Dt/R^2 and $(Dt/R^2)^{\frac{1}{2}}$ can be drawn. Assuming that theory and experiment agree at one point (say, $M_t/M_\infty = 0{\cdot}2$), a comparison of $(M_t/M_\infty)_T$ obtained from $(Dt/R^2)^{\frac{1}{2}}$ can be made with $(M_t/M_\infty)_E$ obtained from $(t/R^2)^{\frac{1}{2}}$. The curve obtained of $(M_t/M_\infty)_T$ against $(M_t/M_\infty)_E$ should be a straight line of slope 45°. It will be seen from Fig. 4 that close agreement is obtained with theoretical prediction, suggesting that the calculati[illegible] procedures are valid.

In view of the fact that samples were taken from different tubers of differing maturities, the results shown here are in good internal agreement for a biological system.

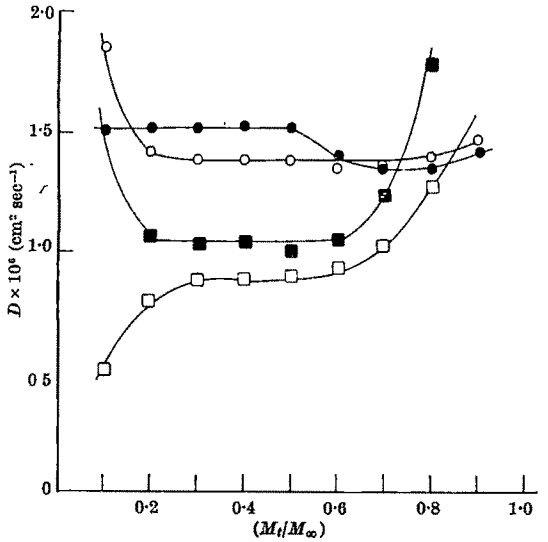

Fig. 3 The variation of D with M_t/M_∞ for different geometric shapes of samples. The samples are taken from Pentland Crown (○, cylinder; □, disk) and Arran Banner (●, cylinder; ■, disk) potatoes and each curve is the average of several dehydrations at 31° C and zero humidity

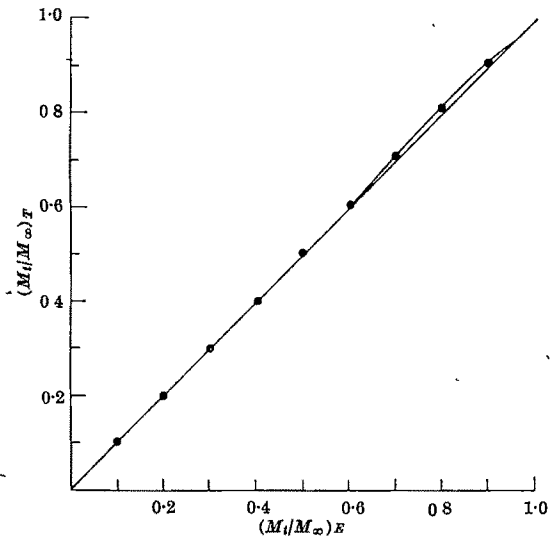

Fig. 4. Correlation curve to compare theoretical and experimental results as functions of M_t/M_∞

The value of D obtained is of the order of 10^{-6} cm² sec⁻¹, whereas the coefficient of self-diffusion for water obtained by Graupner and Winter[7] is $2{\cdot}04 \times 10^{-5}$ cm² sec⁻¹ at 25° C. It would thus appear that diffusion of water in potato is more than one order less than diffusion of water in water. There thus appears to be a greater resistance to water transport in potato than in water.

There is much greater scatter of results at 10 per cent dehydration than later in the dehydration. This scatter is possibly due to surface water obtained in cutting the samples and also to errors in measurement of the time of dehydration. Errors in timing decrease as the dehydration proceeds and the sample surface rapidly reaches equilibrium with the surrounding atmosphere, so that as dehydration proceeds the results increase in accuracy. It should thus be possible to get very accurate results over the last 10 per cent of dehydration. Before doing so, a number of equations must be solved and this programme has not yet been carried out. The programme is an extension of that described previously involving evaluation of equations (1) and (2) at small intervals between $M_t/M_\infty = 0{\cdot}9$ and $M_t/M_\infty = 1{\cdot}0$.

Fish[6] has obtained a value for D of $2{\cdot}4 \times 10^{-7}$ cm² sec⁻¹ at 25° C for the coefficient of diffusion of water in starch gel and a similar value for blanched potato cells of high starch content. This value decreases rapidly at below 30 per cent moisture content on a dry weight basis. This is in reasonable agreement with the value which we obtained in potato at a slightly higher temperature. The difference between the values may be explained by the different starch contents.

The advantages of the method are that it is more rapid, can be carried out on the tissue immediately after cutting before enzymatic attack occurs and it requires only a few simple measurements.

BIOCHEMISTRY

Substrate Specificity of Mycodextranase

Mycodextran (nigeran) is an unbranched polysaccharide composed of a regular alternating sequence of α-(1→3) and α-(1→4) linked glucopyranosyl units. It is produced in the mycelia of various species of moulds[1]. Reese and Mandels have recently reported[2] the isolation and partial purification of an inducible glucanase (mycodextranase) produced in the culture filtrates of selected species of fungi grown on a medium containing mycodextran as a carbon source. The enzyme is an endoglucanase that hydrolyses nigeran to produce hexameric and tetrameric units which are subsequently hydrolysed to produce the disaccharide nigerose (*O*-α-D-glucopyranosyl-(1→3)-D-glucose) as the final product[2].

On the basis of their experimental results, Reese and Mandels suggest that this α-glucanase is specific for the nigerosyl moiety in the polymeric chain, binding to this group and then splitting the glycosidic bond immediately to the right of the α-(1→3) linkage. Further, they suggest that this enzyme is not specific for α-(1→4) linkages (which is the one cleaved in nigeran by this enzyme). Other research[3-5] has suggested that certain β glucanases (such as laminarase and cellulase) are not specific for the linkage they attack but rather are specific for the substitution on the glycosyl unit that becomes the reducing group of the unit liberated[4].

We wish to present evidence that the enzyme mycodextranase does require α-(1→4) linkages for its action and that these linkages must be located in specific positions in the repeating sequence(s) relative to the α-(1→3) linkages also present.

Growth of *Aspergillus niger NRRL* 326 on glucose or sucrose results in the formation of nigeran. However, growth of this organism on starch results in the formation of a new linear intracellular polysaccharide ($[\alpha]_D^{20} + 242°$ (c 0·6, NaOH)) which contains 87 per cent α-(1→3) and 13 per cent α-(1→4) linkages[6] and differs from nigeran in that it is insoluble in hot water. Treatment of this 'pseudonigeran' with periodate followed by reduction with sodium borohydride and mild acid hydrolysis gives polymer[6] which is insoluble in water, consumes no periodate and has a high positive optical rotation ($[\alpha]_D^{20} + 135°$

(*c* 0·3, dimethyl sulphoxide)). It yields only glucose on acid hydrolysis. It is evident that this polysaccharide is a linear α-(1→3) glucan. This novel substrate and 'pseudonigeran' were used to gain more information on the specificity of mycodextranase.

Mycodextranase was isolated from culture filtrates of *Penicillium melanii* and purified by the method outlined by Reese and Mandels[2]. The final product has a protein concentration of 34 μg/ml.[7]. Assay mixtures were set up as follows: 60 μmoles sodium citrate buffer, *p*H 4·5; 2·0 mg polysaccharide and enzyme were incubated together in a total volume of 1·2 ml., at 43° C. The high assay temperature is permitted by the thermal stability of this enzyme. Aliquots of the reaction mixture were withdrawn and assayed for reducing power[8]. Liberation of reducing power was proportional to enzyme concentration over at least a four-fold increase in enzyme concentration. A unit of enzyme activity is defined as that amount causing the liberation of 1·0 micromole of glucose equivalent from nigeran in 10 min under the above conditions.

The purified mycodextranase readily hydrolysed nigeran but had no activity toward starch or maltose. These activities (amylase and maltase) are well separated from the mycodextranase by DEAE-'Sephadex' chromatography. Reese and Mandels have shown the enzyme to be highly specific when tested with a wide variety of polysaccharides[2]. Incubation of the α-(1→3) glucan or 'pseudonigeran' with 1·2 units of the enzyme for very long periods (up to 24 h) and at polymer concentrations up to 0·4 per cent failed to yield any detectable reducing power while nigeran was rapidly hydrolysed under the same conditions. Enzymatically liberated reducing groups can be readily detected by their reduction with tritiated sodium borohydride to labelled alcohol groups, and this principle was used to develop a more sensitive test of enzymatic cleavage. 2·5 mg samples of α-(1→3) glucan and 'pseudonigeran' were reduced with sodium borohydride washed and incubated as above for 17 h in the presence and absence of mycodextranase. Twenty μg of glucose were also incubated without enzyme. These reaction mixtures were then made alkaline and treated with excess tritiated sodium borohydride (20×10^6 DPM). After 4 h the *p*H was adjusted to 2 with hydrochloric acid and the excess tritium removed by exchange with water and repeated evaporation of the solution to dryness at 40° C. The residues were then suspended in 1·0 ml of water and 10 μl. withdrawn for counting. No radioactivity above control level was incorporated into polysaccharide samples incubated with mycodextranase. (A small amount of activity above background was present in both control and reaction samples.) The sample of glucose which had been reduced with tritiated sodium borohydride had approximately 2·5 per cent of the added radioactivity ($5{\cdot}1 \times 10^5$ DPM) incorporated. From this amount of tritium incorporated in 20 μg glucose it may be calculated that if one glycosidic bond in 250 were split by the mycodextranase in either polysaccharide preparation, 2,500 DPM would be present in the aliquot taken for counting.

Nigeran polyalcohol was prepared by periodate oxidation and sodium borohydride reduction of nigeran[9]. The parent nigeran consumed 0·51 mole of iodate per mole of anhydrohexose unit. The polyalcohol was desalted on 'Sephadex *G*-25' and a portion subjected to acid hydrolysis. Only glucose, erythritol and glycerol were detected after paper chromatography of the neutralized hydrolysate in two solvent systems. When a 5-mg sample of the polyalcohol was tested for hydrolysis with 1·2 units of mycodextranase no reducing power was liberated, even after 4 h of incubation. This evidence indicates that for demonstrable activity the enzyme requires an intact glucosyl residue immediately to the right or left (or both) of the glucosyl unit which is substituted in its 1 and 3 positions.

It appears, therefore, that this enzyme is specific for more than just nigerosyl moieties to allow enzyme binding since the α-(1→3) glucan and the 'pseudonigeran' provide large areas of uninterrupted α-(1→3) linkages for this purpose. Specificity for the bond being cleaved certainly appears to play a part in the mechanism of action. The failure of the enzyme to liberate detectable reducing groups from the 'pseudonigeran' poses some interesting questions. Since the polymer contains 13 per cent α-(1→4) linkages and is linear, this means slightly more than one unit in eight is linked α-(1→4). If the (1→4) links occur in a regular fashion in the chain, the largest α-(1→3) glucan that could be liberated on periodate oxidation, borohydride reduction and mild acid hydrolysis would be seven glucose units in length and would be water soluble. Since the glucan formed is not soluble this indicates the α-(1→4) groups must be in close proximity to one another in the 'pseudonigeran', possibly in one or two continuous segments. If this is the case and the enzyme cleaved the one or two α-(1→4) linkages in this polymer which would be adjacent to an α-(1→3) linkage, then the radioisotope technique employed in the present investigation should have detected this. Perhaps 'pseudonigeran' is not attacked because the relationship of two α-(1→4) linkages to one another is not that required for the binding and(or) release of a hexameric or tetrameric unit as is the case with nigeran. Another explanation that would account for both the failure of the enzyme to attack and the water insolubility of the periodate-treated material is that 'pseudonigeran' is a mixture of a α-(1→3) linked glucan and a periodate susceptible contaminant. Further work is in progress to elucidate the structure of 'pseudonigeran'. It remains clear, however, that at least part of the specificity of mycodextranase must involve the bond being hydrolysed in addition to the moiety being bound and that the Perlin mechanism[4] will not explain the action of this enzyme.

Chemical Phenotypes of Pteridine Colour Forms in *Pieris* Butterflies

THE biochemical analysis of genetic variation has only rarely been extended to hereditary variation isolated from wild populations. This communication deals with a series of colour forms, whose genetics has been studied[1–3], and which were originally isolated from wild populations of the *Pieris napi-bryoniae* species complex. These genotypes govern changes in pteridine content of the scales of the wings, and have here been analysed by methods developed for investigations on pteridines of the related *Colias* butterflies[4,5].

The wild-type phenotype of the *P. napi-bryoniae* complex has yellow ground colour on the underside of the hindwing and on the tip of the forewing, and white ground

colour on other parts of the wings. Black markings, composed of melanin-bearing scales, occur on both sides of the wings; the appearance of 'green' markings on the hindwing underside results from the distribution of black scales among pteridine-bearing scales, and no green pigment is actually present. In the colour form 'subtalba', all normally yellow ground colour is turned white. Two 'sulphurea' colour forms are known: one ('bright yellow') shows pronounced yellow ground colour on all wing surfaces, the other ('pale yellow') has a very pale yellow colour in those areas usually white, while preserving the normal yellow areas. (In certain populations some or all of the females, but never the males, have the white upperside colour replaced by an ochreous yellow; this sex-limited variation is not considered here.) None of these variants affects the black markings. Wild-type and all three variant colour forms are maintained in culture by one of us (S. R. B.) and specimens for analysis are shipped to the other (W. B. W.) to be stored frozen until analysed.

For reasons explained later, wild-type specimens of *Pieris brassicae* L. were also analysed. These had been obtained commercially, and were labelled "All bred Cambridge (England) 1963" by the dealer.

The methods used for pteridine identification have been described previously[4]. Quantitative analysis is performed as follows: Extraction of the pteridines is accomplished by heating one fore and one hindwing of a specimen in 0·5 ml. *p*H 10 carbonate–bicarbonate buffer[6] on a boiling-water bath for 1 min. After removal of the wing residues, 50 μl. (for electrophoresis) or 100 μl. (for chromatography) of the solution are streaked on to strips of Whatman No. 3*MM* chromatography paper with calibrated micropipettes. Electrophoresis is performed at *p*H 10 in a Markham–Smith apparatus[7]; descending chromatography is performed with the organic layer of 4 : 1 : 5 *n*-butanol : acetic acid : water as solvent. Separated fractions are located by fluorescence under 254 mμ ultra-violet light and eluted from the paper with 2 ml. 0·1 N sodium hydroxide for 1·5 min at 100° C; absorbances are then determined against eluates of blank strips in a Zeiss *PMQ* II spectrophotometer. Under these conditions, sepiapterin decomposes (after separation, during elution) to 2-amino-4-hydroxy-6-carboxylpteridine; while the decomposition can be avoided, in this work it was allowed to proceed to completion and sepiapterin was assayed as the carboxyl derivative. Relevant R_F values, migration distances, absorption peaks, and extinction coefficients are presented in Table 1. Overall reproducibility of the technique is about ±3 per cent. Data are converted to total μmoles per insect.

In one brood, it was necessary to examine the content of only those areas which are yellow in wild-type (see following explanation). Scales of those areas normally white were removed from one fore and one hindwing of the specimen with a camel-hair brush moistened with glycerol, leaving the scales required for analysis on the wings. The wings of the insect's opposite side were analysed whole.

The following pteridines were found in *Pieris*: xanthopterin, isoxanthopterin, leucopterin, erythropterin, sepiapterin, 2-amino-4-hydroxy-6-carboxylpteridine. The carboxylpteridine is perhaps not a natural product but may result solely from decomposition of sepiapterin *in situ* or during extraction (not to be confused with the intentional conversion of sepiapterin to the carboxylpteridine used in the assay procedure). Its concentration is less than 10 per cent that of sepiapterin, and thus it is in measurable amounts only in 'bright yellow' specimens. Since the changes in its amount exactly parallel those of sepiapterin, it has not been tabled here. Erythropterin was found only in *P. brassicae*. Uric acid, present in all the *Pieris*, is found with isoxanthopterin on the chromatograms, but has no absorbance at 339 mμ so that it does not interfere with the isoxanthopterin assay. It does not correlate with any of the genetic forms.

From the quantitative results, presented in Table 2, it may be seen that sepiapterin is responsible for the yellow pigmentation of *Pieris napi* L. The action of the 'subtalba' allele is to eliminate sepiapterin; the action of the 'sulphurea' alleles is to raise sepiapterin above normal levels. In brood 1963-*r*, areas yellow in wild-type were analysed separately from whole wings in wild-type and 'bright yellow' phenotypes, to see whether in the latter form sepiapterin increased in normally yellow areas as well as normally white areas; in fact, it does, though not to such an extent. In the 'bright yellow' form, the colourless isoxanthopterin and leucopterin are significantly reduced

in comparison to wild-type. We appear to be dealing here with changes in kinetic balance throughout the pteridine metabolic pathway, resulting probably from a rate change at some individual reaction step. It is of interest that the colour forms appear to be allelic (or very closely linked)[1,2], and that a dominance order exists among them such that, in any pairwise combination of the three variant alleles and wild-type, that allele yielding less yellow when homozygous is dominant in the heterozygote. Further investigations of this phenomenon are planned.

While the work on *P. napi* was in progress, Harmsen[8] reported finding xanthopterin, leucopterin, isoxanthopterin and erythropterin in wild-type *P. brassicae*, and reported that a yellow form ('jauni'), of that species had increased amounts of xanthopterin and erythropterin. His failure to find sepiapterin stimulated us to examine wild-type *P. brassicae*, which as shown in Table 2 does contain small amounts of sepiapterin, similar in quantity to erythropterin. We are not able to explain the discrepancy, since Harmsen did not give sufficient account of his separation methods and gave no criteria for pteridine identification. The *P. brassicae* 'jauni' form cannot be truly analogous to the *P. napi* 'sulphurea' forms in any case, since the latter contain no erythropterin and show no increase of xanthopterin. It would be of interest to know whether sepiapterin increases in the *P. brassicae* 'jauni' form.

We thank Dr. C. L. Remington for his advice and suggestions.

Effect of Vitamin A Deficiency on the Incorporation of ^{14}C-Leucine into Tissue Proteins of Rats

THOUGH vitamin A is known to be essential for growth and to be involved in specific functions in the body such as the visual process and mucopolysaccharide synthesis[1], direct involvement of vitamin A in the regulation of protein metabolism has not been clearly established. There is, however, some indirect evidence pointing to a relationship between vitamin A and protein metabolism. Thus the level of protein in the diet has been shown to influence the storage of vitamin A in the liver and its utilization[2]. Serum proteins, especially serum albumin, have been shown to be lowered in vitamin A deficiency in rats[3] and swine[4]. A study of the capacity of tissue proteins to incorporate amino-acids in rats deficient in vitamin A may throw light on the possible direct role of vitamin A in protein utilization. In such a study we have used ^{14}C-amino-acids.

Thirty-four weanling male rats were divided into two groups of seventeen animals each. One group received 18 per cent protein (vitamin-free casein) diet without vitamin A, while the second group was fed the diet with vitamin A. The composition of the diet was similar to the one described by Jagannathan and Patwardhan[2]. After 6 weeks of *ad lib.* feeding, by which time growth had ceased and signs of vitamin A deficiency had appeared in the deficient group, a study of the incorporation of (1-^{14}C) DL-leucine (obtained from Atomic Energy Establishment, Trombay, India) was carried out by means of both *in vivo* and *in vitro* experiments.

For the *in vivo* experiment, four animals from the control group (group II), four animals from the deficient group (group I) and four vitamin A deficient animals which were fed 1,200 I.U. vitamin A the previous day (group I*a*), fasted overnight, and then were injected intraperitoneally with ^{14}C-leucine solution. The dose administered was about 1 μc./100 g body-weight. The exact quantity of solution injected was determined by weighing the syringe before and after. Five hours after the injections the animals were killed and liver, kidney, thigh muscle, small intestine and pancreas were removed. ^{14}C-activities of the isolated proteins of these tissues were assayed as previously described[5].

For the *in vitro* study, six rats each from the control and vitamin A deficient groups were killed with a sharp blow, their livers were removed rapidly and thin slices were prepared by the free-hand technique. Two slices from each rat were incubated in 2 ml. of buffer[6] containing 3 μc. ^{14}C-leucine, 2 mg glucose and 0·3 mg tryptophan-cystine fortified acid hydrolysate of casein for 3 h at 37·5° C under an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide. After the incubation, slices were thoroughly washed with buffer and dropped into 5 ml. of 10 per cent trichloroacetic acid containing 50 mg cold leucine. The carbon-14 activity in the isolated protein was measured.

The results of the *in vivo* study (Table 1) indicated that the specific activities (c.p.m./g of dry protein expressed as a percentage of the injected dose) in liver ($P < 0·01$), intestine ($P < 0·02$) and pancreas ($P < 0·001$) were significantly higher in vitamin A deficient animals than in vitamin A fed controls. The carbon-14 specific activity of

the protein of muscle was not affected by vitamin A deficiency. Pre-treatment of deficient animals with vitamin A had no demonstrable effect on ^{14}C-leucine uptake by the tissues studied. The total ^{14}C-activity (specific activity × organ weight), which may be a more reliable index of incorporating capacity[5] of an organ, was significantly increased in intestine ($P < 0.02$) and pancreas ($P < 0.01$) of the vitamin A deficient animals. But the total ^{14}C-activity of livers of vitamin A deficient rats in the three groups did not significantly differ one from another. The *in vitro* results in Table 1 show that the carbon-14 specific activity (c.p.m./mg of dry protein) of the liver slice of vitamin A deficient animals was significantly ($P < 0.05$) higher than that of the control animals.

These results indicate that vitamin A deficiency in rats does not adversely influence protein synthesis as judged by the *in vivo* ^{14}C-amino-acid incorporation into tissue proteins. On the other hand, there was increased incorporation of ^{14}C-amino-acid, both *in vivo* and *in vitro*, associated with vitamin A deficiency. This increased incorporation (*in vivo*) was observed in pancreas and intestine (both specific activity and total activity) and in liver (specific activity only). Increased *in vitro* incorporation was also observed in liver. Thus the increased incorporation appears to be confined to organs which have a high protein turnover such as the pancreas, intestine and liver. Increased incorporation of amino-acid in vitamin A deficiency has also been observed by Roels *et al.*[7], who have shown that the *in vitro* incorporation of (methyl ^{14}C)-methionine and (U-^{14}C)-phenylalanine by diaphragm muscle of rats increases in vitamin A deficiency. One possible reason for increased incorporation may be an increased mobilization of amino-acid into the cells of these tissues in vitamin A deficiency, perhaps because of alterations in cellular permeability[7]. But the free amino-acid concentrations of tissues are not increased except for tyrosine and phenylalanine in blood, liver and kidney of vitamin A-deficient rats[8]. An apparent increase of amino-acid incorporation could also be due to an inhibition of the release of synthesized protein from the tissue in vitamin A deficiency. In fact, it has been shown that one of the functions of vitamin A is the release of proteolytic enzymes from intracellular particles[9]. This kind of inhibition may be particularly important in pancreas. By analogy, the observed low serum albumin in the face of an increased incorporation of amino-acid by liver in vitamin A deficiency may be due to an inhibition of release of albumin from liver cells. Whether particular enzyme systems involved in protein synthesis are stimulated in vitamin A deficiency has also to be considered in this connexion. Stimulation of amino-acid activating enzymes of the liver in protein deficiency, which also causes an increased incorporation of ^{14}C-amino-acids into liver protein[5], has been described[10].

I thank Dr. C. Gopalan, director, Nutrition Research Laboratories, for his interest and encouragement, Mr. R. Keshavan for technical assistance and Mrs. Shanta Madhavan for carrying out the statistical analysis of the results.

Metabolism and Sodium Transport in the Isolated Rat Intestine

IT is well known that sodium is actively transported through many biological membranes[1–7] and several authors have also determined the amount of energy necessary for this[8–18]. The ratio between energy and transported sodium has usually been calculated by determining the increase of oxygen consumption (or lactic acid production) and the associated increase of sodium transport. These increases were obtained by modifying the quantity of available sodium[8,10,11,15,16], or by stimulating the sodium pump (posthypophyseal hormones)[8,9] or by modifying the quantity of chemical energy at the disposal of the membrane[13,26]. In this work the third procedure has been followed, and results are reported concerning the relationship between the sodium transport, the oxygen consumption and the lactic acid production in the isolated rat intestine perfused *in vitro* with different concentrations of glucose.

The jejunal tract of the albino male rat (Wistar strain) was used. The isolated intestine was everted according to the Wilson and Wiseman technique[19] and incubated *in vitro* for 1 h at a temperature of 28° C in 50 ml. of Krebs–Henseleit solution[20]. To this mucosal incubation fluid, glucose at a concentration of 1·39 mmoles/l. or 2·78 mmoles/l. or 13·9 mmoles/l. was added. Before tying off the everted sac, 2 ml. of Krebs–Henseleit solution was introduced. The mucosal incubation fluid was saturated by a gas mixture of 95 per cent oxygen and 5 per cent carbon dioxide; 20 ml. of this mixture, at a constant rate flow of 20 ml. per min, were made to recirculate continuously within the system (glass container and 'Tygon' tubes), without connexion with the outside. The oxygen pressures were recorded during the whole experimental period by means of an oxygen cathode[21] in the gas phase, transduced by a 'Combi-Analyser' (Eschweiler, Kerl) and at the same time recorded on a Metrawatt registering device[26].

At the end of the experiment the sodium concentration was determined in the serosal fluid by means of an 'Optica C F_4' flame spectrophotometer ($\lambda = 589$ mμ). The amount of the net sodium transport across the intestinal epithelium was calculated on the assumption that the concentrations of sodium are the same in the serosal liquid, and in 20 per cent of the fresh tissue. Lactic acid and glucose were determined both in the mucosal and serosal fluids according to enzymatic methods[22,27]. The amount of lactic acid present in the serosal space was calculated by assuming an equal distribution in the serosal fluid and in 80 per cent of the fresh tissue. The volume of the solution transported across the intestinal wall was determined by weighing the intestinal sac before and at the end of the incubation period.

Fig. 1 clearly shows a correlation between sodium transport and oxygen consumption (*A*) [O_2 (μmoles g^{-1} h^{-1}) = 37·6 + 0·088 sodium (μequiv. g^{-1} h^{-1}); *S.D.* ± 8·2], as well as between sodium transport and lactic acid production (*B*) [lactic acid (μmoles g^{-1} h^{-1}) = 46·7 + 0·471 sodium (μequiv. g^{-1} h^{-1}); *S.D.* ± 37·5]. These regression lines were calculated by using all the experimental values, because there exists a regression within the single groups, as well as a regression among the mean values of the three groups.

In order to compare the total available energy with the sodium transport, the total amount of ATP was calculated. Assuming a 1 : 1 molar ratio between the synthesized ATP and the lactic acid arising in the glycolytic process from glucose, and a molar ratio of 38 : 6 between the synthesized ATP and the oxygen consumed in the glucose oxidation[23], it was possible to draw the regression line reported in Fig. 1*C*. Like the others (Fig. 1*A* and *B*), this regression line [ATP (μmoles g^{-1} h^{-1}) = 287·0 + 1·017 sodium (μequiv g^{-1} h^{-1}); *S.D.* ± 70·4] has been

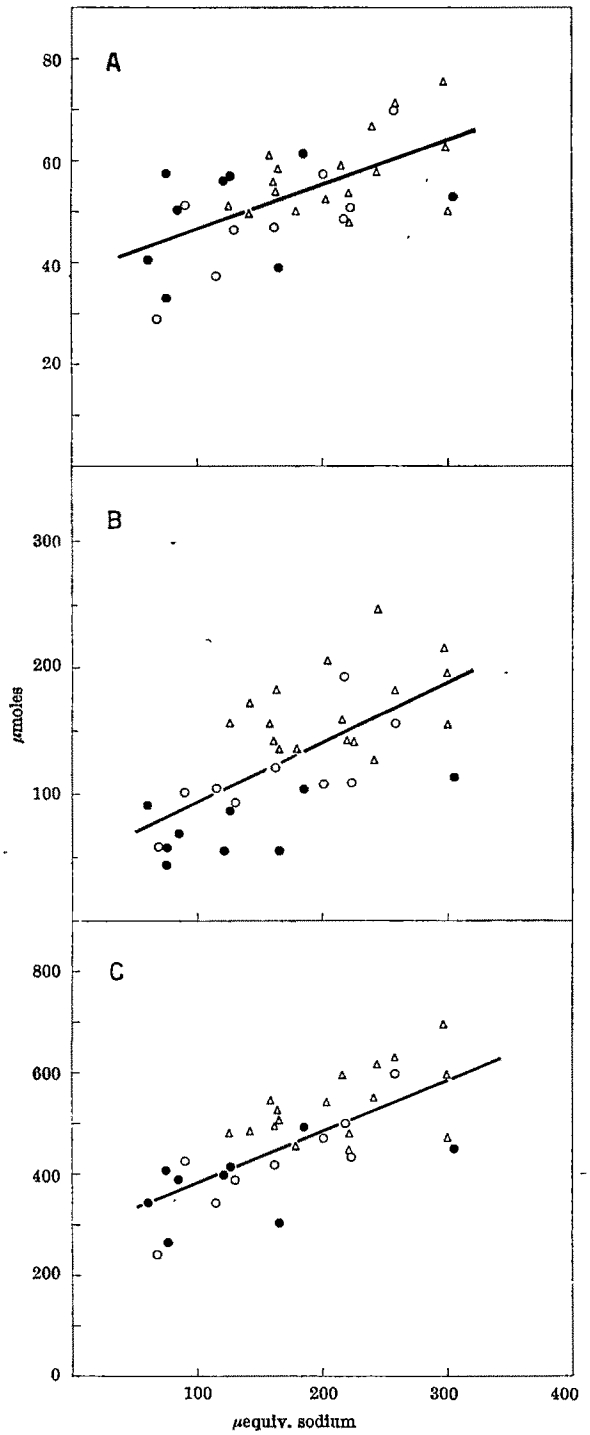

Fig. 1. Abscissa, sodium net transport μequiv. g^{-1} h^{-1}. Ordinate, *A*—oxygen consumption μM g^{-1} h^{-1}; *B*—lactic acid production μM g^{-1} h^{-1}; *C*—ATP produced μM g^{-1} h^{-1}. Glucose concentrations of the mucosal fluid: ●, 1·39 mM; ○, 2·78 mM; △, 13·9 mM. The values and standard deviation of regression lines (according to Croxton[24]) are reported in the text

calculated by utilizing all the experimental values obtained at different glucose concentrations and it is statistically significant ($P \ll 0.01$). The ratio ΔATP/Δsodium turned out to be nearly unity.

Another regression line was calculated by plotting the values of ATP against the sum of the sodium and the glucose transported at the same time through the intestine [ATP (μmoles g^{-1} h^{-1}) = 288·7 + 0·934 (sodium + glucose) (μequiv. + μmoles g^{-1} h^{-1})]. This regression was also highly significant, with a P lower than that for the regression of Fig. 1*C*. This seems to suggest that the energy required for the transport of glucose does not vary much from that required for the transport of sodium.

The values of basic metabolism which can be extrapolated from two regression lines are about the same—in other words, 287 and 289 μmoles of ATP g^{-1} h^{-1}, respectively. The ratio ΔATP/Δsodium obtained is much higher than those calculated from the data obtained from the bladder of *Bufo marinus*[10], in the mammalian kidney[11,16], and in the stimulated skin of *Rana temporaria*[8,9]. On the contrary, our ratio is similar to those obtained in the *Loligo* giant axon[13], in the frog muscle[17] and in the unstimulated frog skin (in which the basic metabolism had not been subtracted[8]).

Some of the remarkable differences in the ratios reported for ΔATP/Δsodium may possibly be accounted for by the procedure followed in the determination of the basic metabolism.

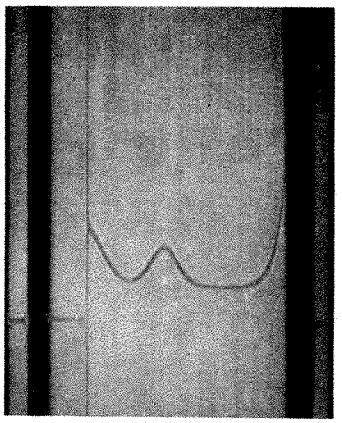
Purification and Properties of Lipase from *Torulopsis*

The production of lipolytic enzymes by micro-organisms is widely recognized, and several have been partially purified from certain bacteria[1–4] and fungi[5–8]. Recently, Baskys *et al.*[9] have obtained pancreatic lipase purified with calcium phosphate, which was homogeneous on ultracentrifugation and free-boundary electrophoresis at *p*H 8·6, but they observed at least two components on starch-gel electrophoresis at *p*H 8·0 and DEAE-cellulose chromatography. The milk lipase prepared by 'Sephadex *G*-50' was found to be homogeneous on ultracentrifugation and starch-gel electrophoresis at *p*H 8·5 by Chanden *et al.*[10]. We have isolated from soil a strain of *Torulopsis* which produces high lipolytic activity in the culture



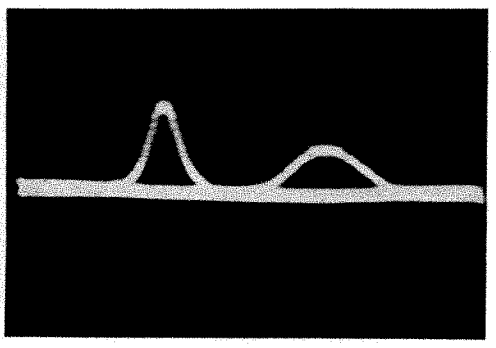


Fig. 1. Ultracentrifuge pattern of *Torulopsis* lipase. Picture taken 120 min after 60,000 r.p.m. was reached. The computed S_{20w} is 3·4 *S*

Descending Ascending

Fig. 2. Electrophoretic pattern of *Torulopsis* lipase at *p*H 6·9 (6 m.amp, 4 h)

broth. The extracellular lipase was also obtained in a highly purified state from the culture broth by the use of ammonium sulphate fractionation, DEAE-cellulose chromatography and 'Sephadex *G*-100' gel filtration. The highly purified enzyme preparation was found to be essentially homogeneous by such criteria as sedimentation in the ultracentrifuge and free electrophoresis.

The culture grown overnight on peptone medium was intensively aerated for 40 h in a soybean medium at 30° C. The lipase activity was assayed at *p*H 6·5 by the method of Yamada *et al.*[11]. The culture supernatant was precipitated at 60 per cent saturated ammonium sulphate, and precipitate was centrifuged at 4,000 r.p.m. for 30 min. The precipitate was then dissolved in 0·01 M phosphate buffer, *p*H 5·9, and dialysed against the same buffer for 2 days at 5° C. The dialysate was absorbed on DEAE-cellulose at *p*H 5·9. After washing with 0·1 M sodium chloride in 0·01 M phosphate buffer, *p*H 5·9, the DEAE-cellulose bed was extracted with 0·2 M sodium chloride in the same buffer. This fraction was dialysed against 0·01 M phosphate buffer, *p*H 5·9, and subjected to chromatography on DEAE-cellulose (linear salt gradient, 0–0·15 M sodium chloride in 0·01 M phosphate buffer, *p*H 5·9, column dimension 2 × 60 cm, flow rate 30 ml./h). Chromatography of the dialysed lipase fraction on DEAE-cellulose was then performed again, under the same conditions. The effluent fraction, partially purified with DEAE-cellulose, was dialysed against 0·01 M ammonium acetate buffer, *p*H 4·9, and lyophilized. Further purification of this partially purified enzyme preparation was attempted using a 'Sephadex *G*-100' column (3 × 70 cm) buffered with 0·01 M ammonium acetate buffer, *p*H 4·9, at a flow rate of 5 ml./h. The yield of the lipase through this purification procedure was more than 30 per cent and the specific activity was about 230 times that of the initial solution.

Analysis of the purified lipase performed on the ultracentrifuge at 60,000 r.p.m. in acetate buffer, *p*H 5·05, at a concentration of 2 per cent showed a single component with an S_{20w} of 3·4 *S* (Fig. 1).

Electrophoretic analysis of the purified lipase showed apparent homogeneity at *p*H 2·0, 3·0, 5·1 and 6·9. Fig. 2 shows the electrophoretic pattern at *p*H 6·9. The isoelectric point has been found to be below *p*H 2·0 in acetate buffer.

These experiments with purified lipase indicate that the enzyme has the following properties and specificity: the *p*H optimum for hydrolysis of some substrates (tributyrin, triolein, olive oil) is 6·5; the lipase is quite stable at *p*H 3–8 at 37° C for 1 h; temperature optimum is 45° C; the lipase is stable at temperatures of up to about 65° C at *p*H 5·0 for 10 min, but rapid inactivation occurs at temperatures above 70° C. The order of hydrolysis rate of some triglycerides by highly purified lipase is as follows: tributyrin > triolein > tristearin > tripalmitin > triacetin, trilaurin. Triacetin and trilaurin were not hydrolysed at all. The lipase activity can be inhibited by such metal ions as Fe^{++}, Fe^{+++}, Cu^{++}, Cd^{++}, Ag^{+} (0·005 M, *p*H 5·0). Meanwhile, the enzyme activity can be inhibited by cyanogen bromide, *N*-bromosuccinimide, iodoacetic acid, bromoacetic acid, diazobenzene sulphonic acid and sodium lauryl sulphate. Photo-oxidation of lipase with ultra-violet light in the presence or absence of a catalyst (such as methylene blue or riboflavin) resulted in the rapid inactivation of the enzyme. It seems that the activity of lipase requires methionine and histidine as essential groups.

A detailed account of the isolation and properties of this unique protein will appear elsewhere.

We thank Miss Kazuko Kunimatsu for her excellent technical assistance.

PHYSIOLOGY

Muscle Glycogen Synthesis after Exercise: an Enhancing Factor localized to the Muscle Cells in Man

IT is well known that glycogen is utilized during muscular work, but there is very little information available about the resynthesis of glycogen after exhaustive exercise. Goldstein[1] has shown that a humoral factor, which decreases the blood glucose concentration, is released during exercise. Furthermore, it is known that the insulin requirement decreases in diabetic subjects during exercise.

In a recent study of the resynthesis of muscle glycogen after exercise (glycogen values down to zero) we found that a carbohydrate-rich diet increased the muscle-glycogen content far above the basal values (1·0–2·0/100 g fresh muscle). In order to clarify whether a humoral factor similar to the Goldstein factor or a local factor in the muscle cells is in operation, we performed the following experiment.

Two normal subjects (J. B. and E. H.) were placed on either side of a bicycle ergometer. Exercise was performed with one leg while the other leg was in complete rest. Thus J. B. worked with his left leg and E. H. worked simultaneously with his right leg. The load was 1,200 kpm/min. Periods of exercise from 5 to 20 min were interrupted by rest periods of the same duration. The exercise was continued until both subjects were completely exhausted (that is, unable to work continuously for more than 1 min). After this procedure, biopsies of the quadriceps femoris muscles of both legs were performed, and the glycogen content was determined in the specimens[2–4]. During the rest of the day and on the following two days both subjects consumed a diet which consisted almost exclusively of carbohydrates. J. B.'s caloric intake was 2,200 kcal per day (35 kcal/kg body-weight), and E. H.'s was 2,600 kcal per day (33 kcal/kg).

Muscle biopsies on both legs were performed in the morning after 1, 2 and 3 days on a carbohydrate diet, and glycogen was determined in the muscle specimens. A comparison of the exercised leg with the 'resting' leg should disclose any local enhancement of the glycogen resynthesis.

The results are shown in Fig. 1.

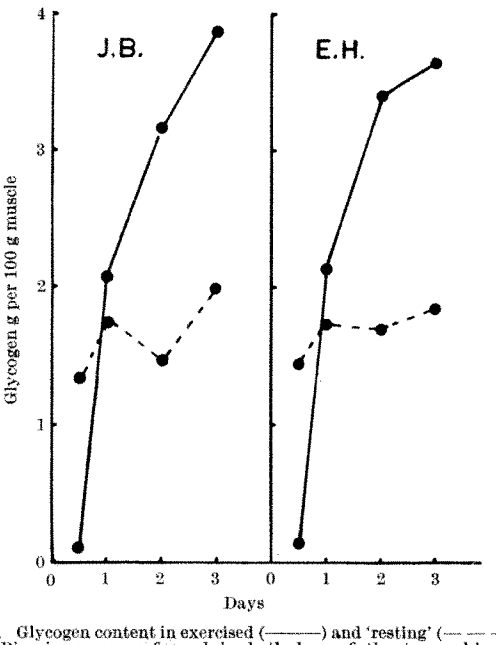

Fig. 1. Glycogen content in exercised (———) and 'resting' (— — — —) leg. Biopsies were performed in both legs of the two subjects at approximately the same time (within 15 min) on each occasion

The muscle glycogen content in the exercised leg was very low immediately after exercise, while the resting leg had a normal glycogen content. The effect of the carbohydrate diet was drastic. After 1 day the glycogen content in the exercised leg had risen from practically zero to higher values than in the resting leg, where only a small increase of the glycogen content was found. The glycogen content of the exercised leg continued to rise dramatically during the following 2 days on the carbohydrate diet, until the values were about twice as high as those in the other leg. The glycogen changes showed the same pattern and were of the same magnitude in both subjects.

From this experiment it can be concluded that exercise with glycogen depletion enhances the resynthesis of glycogen. The factor operates locally in the exercised muscle and the effect persists for at least 3 days.

The nature of the mechanisms involved is unknown. It could be that a stimulation of one or more of the factors directly involved in glycogen synthesis takes place or that an effect is provided on the cell membrane, stimulating glucose uptake. It is possible that some of the beneficial effects of exercise in normal as well as in diabetic subjects are mediated by this factor, thus promoting the storage of carbohydrate as glycogen instead of fat.

Soluble Saccharin Preference: a Nutritive Basis for Persistence

ANIMALS will drink more of a saccharin solution than water, and will run a maze or bar-press for a saccharin reward. It has been suggested that since saccharin is non-nutritive, such behaviour may be hedonic rather than drive reducing[1]. Sheffield and Roby, and Carper and Polliard maintain that the taste of saccharin is a primary re-inforcer, because hungry animals do not extinguish their response to it as would be expected for an acquired reward related to drive or need reduction[2–4].

Since it is the sodium salt of saccharin ($C_6H_4CONSO_2Na$, 'soluble' saccharin) which is regularly used, the validity of ignoring nutritive effects is questionable. The Na^+ ion is an essential food item, and rats and mice on the usual laboratory chow show a preference for weak sodium chloride solutions to water[5,6]. Thus the persistence in preferring sodium saccharin (Na-saccharin) to water might depend on the re-inforcing value of sodium.

The 'insoluble' saccharin ($C_6H_4CONHSO_2$) is sufficiently soluble to sweeten water to the extent used in motivational studies[7]. It was expected that if the Na^+ ion is indeed a factor in preference, animals should respond differentially to equimolar Na-saccharin and saccharin. Accordingly, eighteen *NIH/N* albino male mice were tested with one or the other of these solutions. Preference was determined by the two-bottle choice technique, the experimental solution paired with water. Consumption was measured to the nearest 0·1 ml. daily. Sides were alternated every other day and stainless steel drinking tubes were alternated daily. In this way the results were controlled for side preference and/or tube preference. Animals had 'Purina' laboratory chow constantly available.

The results are summarized in Figs. 1 and 2. Equimolar concentrations ($8{\cdot}2 \times 10^{-3}$ M) of saccharin and Na-saccharin are each preferred to water ($P < 0{\cdot}001$). The Na-saccharin group maintained a high level of preference over a three-week interval (Fig. 1) and maintained a significantly increased ($P < 0{\cdot}001$) daily fluid intake (Fig. 2). On the other hand, mice on saccharin showed a decreasing preference, and total fluid consumption (which initially rose) was soon equal to the volume taken when water was in both drinkers. Following this period, all the mice received water from both drinkers for three days. The the total fluid consumed by both groups was the same (Fig. 2).

On the 23rd day concentrations were doubled ($1{\cdot}6 \times 10^{-2}$ M) for both the saccharin and Na-saccharin animals. The next day both groups showed preference for the

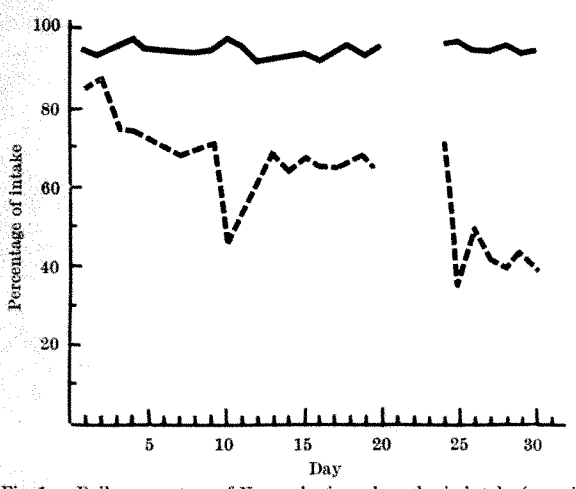

Fig. 1. Daily percentage of Na-saccharin and saccharin intake (experimental solution/experimental solution + water) (× 100). Solid line is Na-saccharin; broken line is saccharin

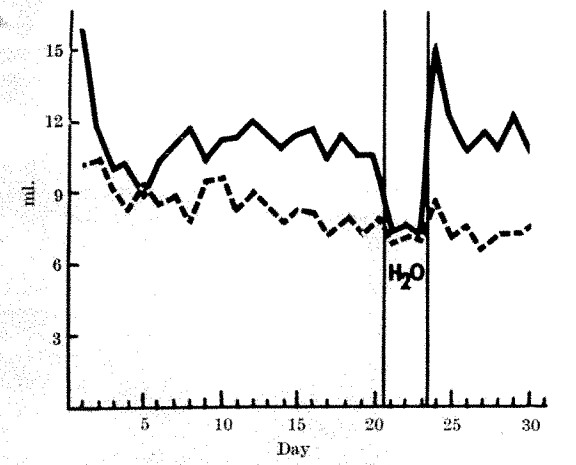

Fig. 2. Mean daily fluid intake. Solid line is Na-saccharin + water; broken line is saccharin + water

'sweet' flavoured water. But the second day on this increased concentration the saccharin group reversed its preference and was drinking considerably more water than saccharin and this persisted throughout the testing period. In order to determine whether the initial saccharin preference at this higher concentration resulted from prior experience with the weaker concentration, a group of six 'naïve' animals was tested with this concentration. The initial preference followed by aversion was not significantly different from that shown by experienced animals.

Doubling the concentration for the Na-saccharin group produced none of the marked changes observed for saccharin. These mice continued to show the same preference and increased fluid intake as with the weaker concentration.

The results cast doubt on the validity of considering the sweet taste as a primary re-inforcer, in the sense in which it is usually used, that is, "sweet for sweet's sake"[8]. Although mice initially preferred both concentrations of saccharin, preference declined with time. This is in keeping with behaviour towards a secondary re-inforcer no longer associated with a reward. The persistence of Na-saccharin preference, without diminution over extended periods, may be explained by the reward value of the sodium ion. In apparent contradiction to this thesis are the observations that animals will bar-press or run mazes for amounts of Na-saccharin of negligible physiological consequence[2–4]. However, Smith and Capretta[9], and Capretta[10], have shown that it is possible to consider that re-inforcement may be associated with juxtaposition of feeding schedules and experimental periods. These investigators have demonstrated that the taste of an Na-saccharin 'reward' gained in re-inforcing strength the more frequently it had been associated with food already in the stomach. Further, some of the initial motivating value of Na-saccharin was lost when there was no association with need reduction in the food-deprived animal. The problem of why an animal shows a preference for a 'sweet' substance in the first place is still not resolved.

Recovery from the Increase of the Stiles–Crawford Effect after Bleaching

THE Stiles–Crawford effect[1,2], or the dependence of luminous efficiency on the eccentricity of the point of entry of the light in the pupil, is a function of the wavelength of the light. In Fig. 1 is given the inverse $1/\eta$ of the luminous efficiency as a function of wave-length at a distance of 3·5 mm from the point of maximum efficiency, according to the measurements of Stiles[3]. In the same graph is a theoretical curve according with the explanation by Walraven and Bouman[4]. The dip in the curve in the yellow-green is due to the high absorption (about 80 per cent) by the visual pigments of perpendicularly incident light in that region of the spectrum. Perpendicularly, light traverses the whole amount of pigment, while obliquely incident light leaks out of the receptor and therefore has a much shorter absorbent pathway to travel. But shortening of the pathway through a solution of high optical density is accompanied by a narrowing of the spectral absorption curves of the pigments. In other words, when the pigment has a high absorption, there is only a small chance that light will leak out of the receptor obliquely, so that nearly all of it will be absorbed. With low density, however there is more opportunity for leakage, which is why the Stiles–Crawford effect is larger at both ends of the spectrum than in the middle.

A consequence of this theory is that the dip in Fig. 1 disappears when the absorption of the pigment is low throughout the spectrum, which can be achieved by bleaching the pigments. Stiles[5] indeed found an increase of the directional effect in the middle of the spectrum with a retinal illumination of 2×10^4 trolands. Miller[6] found recently the same effect with a retinal illumination of 10^4 trolands. In her experiments, the test patch was superimposed on the white background. In our experiments, the Stiles–Crawford effect is measured after presentation of a bright (10^5 trolands) adaptation field of 10 degrees diameter with monochromatic light of 650 nm. The eye was adapted to these conditions during a period of 2 min.

Changes of the Stiles–Crawford effect could be detected by brightness-matching two half-fields of equal wavelength together subtending one degree. One half-field was focused on the retina by light through the centre of

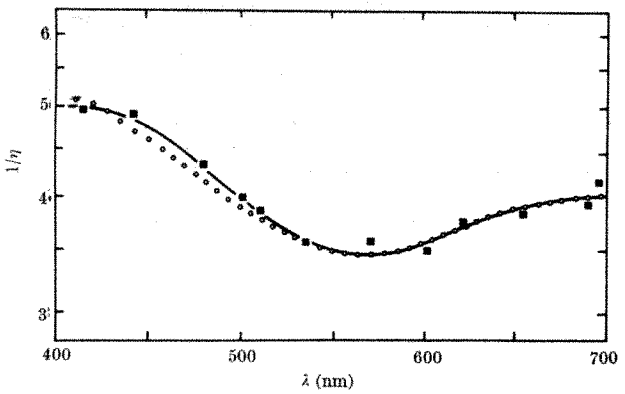

Fig. 1. Reciprocal of the luminous efficiency as a function of wave-length according to Stiles (ref. 3) (■) and according to the theory after Walraven and Bouman (ref. 4) (○). Eccentricity, 3·5 mm

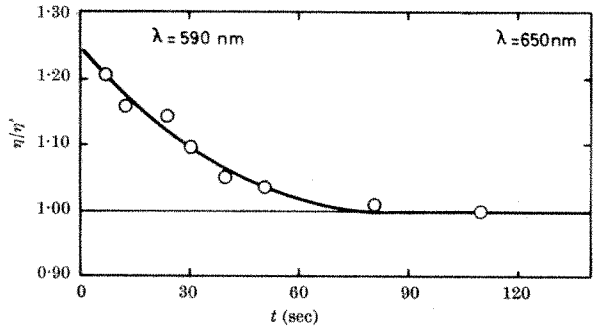

Fig. 2. Recovery of the increase of the Stiles–Crawford effect after bleaching at a wave-length corresponding with the dip in Fig. 1. Pre-adaptation time, 2 min; eccentricity, 3·5 mm; retinal illumination, 10^5 trolands

the pupil, and the other by light through a point 3·5 mm eccentric in the pupil. A match was first established before presenting the adaptation field. Any change in $1/\eta$ due to adaptation would upset this match. At a wave-length of 630 nm no significant disturbance could be measured, as might be expected.

Miller[6] found some increase even at the ends of the spectrum, and this may be obscured in our measurements because the accuracy is not better than a few per cent. At 590 nm, however, a large increase could be detected (Fig. 2) and the recovery of this increase as a function of time after the offset of the adaptation field was followed. One can see in the graph that the reciprocal $1/\eta$ is changed by about 20 per cent to the value of $1/\eta'$ after the adaptation and that the time constant of recovery is about 30 sec. The curve drawn is the best-fitting exponential curve. This same time constant has been found in the recovery of the change in the anomaloscope setting after adaptation to bright light, which suggests that we can interpret the change in $1/\eta'$ as a photochemical reaction in the receptors[7].

The characteristics, the time constant of the recovery from the increase of the Stiles–Crawford effect after bleaching, and the size of the effect, add evidence in support of a high value for the absorption of the visual pigments, which has been derived from other data[4,8].

Physiological Competition between Host and Implanted Ganglia in an Insect (*Periplaneta americana*)

BODENSTEIN[1] found evidence that ganglia from the central nervous system implanted into coxae which had been denervated were, at least to a small degree, able to mediate local reflexes. This observation suggests possible ways of studying the competition for motor and sensory functions of a limb by host and donor ganglia.

Larval cockroaches were selected in the middle and late stages of growth, that is to say, between the sixth and ninth instars, and donor abdominal or thoracic ganglia derived from a similar insect were implanted near the base of the coxa. The fifth nerve on that side was cut through near the point of ganglion implantation.

After 5 or more weeks the operated limb showed signs of recovery, although anomalous postures occurred, especially those involving hypercontraction of the tibial depressor muscles. Anatomical investigations of the graft area involved dissections, and the preparation of sections stained by a modification of the Holmes's silver technique. Some material was examined under the electron-microscope. The electrical activity of axons in the graft area was studied in partially dissected preparations, and recordings were also made from the tibial depressor muscles, which are normally innervated solely by the fifth nerve. A few simultaneous records from operated and unoperated parts of the insect were made using five channels of a Grass *P7* polygraph.

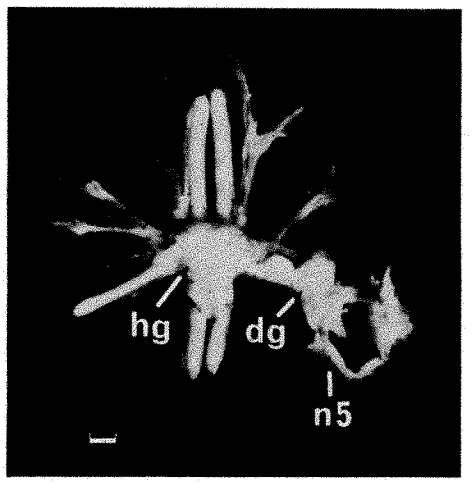

Fig. 1. Isolated host and graft ganglion. Scale: 0·5 mm. *Hg*, Host ganglion; *Dg*, donor ganglion; *n5*, fifth (podial) nerve

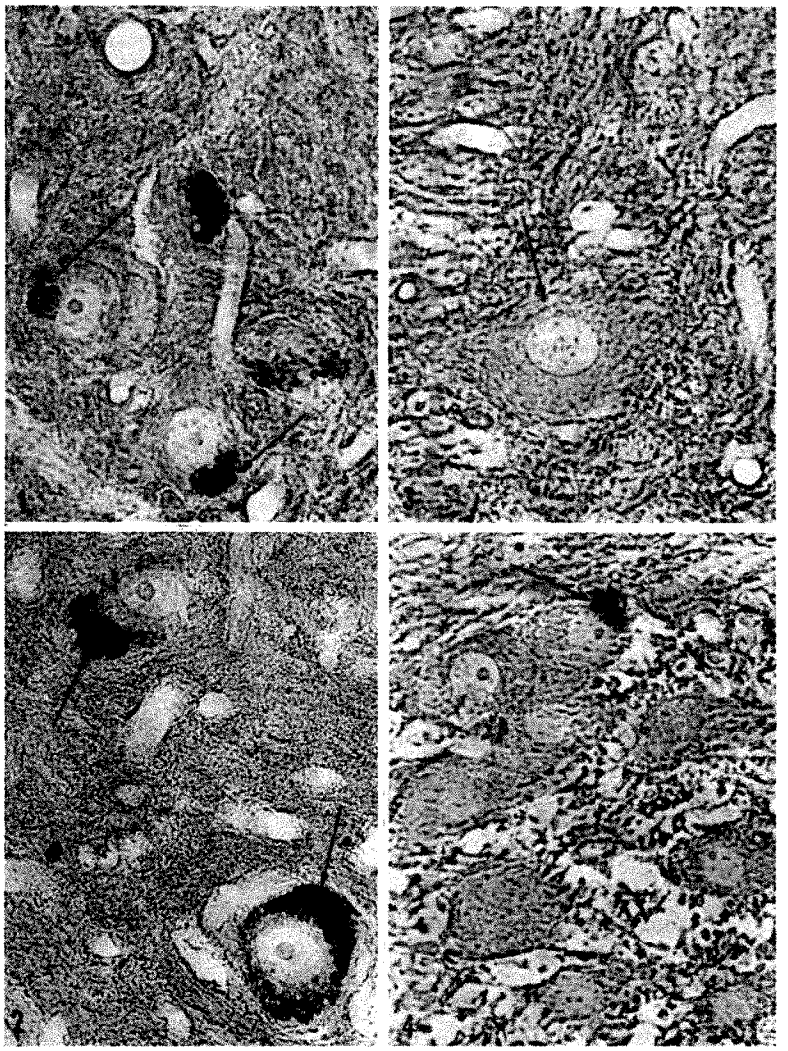
Fig. 2. Response of graft motor axons in the tibial depressor muscle to the repetitive stimulation of a tibial spine. Scale, 20 msec

Following implantation, the donor ganglion developed a new growth of axons so that a fine feltwork of processes eventually united the donor to the host ganglion (shown in Fig. 1). In some specimens considerable rearrangement of the internal ganglionic tracts occurred, in others the normal appearance was fairly well preserved. In rare examples the donor ganglia exhibited a complete absence of transverse tracts, and in some instances the normal peripheral cell bodies had wandered out into the central neuropile. The dictyosomes and the main cell process of the neurones often appeared particularly dark as if some argyrophil substance was localized at these points. Sections of the synaptic zones of donor ganglia examined with the electron-microscope have so far shown a fairly normal structure.

Early investigations of the physiology of these limbs, mostly after implantation of abdominal ganglia, were disappointing. Section of the donor–host connexion usually abolished contractions in muscles innervated by the fifth nerve, which suggested that the donor ganglion was functioning merely as a conduit for host ganglion motor neurones; on the other hand, the donor ganglion was clearly capturing most of the regenerating sensory fibres. Recording from the graft area was hampered by the large amount of connective tissue that had developed around the axons, and by the delicacy of donor cells following exposure by dissection. Nevertheless, it was possible to demonstrate spontaneous activity, often of great regularity. This is sometimes characteristic of autonomous neurones which are not part of a hierarchical system.

Implantation of thoracic rather than abdominal ganglia resulted in the leg muscles, especially the tibial depressors, retaining much more of their function after the host ganglion had been removed. Recordings from the leg muscles themselves, after this treatment, indicated a high level of tonic activity, and stimulation of spine sense organs produced well-defined reflex discharges accompanied by muscular contractions.

Repetitive stimulation of this kind was sometimes accompanied by a regular augmentation of the response that may have been due to the activation of additional elements within the donor ganglion. The latter is therefore capable of a complex response (see Fig. 2).



The functional interaction between donor and host ganglia is somewhat obscure, but removal of the host ganglion often results in increased activity and responsiveness in the graft.

This work was aided by grants from the Medical Research Council and the Science Research Council.

PHARMACOLOGY

Effect of Centrophenoxine on the Lipofuscin Pigments in the Neurones of Senile Guinea-pigs

CLINICAL and psychological studies indicate that a decline in the functions of the nervous system occurs in old age. Although it is difficult to evaluate the physiopathological changes in the neurones in senescence, the cells nevertheless show changes which they have acquired during functional activities in the past. Neurones are particularly suitable for the study of the effects of time on living cells as these are not generally replaced during life.

The accumulation of lipofuscin (old-age) pigments in the cytoplasm is possibly the constant cytological evidence of ageing in neurones, although the nature of the former and their mode of appearance are not definitely known. The present report deals with the effect of a new drug, ANP-235 (centrophenoxine), on these old-age pigments in the neurones of the central nervous system in guinea-pigs.

ANP-235 is a new drug synthesized by Thuillier[1] and does not belong to any of the pharmacological classifications. Numerous clinical experiments have shown rather striking results in the treatment of confusional states, apathy, disturbance of memory and intellectual concentration, states of agitation and fatigue in senescence[2–11].

In a histochemical study of the effects of this drug on the enzyme systems of guinea-pig neurones a striking decrease was observed of lipofuscin granules in the neurones of the treated animals.

About 100 guinea-pigs belonging to the age groups of 4–6 years were used in this project. The animals were injected intramuscularly or intraperitoneally (80 mg/kg of body-weight) daily for 4–8 weeks and the untreated animals of the same age groups were studied as controls. The animals were perfused with Lillie's 10 per cent buffered neutral formalin and the cerebrum, cerebellum and brain-stems were dissected out and fixed in the same solution for 3 days or more. Similar tissues from control animals of the same age groups were taken as controls. Paraffin blocks were prepared and sections (10μ) were stained for lipofuscin pigments by the following methods: periodic acid–Schiff (PAS) stain with diastase digestion as control, Schmorl's ferric–ferricyanide method, Hueck's

Nile blue stain with hydrogen peroxide bleaching to eliminate melanin, Lillie's Nile blue stain with and without acetone extraction to distinguish from melanin, Gomori's chrome alum–haematoxylin method, Long Ziel-Neelsen's stain for acid-fast lipofuscin and Sudan black *B* stain. Apart from the stains for lipofuscin pigments, the tissues of both control and drug-treated animals were stained with toluidine blue for Nissl's substance. Six untreated young guinea-pigs (less than 2 years) were studied as additional controls.

As no stain is at present available which specifically demonstrates the lipofuscin pigments, various tests have been used to eliminate possible sources of errors in its demonstration. The pigments were stained pinkish with PAS method and the colour was resistant to diastase digestion. These were stained dark blue with Schmorl's method and blue with Nile blue even after treatment with 10 per cent hydrogen peroxide for 48 h[12], but quickly disappeared after treatment with acetone[13]. In the chrome–alum haematoxylin method the pigments were stained dark-blue and with carbol fuchsin they were coloured bright red.

Lipofuscin pigments are present in most neurones of both young and old animals. They become more prominent at about the age of four years and thereafter increase steadily until they occupy a considerable part of the cytoplasm at 6 years. The pigments appeared rather scattered in younger animals but tended to accumulate in one part of the cytoplasm near the nucleus after the age of 5 years.

Hermann[14] observed progressive accumulation of lipofuscin pigments in the increasing age groups in the neurones of vagal and sympathetic ganglia.

A difference in the regional distribution of the lipofuscin pigments has been observed in the neurones of the central nervous system of these animals. While the largest accumulation of the pigments occurred in the neurones of the reticular formation of the brain stem (Figs. 1 and 2) and olivary nuclei, a lesser amount was observed in the neurones of the cerebral cortex and hypothalamic nuclei. It was interesting to note that the Purkinje cells of the cerebellum show very little of these pigments and this is in contrast to the large neurones of other regions of the central nervous system which show considerable pigment accumulation. The regional difference in the distribution of the pigment in man has been also reported by Vogt and Vogt[15], Sanides[16] in the amygdala, Balthasar[17] in cortical pyramidal cells, Hopker[18] in the dentate nucleus and Von Buttlar-Brentano[19] in the hypothalamic nuclei. We have also investigated[20] the difference in the distribution of the pigments in various parts of the central nervous system of the guinea-pigs of various age groups.

The nuclei and the Nissl substance also showed certain changes in the older neurones compared with the younger ones with the toluidine blue stain. While the Nissl bodies showed an increased staining with a clumpy appearance, the nuclei were more variable in shape and size with increased basophilia in the nucleolus. The underlying causes for such changes is by no means clear, but they may be a compensatory reaction prior to nuclear and cytoplasmic hypochromidia.

In animals treated with the drug, the neurones showed a notable diminution of the lipofuscin pigments in most parts of the central nervous system. The intensity of the effect of the drug was largely dependent on the duration of the treatment and a marked effect was observed after 8 weeks. Observation after varying periods of treatment with the drug showed the pigments to occupy a smaller and smaller area in the cytoplasm as if gradually shrinking away (Figs. 3 and 4).

It is generally believed that the gradual accumulation of these pigments was the constant sign of ageing and prolonged functional stress and strain in the neurones[21]; no drug, to our knowledge, has hitherto been reported which has exerted any influence on their gradual and progressive accumulation. Clinical data have indicated a marked improvement in the treatment of functional activities of senescence as a result of the drug, and the reduction of the lipofuscin pigments may be at least one of the important ways by which the drug ANP-235 renders its beneficial effects.

This work was carried out with the assistance of grants from the Animal Resources Branch, from the National Heart Institute, and from the Division of Research Facilities and Resources, National Institutes of Health.

We thank Dr. J. B. Rogers, of the Institute of Animal Geriatrics, Louisville, Kentucky, for the supply of senescent guinea-pigs used in this work.

HAEMATOLOGY

Role of Plasma Factors in the Transformation of Peripheral Blood Lymphocytes into Lymphoblasts

HUMAN peripheral blood lymphocytes maintained in tissue culture can be stimulated to transform into lymphoblasts and to undergo mitosis by phytohaemagglutinin (PHA)[1] and by antigens to which the donor of the lymphocytes is allergic[2,3]. In the previous reports describing the transformation of lymphocytes *in vitro* the culture medium has always contained plasma from the lymphocyte donor.

The present investigation was designed to assess the importance of plasma from the lymphocyte donor Three subjects were used as plasma and lymphocyte donors. The first was a man aged 32 who gave a positive reaction (erythema and induration of 2 cm. diameter) on intradermal testing with 1/1,000 old tuberculin and who had been vaccinated several times against smallpox. An accelerated scratch test reaction to vaccinia virus occurred at the most recent smallpox vaccination. The second was a 24-year old woman who had never been vaccinated against smallpox. The third was a 9-year old girl who gave a negative reaction when tested intradermally with 1/100 old tuberculin. Ten ml. of venous blood from each subject was taken in a sterile polystyrene tube containing 200 U. of lithium heparin. The tube was sealed, shaken gently and stood upright at 37° C for 1 h. The supernatant leucocyte-rich plasma and a small volume of erythrocytes were removed and centrifuged at 250*g* for 3 min. The plasma was then centrifuged at 20 min three times at 1,000*g* in order that all blood cells be removed completely. The original

C	*C*	−	+	70	+	Not done

Subject *B*, male, 32, Mantoux positive with 1/1,000 old tuberculin.
Subject *C*, child aged 9, Mantoux negative with 1/100 old tuberculin.
+, Large numbers of mitoses present.
* PHA cultures were harvested after 3 days.

cellular deposit from the leucocyte rich plasma was washed four times with 0·15 M sodium chloride, pre-heated to 37° C, the cells being deposited after each washing by centrifuging at 250*g* for 5 min. A total white cell count was made after the final washing. The tissue culture medium was made by adding 0·4 ml. of the subject's plasma to 1·6 ml. of tissue culture 199 (ref. 4) containing 200 u penicillin per ml. and 100 µg streptomycin per ml. in 1 × 8 cm capped polystyrene tube[illegible] the appropriate subject[illegible] of $1{\cdot}2 \times 10^6$ cells per[illegible] culin to a final c[illegible] one vial of h[illegible] light blue cytoplasm of 'frosted-glass' appearance often containing several vacuoles. Mitotic figures arrested in metaphase were seen in cells of the same order of size as lymphoblasts and with similar cytoplasmic features. In the autoradiographs, cells were accepted as being labelled if they contained more than twenty silver grains over the nucleus.

The degree of lymphoblast transformation, mitotic activity and uptake of tritiated thymidine is shown in Tables 1 and 2.

These results show that old tuberculin and heat-killed vaccinia virus induce lymphoblast transformation of peripheral blood lymphocytes from an immune donor in the absence of autologous plasma. They also demonstrate that the plasma from an immune individual does not confer the potential for lymphoblastic transformation *in vitro* in the presence of antigen to lymphocytes from a non-immune individual. This finding is consistent with the ability to transfer delayed-type tuberculin sensitivity *in vivo* with lymphocyte suspensions and not with plasma[5].

In these experiments, PHA stimulated lymphoblast transformation in the absence of autologous plasma. The considerable quantitative differences between the dynamics of lymphoblast transformation caused by antigens and that caused by PHA suggest that PHA acts as a direct cellular stimulant and not as an antigen[6]. This is supported by our recent finding that PHA stimulates mitosis in epithelial cells of adult human skin grown in an organ culture system *in vitro*[7]. The fact that the plasma from sensitized individuals does not contain any component which can induce the transformation of lymphocytes from unsensitized individuals into lymphoblasts in the presence of specific antigen would indicate the probability that cytophilic antibodies[8] were not involved in this reaction.

We thank Mr. P. Gaylard for technical help and the Herbert E. Dunhill Trust for support.

Table 1. DISTRIBUTION OF HAPTOGLOBIN TYPES IN TURKISH PEOPLE

No. tested	Distribution of haptoglobin types (per cent)					Gene frequency	
	Type 1–1	Type 2–1	Type 2–2	Type 2–1M	Type Johnson	Hp^1	Hp^2
300	8	46	45·1/3	1/3	1/3	0·31	0·68

haptoglobin types were determined by the vertical starch-gel electrophoretic method of Smithies[2]. The position of the haptoglobin bands was determined by staining with orthodianisidine[3]. The results of these investigations are presented in Table 1.

The distribution of the major haptoglobin types is quite uniform in populations living in different European countries : Hp 1-1, 14–17 per cent ; Hp 2-1, 47–49 per cent ; and Hp 2-2, 36–40 per cent[4–12]. Gene frequencies for Hp^1 and Hp^2 are also very similar : 0·36–0·40 and 0·60–0·66 respectively[4–12]. On the other hand, in Africa, Hp 1-1 is much more frequent (49–54 per cent), and the gene frequency of Hp^1 is much higher (0·60–0·72) (refs. 13–15). In Asia, on the contrary, the percentage of type 1-1 is lower (5–10 per cent) and so is the gene frequency of Hp^1 (0·21–0·31) (refs. 16–19).

As can be seen from Table 1, the distribution of major types in Turkish people is similar to that seen in Asiatic countries. This is not surprising, considering the historical fact that the Turks emigrated for several centuries from Central Asia to Asia Minor. On the other hand, a survey of different blood-group frequencies (ABO–MNS, Rh, Lutheran, Kell and Duffy) in Turkish people[20] showed that they did not differ greatly from the values commonly found in Europe. Such a discrepancy also occurred in the case of the Bushmen of Southern Africa. Although their physical appearance suggested a Mongoloid ancestry, blood-group studies performed by Weiner *et al.*[21] enabled them to conclude that the blood group frequencies of Bushmen showed a negroid pattern. But the distribution of haptoglobin types in Bushmen was different from other Africans and similar to the distribution of haptoglobin types in Chinese[19,22]. These two examples of discrepancy between blood group frequencies and the distribution of haptoglobin ty[illegible]

Microsomal Incorporation of *N*-Acetyl-D-galactosamine into Blood Group Substance

SOLUBLE blood group A and H substances from hog gastric mucosa consist of a protein 'backbone' to which numerous oligosaccharide units are attached[1,2]. These oligosaccharide units are supposed to consist of a chain of D-galactose and *N*-acetyl-D-hexosamines to which L-fucose residues are laterally linked[3–5]. Group A substance is considered to differ from group H substance only by an additional α-*N*-acetylgalactosamine residue at the non-reducing end of the sugar chains. In fact, substances showing H specificity can be obtained from A substances by treatment with α-*N*-acetylgalactosaminidases[6,7].

The mechanism of the biosynthesis of blood group substances is unknown. *In vivo* labelling experiments in which [^{14}C]-glycerol was injected into the gastric artery of hogs indicated that blood group substances are synthesized on the microsomes of the gastric mucosa[8]. This communication describes the transfer of ^{14}C-labelled *N*-acetylgalactosamine from uridine diphosphate (UDP) [^{14}C]-*N*-acetylgalactosamine to terminal positions of blood group H substance in the presence of microsomes from hog gastric mucosa.

A mixture of UDP-[^{14}C]-*N*-acetylglucosamine and UDP-[^{14}C]-*N*-acetylgalactosamine was prepared by injection of glucosamine-1-^{14}C (10·0 mc./m mole, obtained from New England Nuclear Corporation) into the tail vein of rats, and the UDP-*N*-acetylhexosamines isolated from the livers according to the method of O'Brien and Neufeld[9].

Microsomes were prepared from hog stomachs freshly obtained from the slaughter-house. The mucosal linings were stripped off, separated from the underlying muscularis mucosa, and homogenized in a Waring blender in 0·35 M sucrose, 0·025 M potassium chloride, 0·01 M magnesium chloride, 0·001 M ethylenediamine tetraacetic acid, 0·05 M *tris* pH 7·6 (3 ml. per g of mucosa). The homogenates were centrifuged at 15,000*g* for 20 min and the [illegible] assayed for blood group activity by haem- [illegible] further centrifuged at [illegible]llet from 5 g mucosa [illegible]ernatant. To the [illegible]oles adenosine

Table 1. *In vitro* INCORPORATION OF [^{14}C]-*N*-ACETYLHEXOSAMINES INTO BLOOD GROUP SUBSTANCE BY MICROSOMES OF A- AND O(H)-ACTIVE HOG GASTRIC MUCOSA

Blood group specificity of gastric mucosa	Time of incubation (min) of microsomes with UDP-[^{14}C]-*N*-acetylhexosamines	C p.m. incorporated into blood group substance
A	60	900
A	120	1,750
O (H)	120	70

In the following experiments, microsomal preparations from gastric mucosa showing a strong A activity were used and the incubation was stopped after 2 h. As shown in Table 2, the amount of incorporated radioactivity could be increased nearly three-fold by the addition of soluble blood group H substance. Sonication of the microsomal suspension prior to incubation resulted in a further two-fold increase in incorporating ability. This treatment obviously facilitated the approach of UDP-*N*-acetylhexosamines to the sites of synthesis on the microsomes.

Table 2. INCORPORATION OF [^{14}C]-*N*-ACETYLHEXOSAMINES INTO BLOOD GROUP SUBSTANCE BY MICROSOMES OF A-ACTIVE MUCOSA

Stimulation by the addition of extraneous H substance and by sonic treatment of the microsomal preparations

Sonic treatment of microsomes	Addition of extraneous H substance	C.p.m. incorporated into blood group substance
Not sonicated	No addition	500
Not sonicated	H substance added	1,400
Sonicated	H substance added	2,950

More than 90 per cent of the incorporated label (1,850 c.p.m. out of a total activity of 1,975 c.p.m.) could be removed from the blood group substance present in the incubation mixture by treatment with an α-*N*-acetylgalactosaminidase, which had been purified from the hepatopancreas of the snail, *Helix pomatia*. This enzyme had previously been shown to release terminal *N*-acetylgalactosamine from blood group A substance[7]. This result indicated that the incorporation of radioactivity into blood group substance was mainly due to the attachment of terminal *N*-acetylgalactosamine residues to oligosaccharide units of blood group A precursor substances present in the microsomal fraction and of H substance added to the incubation mixture.

The experiments reported here suggest that the microsomal preparations obtained from hog gastric mucosa showing blood group A activity contain an enzyme which catalyses the transfer of *N*-acetylgalactosamine from UDP-*N*-acetylgalactosamine to blood group H substance. This enzyme is formed under the control of the *A* gene and is absent or inactive in individuals of blood group O(H). The results of the present investigation are consistent with the scheme of Watkins and Morgan[11], which postulates the conversion of pre-formed blood group H substance into A substance by the attachment of non-reducing α-*N*-acetylgalactosamine residues.

We thank Dr. G. Hertting for his co-operation in the preparation of labelled UDP-*N*-acetylhexosamines.

GENETICS

Serum Transferrins of some Gadoid Fishes

SERUM transferrin polymorphism has been demonstrated in carp (*Cyprinus carpio*)[1] and cod (*Gadus morhua*)[2]. Investigations undertaken at this Institute indicate that serum protein polymorphism, and especially transferrin polymorphism, is a common feature among fishes, and we hope to use these characteristics in population studies of several species of commercial value. This report deals with preliminary results from studies of coalfish (*Gadus virens*), pollack (*G. pollachius*), and whiting (*G. merlangus*).

The blood was collected by cardiac puncture. Blood was obtained from small fish by cutting the tail. After clotting, the blood was centrifuged and the sera pipetted off. Most sera were stored for some time in deep freezer until the analyses were carried out.

Most coalfish sera were taken from immature fish caught by purse seine on the west coast of Norway. Thirteen specimens were taken from larvae from Vestfjorden, Northern Norway. The pollack sera also were taken from fishes caught by purse seine. The whitings were caught by purse seine or otter trawl, and several year groups were represented. Numbers in samples, month of sampling and catching areas are shown in Table 1 (coalfish), Table 2 (pollack), and Table 3 (whiting).

The sera were examined by the combined starch/agar-gel electrophoresis described by Sick[3] and Møller[2]. Autoradiography has been carried out as for cod sera[2] based on the methods of Giblett, Hickman and Smithies[4].

An outline of the transferrin bands of the electrophoretograms, identified by autoradiography, is shown in Fig. 1 together with the general transferrin pattern in cod[2]. Regarding pollack and whiting three transferrin groups (phenotypes) were found: two with one single transferrin band each, and a third with both these bands. In coalfish only two groups were detected, one with a single transferrin band, the other with a double band.

For each species the fastest moving component is called Tf A, and the slowest moving component Tf B. The phenotype possessing only Tf A is labelled AA, that containing only Tf B is labelled BB, and when possessing both transferrins the phenotype is labelled AB.

None of the four species seems to have any transferrins in common, and the electrophoretic mobilities of transferrin molecules differ widely despite the fact that the species are closely related. The transferrin molecules of pollack move fastest towards the anode at *p*H 9·0, and the mobilities of the five cod transferrins are intermediate

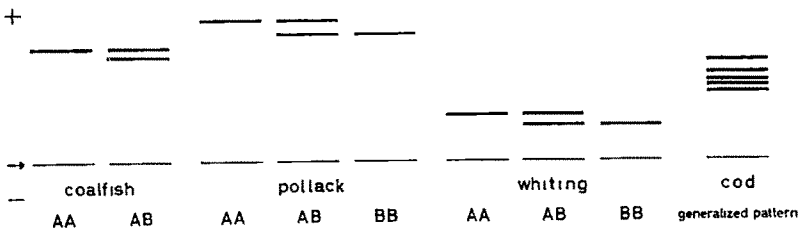

Fig. 1. Transferrin pattern of three species of gadoid fishes revealed by starch-/agar-gel-electrophoresis at *p*H 9·0. Duration of run, 90 min. Arrow indicates the point of application. The general transferrin pattern of cod is given for comparison

between the transferrins of coalfish and of whiting, which possess by far the slowest moving transferrin molecules of the four species yet investigated.

The observed distributions of the phenotypes in the collected samples of coalfish, pollack, and whiting are shown in Tables 1–3.

A hypothesis of hereditary control involving two co-dominant alleles (called Tf^A and Tf^B) has been adopted to explain the observed heterogeneity. Corresponding gene frequencies have been calculated and are shown in the last columns of the tables, and expected distributions according to the Hardy–Weinberg law are given in the lines signed 'n_{exp}' in Tables 1–3. The phenotype BB is not found in coalfish sera, but it follows from Table 1 that, due to the rareness of the gene Tf^B, the expectance of this gene in a homozygous state is low in this material.

It is seen from Tables 1–3 that the accordance between observed and expected distributions is very good, and this strongly supports the hypothesis that the transferrins in these species are controlled by two co-dominant alleles.

Individual differences were indicated also in other serum proteins, but with the technique used here, these differences were not clear enough for proper classification of the specimens. Similar investigations of haddock (*G. aeglefinus*) sera have also revealed individual differences, but the genetic basis of these differences seems to be complicated and has not yet been worked out. Investigations are now being carried out on herring (*Clupea harengus*) and sprat (*C. sprattus*) and have so far revealed individual variations in serum proteins in both species.

No differences were found when results from fresh and frozen sera were compared; moreover, sera can be stored in the refrigerator (0°–4° C) for 4–6 days before any decomposition of proteins occurs.

These preliminary results suggest that polymorphism in serum proteins are common in fishes and may become useful in fishery biology for identification of populations.

HISTOLOGY

Free Aldehydic Groups in Collagen and Other Tissue Components

THE reaction of free carbonyl groups with *N*-methyl benzothiazolone hydrazone (MBTH) is a very sensitive and specific method for the quantitative determination of free aldehydes[1,2]. Carbonyl compounds react with 1 mole of MBTH to form an azine derivative. Azines of aldehydes react sequentially with a second mole of MBTH, oxidized by ferric ion under acid conditions, to form blue-green tetraazopentamethine cyanine dyes[3]. These products can be specifically identified for aldehydes by their absorption spectra[2,4–6]. While a variety of compounds will form azines with 1 mole of MBTH, the second stage of the reaction is specific for aldehydes and can be carried on in the presence of other carbonyl compounds. Carbohydrates having pyranose structures do not react with MBTH, nor do they interfere with the reaction of aldehydes with MBTH. The reaction is at least 100 times more sensitive than the Schiff reaction[7]. It differs from the periodic-acid–Schiff (PAS) reaction[8] in that the MBTH reaction detects 'natively' free aldehydic groups while the PAS reaction uncovers the aldehydic group through oxidative reactions prior to reaction with Schiff's reagent.

Recently, Gallop *et al.*[4–6,9] have demonstrated the presence of small amounts of an unusual free aldehydic group in collagen, covalently attached to the protein and possibly involved in intramolecular cross-linking. This aldehyde does not seem to be one of a variety of simple aldehydes nor one of various commonly encountered carbohydrate substances[4]. On the basis of their demonstration of the great sensitivity of MBTH in detecting minute quantities of aldehyde coupled to protein molecules, we postulated that the reaction might be a useful test for free aldehydic groups when carried out directly with tissue sections. It might, furthermore, provide helpful chemical information about collagen in tissue, since the MBTH reaction permits the specific examination of an aldehydic function which may be important to maturation phenomena of collagen or disorders of collagen structure.

The investigations were performed mostly with paraffin-embedded tissue which had been fixed in 10 per cent formalin buffered to *p*H 7·2 with phosphate. The excess formalin was removed by extensive tissue washing prior to reaction. Fixation of tissue in osmic acid buffered with phosphate at *p*H 7·2 gives results identical to those with formalin fixation; it, therefore, appears likely that formalin fixation does not introduce any artefact. Rat, toad and human tissues give comparable results.

Tissue sections of 2–3μ thickness on glass microscopic slides were deparaffinized through three changes for 5 min each in xylol, three changes for 3 min each in absolute alcohol, two changes for 3 min each in 95 per cent alcohol, and then washed well in distilled water. The staining reaction was adapted for development in conventional staining dishes. In the first dish was an aqueous solution of MBTH hydrochloride (Aldrich Chemical Co.), 2·0 g per 100 ml. In the second dish was an aqueous solution of MBTH hydrochloride, 2·0 g per 100 ml., plus $FeCl_3$, 2·5 g per 100 ml. Slight improvement in the reaction progress was obtained by including in each tray 0·1 M glycine buffer, *p*H 4. The reaction was usually carried on at room temperature, but it is slightly improved at 0° C. The tissue sections, in a rack, were placed in the first dish for 15 min, then transferred to the second dish for 45 min. The sections were then rinsed briefly with distilled water and subjected to a modified, abbreviated dehydration procedure since it had been noted that conventional dehydration caused significant loss of specific staining. From distilled water the sections were dipped three times in two changes of 95 per cent alcohol, three times in three changes of absolute alcohol, twice in xylol, and were then allowed to remain in a second dish of xylol for 5 min before mounting glass cover slips with 'Permount'. Blue-green staining of the sections was grossly evident. For best results the sections should be examined on the first day or second day after preparation, as fading of the reaction ensues thereafter and is quite evident within 3 or 4 days.

Collagen is consistently and apparently specifically stained with MBTH (Fig. 1). This is equally true in all species studied. The collagen fibrils were stained deeply

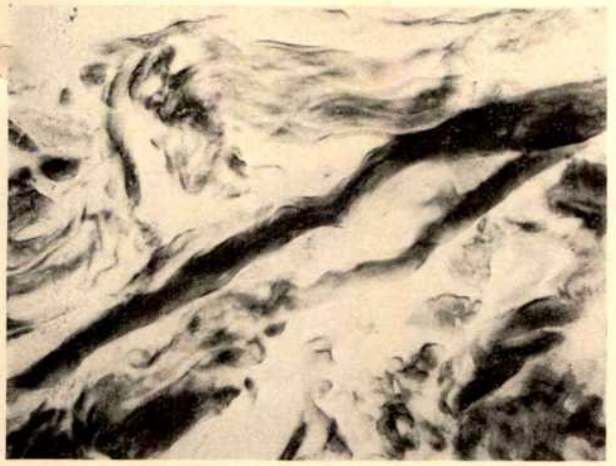

Fig. 1. Section of human skin. Dermal collagen stained by reaction with MBTH followed by reaction with oxidized MBTH, a method specific for free aldehydic groups. Collagen is stained blue-green. (×342)

blue-green and very fine strands can be resolved readily at 200–300 × magnification. Epithelial cells usually are stained a faint pea-green colour, readily distinguishable from the colour of collagen. It seemed possible that the pea-green colour arose from azo compounds formed by the reaction of a diazonium salt with epithelial cell components. MBTH oxidized by ferric ion can itself act similarly to diazonium salts in reacting with phenolic compounds like tyrosine; the products of these reactions are coloured, but have a different absorption spectrum from the tetraazopentamethine cyanine dyes which are formed only on the addition of 2 moles of MBTH with aldehydes. Separate fluorescence microscopic studies of skin stained with *p*-nitrobenzene-diazonium fluoborate, a fluorescent diazonium reagent, showed reaction of this compound primarily in epithelial cells. This distribution of fluorescence is identical with the distribution of the pea-green colour seen on staining with ferric chloride oxidized MBTH. Epithelial cells, then, probably contain some material which readily takes up one mole of MBTH in the presence of Fe^{+++} to form a pea-green-coloured azo product. On the other hand, collagen, containing free aldehydic groups, develops a blue-green colour on addition of two moles of MBTH in the presence of Fe^{+++}.

The only other tissue component which has so far been shown to react comparably to collagen is basement membrane material. Other tissues produce a faint blue colour different from that of collagen on reaction with MBTH. These include mucus and cartilage matrix; occasional cells in lacunae deep in the centre of a section of cartilage stain intensely blue. Presumably, glyco-proteins of basement membrane contain free aldehyde groups or reactive hemiacetals; this may also be true of mucus and cartilage although the nature of the blue reaction product is unknown. Amyloid and elastin do not react with MBTH whereas fibrinoid, as seen in rheumatoid nodule, sarcoid granulomata and the glomerular lesions of disseminated lupus erythematosus, produces a blue colour with MBTH.

Treatment of tissue with periodic acid followed by staining with MBTH intensifies the normal staining of collagen, as may be expected since periodate oxidation of hydroxylysine side-chains form additional protein-bound aldehyde[6]. There is also the appearance of new staining in regions where the periodic acid–Schiff reagent would conventionally stain. Treatment of the tissue with sodium borohydride, which reduces free aldehydic groups[9], prevents subsequent staining of collagen with MBTH.

Further studies with this method for demonstrating free aldehydic groups in collagen and other tissues are in progress. This method provides the advantage of permitting the direct visualization of a specific chemical functional group which may be important in the maturation and cross-linking of collagen and it enables study of this element of protein structure in diseases of collagen. The reaction may also permit the detection of transitory aldehydic intermediates in physiological and pathological reactions.

IMMUNOLOGY

Absorption of Thyroid-stimulating Globulin from Thyrotoxic Sera by Organ Homogenates

RECENT experiments have shown that the long-acting thyroid stimulator present in the serum of patients with Graves's disease[1] has physicochemical and immunological characteristics indistinguishable from those of IgG (7*S* gamma-globulin)[2–6]. These findings and the frequent association of this disease with thyroiditis and other autoimmune disorders suggested that the long-acting thyroid stimulator might be an autoantibody directed against a constituent of the thyroid gland[7–9]. This communication reports the results of absorption experiments which provide further evidence for this hypothesis.

Homogenates were prepared from human organs by dispersion in an MSE top drive blender with 5 vol. of saline. They were filtered through muslin and centrifuged at 14,400*g* for 50 min at 4° C. The pellets were washed successively in 0·9 per cent sodium chloride and in distilled water to disrupt subcellular structures and remove substances which might prove toxic in the bioassay. The final pellets were suspended in small volumes of saline, dialysed for 2 days and recentrifuged as above. The sera of five thyrotoxic patients containing long-acting thyroid stimulatory activity were absorbed with varying weights of human thyroid, liver, kidney, stomach and muscle homogenate for 60–90 min, at 37° C and then overnight at 4° C. Following absorption, the sera were spun and dialysed against saline. This was not always effective in removing toxic products, and in recent experiments it has been found preferable to precipitate the globulin fraction with 14 per cent sodium sulphate. In some experiments the IgG fraction was isolated by chromatography on DEAE-cellulose. For bioassay, comparison was made with globulin fractions similarly prepared from the unabsorbed sera, the absorbed and unabsorbed fractions being tested at the same protein concentration.

The absorbed sera together with the unabsorbed controls were assayed for the long-acting thyroid stimulator by the following modification of Mackenzie's method[10]: Swiss mice weighing 15–20 g were given 6 μc. iodine-131 subcutaneously 3 days before the assay, followed 6 h later by an intraperitoneal injection of 10 μg thyroxine; further thyroxine was given in the drinking water. Twenty-four hours before the assay, the animals received a final injection of 10 μg thyroxine intraperitoneally. 0·5 ml. of each sample to be tested was injected intravenously into each of 6–10 mice. The radioactivity of blood obtained from the retro-orbital sinus was determined before and at 2, 7, and 24 h after injection. Long-acting thyroid stimulatory activity was measured by the radioactivity at 7 h (expressed as a mean percentage of the pre-injection value, ± the standard deviation). Two dose levels of thyroid-stimulating hormone were included to assess the sensitivity of each assay. The absorbed and unabsorbed sera were usually diluted in parallel so as to give a value of 300–400 per cent for the unabsorbed specimen. Under the conditions of assay used, twenty-five normal sera produced 7 h responses of 107 ± 11 per cent.

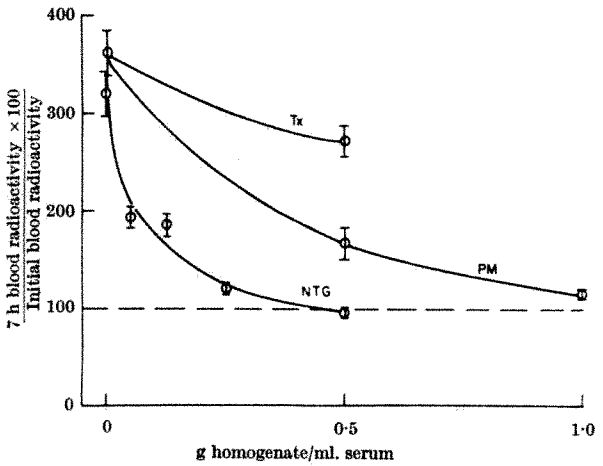

Fig. 1. Absorption of the activity of the long-acting thyroid stimulator by thyroid homogenates. *NTG*, Non-toxic goitre; *PM*, post-mortem; *Tx*, thyrotoxic thyroid. Results are expressed as the mean ± *S.D.*

Complete absorption of long-acting thyroid stimulatory activity was obtained with particulate homogenates of fresh non-toxic colloid goitre using 0·5 g (wet weight) of pellet equivalent to 5–10 g of fresh tissue per ml. of serum. An absorption curve using increasing amounts of homogenate is shown in Fig. 1. Normal thyroid gland obtained at post-mortem was somewhat less effective although 90 per cent absorption was attained using 1 g/ml. serum. Fresh thyrotoxic glands were also less effective than non-toxic goitre possibly due to partial saturation *in vivo* of the combining sites with the patient's own long-acting thyroid stimulator. Results of absorption with different thyroid preparations using 0·5 g homogenate/ml. serum are summarized in Table 1.

Table 1. ABSORPTION OF THE LONG-ACTING THYROID STIMULATOR BY 0·5 G OF DIFFERENT THYROID HOMOGENATES/ML. SERUM

Thyroid	No. of glands	Decrease in activity of the long-acting thyroid stimulator (%)
Non-toxic nodular goitre	2	92, 92*, 102*
Normal (post-mortem)	2	74, 57
Thyrotoxic	1	34
Toxic nodule	1	60

* Different sera absorbed with the same gland.

Of the other organs investigated, post-mortem liver had the least effect on the long-acting thyroid stimulator, absorption with 1 g of particulate preparation/ml. serum giving a 14 per cent reduction of activity. With post-mortem kidney, as little as 0·05 g of tissue preparation

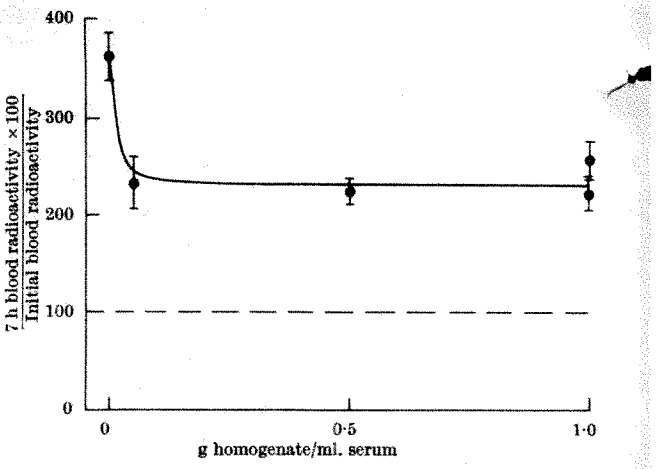

Fig. 2. Absorption of the activity of the long-acting thyroid stimulator by post-mortem kidney. The two absorptions carried out with 1 g/ml. were made with homogenates from different kidneys

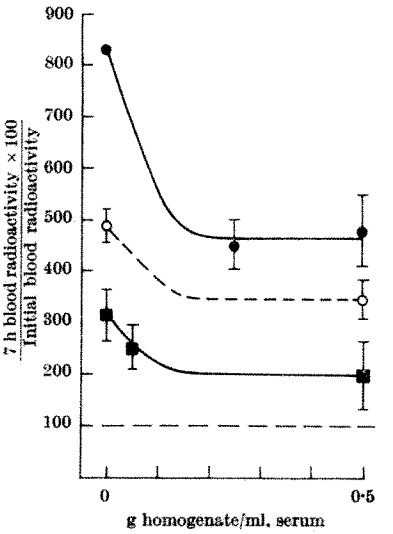

Fig. 3. Absorption of the activity of the long-acting thyroid stimulator by fresh muscle homogenate. ●, Serum from patient Wa.; ○, serum of Wa. diluted 2·5 times; ■, γ-globulin from patient Gi. (the concentration was adjusted to 5 mg/ml.)

reduced the activity of the long-acting thyroid stimulator by about half, but a plateau was reached and no further loss of activity could be demonstrated even when the sera were absorbed with as much as 1 g of tissue pellet/ml. (Fig. 2). A similar phenomenon was observed with fresh skeletal muscle (Fig. 3) and with human gastric mucosa obtained at operation.

Our findings are in accordance with the observations of Kriss *et al.*[5]. In their investigations, although 80 per cent absorption was obtained with human thyroid gland, other human organs were not tested. In experiments with canine tissues, thyroid was more effective than other organs on a weight basis. However, in our investigations partial removal of the activity of the long-acting thyroid stimulator was seen with small amounts of muscle, stomach and kidney, and the absorption with heterologous thyroid reported by Kriss *et al.* could have produced a similar effect without implying that an organ-specific antigen–antibody reaction had taken place. Pincherle *et al.*[11] were unable to demonstrate any absorption of the long-acting thyroid stimulator with slices or cell membranes from a thyrotoxic thyroid gland. On the other hand, Beall and Solomon[12] briefly reported the absorption of long-acting thyroid stimulator by thyroid subcellular fractions.

In the present experiments, the ability of thyroid tissue to remove virtually all the activity of the long-

acting thyroid stimulator from thyrotoxic sera contrasts with the partial absorption observed when other organs were used. Thus it would appear that the absorption of the activity of the long-acting thyroid stimulator depends on at least two components. One of these is thyroid specific and could represent an autoantigen derived from the gland. The non-organ-specific effect is not due to a physical adsorption of IgG to the particulate elements of the tissue preparation since increasing amounts of homogenate did not further reduce the activity of the long-acting thyroid stimulator, and a number of experiments were conducted using IgG concentrations identical with those present in the unabsorbed sera. The possibility cannot be excluded, however, that a proportion of the activity of the long-acting thyroid stimulator is present in an IgG sub-class with a particular tissue-binding affinity. The same arguments make it unlikely that the phenomenon represents an enzymatic inactivation of the long-acting thyroid stimulator, although again there might be a special susceptibility to enzymes of certain sub-classes of immunoglobulin. Recovery of activity by elution from the tissue preparation used for absorption would exclude enzymatic degradation. Loss of activity following absorption is unlikely to be due to a thyroid inhibitor eluted from the tissue homogenate since the decrease in the activity of the long-acting thyroid stimulator was also observed when the γ-globulin was purified by ion-exchange chromatography. The possibility remains that the hypothetical thyroid autoantigen may share some determinants with other organs and that the absorption with non-thyroid tissues is due to an immunological reaction. Whatever the true nature of this phenomenon, the results indicating the existence of a thyroid specific component support the concept that the long-acting thyroid stimulator is a thyroid autoantibody.

We thank Prof. G. W. Harris for helpful comments. We also thank Mr. M. R. Richards and Miss P. Mitchell for their assistance. The work was supported by grants from the Medical Research Council, the Nuffield Foundation and U.S. Air Force.

Note added in proof. Since this work was submitted Dorrington *et al.* (*J. Endocrinol.*, 34, 135; 1966) have described the preferential absorption of long-acting thyroid stimulator by thyroid microsomes. We have now succeeded in recovering activity after absorption on thyroid microsomes, by elution at *p*H 3·6.

RADIOBIOLOGY

Decreased Radiation Mortality in Dogs treated with Typhoid–Paratyphoid Vaccine

Bacterial endotoxins and bacterial vaccines have been shown to decrease X-radiation mortality in small laboratory rodents[1–4]. Typhoid–paratyphoid vaccine (TAB), for example, protects maximally if injected 24 h before irradiation, but, in the mid-lethal dose range, even post-irradiation injection significantly increases survival[2,4]. No such protection of bacterial endotoxins or vaccines, administered pre- or post-irradiation, has been reported for large animals. Byron *et al.*[5] evaluated the effect of post-irradiation treatment with TAB and antibiotics on survival of irradiated rhesus monkeys. A combination of TAB and antibiotic therapy resulted in no greater survival than was observed with antibiotics alone, so no protective effect was ascribed to TAB. The TAB did, however, affect the haematopoietic system; there was a delayed fall and earlier recovery in numbers of platelets and granulocytes. On the other hand, several years ago, Cronkite and Brecher[6] reported that survival was significantly increased and granulocyte recovery occurred earlier in dogs in which an abscess had been produced by a post-irradiation injection of sterile turpentine, bacterial cells, and bacterial components of this mixture.

The purpose of the present work was to determine if TAB injected either before or after irradiation would increase survival in dogs. The present data show that TAB, although quite toxic and pyrogenic, protects dogs when given 24 h before irradiation, but does not significantly increase survival when given 1 h after irradiation.

The dogs used were mongrels weighing 15–30 lb. They were injected intravenously (i.v.) with 1·0 ml. of TAB 24 h before or 1 h after bilateral exposure to 1 MVp. X-rays delivered at ~9 rads/min. No anaesthesia was used. The TAB was a commercial preparation (Parke-Davis) containing $1·5 \times 10^9$ killed organisms per ml. A further description of the experimental animals and of the radiation source may be found elsewhere[7]. Control animals were injected intravenously with 1·0 ml. sterile pyrogen-free saline. Blood samples were drawn aseptically from the forelegs before and following irradiation, and white blood cell and platelet counts were made within an hour of sampling. Standard haematological methods were used.

The intravenously administered TAB produced vomiting, diarrhoea and fever within 2 h, and killed 6 per cent of the animals within 48 h. By 3 h, the average rectal temperature reached a maximum of 104·5° F, and thereafter decreased toward the pre-injection temperature of 101·2° F. By 12 h normal body temperatures were reached, and most signs of acute toxicity had passed. Transitory nausea and vomiting were also produced by exposure to 360 rads.

The 30-day survival data for irradiated TAB- or saline-injected dogs are summarized in Table 1. The injection of TAB 24 h before exposure to 360 rads reduced mortality to 13 per cent as compared with 60 per cent among saline-injected controls. In animals given TAB 1 h after irradiation the mortality was 50 per cent, which is not a statistically significant reduction of mortality. Therefore, if any protective effect at all is produced by post-irradiation injection, it is much less than the protection afforded by TAB injection 24 h before irradiation.

The peripheral leucocyte counts for groups of treated and control dogs are shown in Table 2 and Fig. 1. In the

Table 1. Influence of TAB on 30-day Mortality in Dogs exposed to 360 Rads

‖ 95 per cent confidence intervals are in parentheses.

group given TAB 24 h before 360 rads there was an initial granulocytosis and the granulocyte count was still elevated 1 day after irradiation. At 3 and 5 days' post-irradiation, the counts in the two groups were similar, but between 8 and 13 days there was a significant ($P < 0.05$) elevation of the granulocyte count in the TAB-treated group (Table 2). In dogs given TAB 1 h after 360 rads no rise in granulocyte count was detected during the second post-irradiation week; however, the counts in treated animals were higher than in the controls, and on day 7 the difference was significant. Platelets have been enumerated for 14 days following exposure to 195 rads, a sub-lethal exposure. In animals given TAB 24 h before exposure, the decrease in numbers of platelets occurred somewhat more slowly than in the controls, and at 11 and 14 days the platelet counts in the TAB-treated animals were significantly higher ($P < 0.05$) than in the controls.

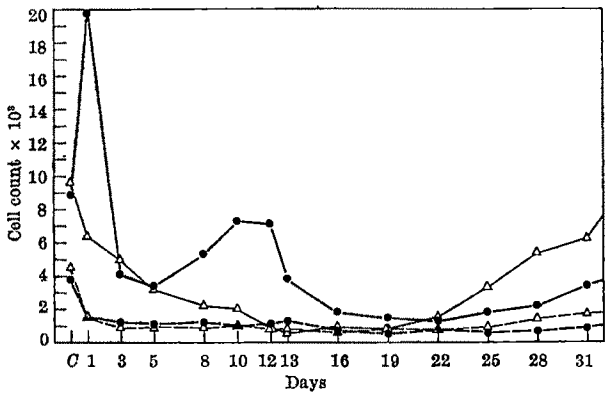

FIG. 1. Granulocyte (—— and ——) and agranulocyte (– – – and – – –) counts as a function of time after irradiation. Groups of seven dogs were given TAB or sodium chloride 24 h before 360 rads. The *C* on the *X* axis indicates the mean of three pre-irradiation cell counts ●, TAB 0/7, △, sodium chloride 4/7

The present data show that TAB significantly increases survival in dogs when given 24 h before mid-lethal exposure, whereas a post-irradiation injection at 1 h has little or no effect on survival. Thus, both in monkeys receiving supra-lethal exposures[5] and dogs receiving mid-lethal exposures, post-irradiation injection of TAB would not seem to increase 30-day survival. This may partially relate to combined toxicity responses to TAB and irradiation, because in animals treated after irradiation the toxic manifestations produced by TAB are superimposed on the nausea and vomiting which occur for several hours following exposure to 360 rads. No attempt has been made so far to mitigate the toxicity or to evaluate the protective effects of lower doses of TAB. Based on the reduction of mortality shown here and the radiation dose-response curve for our mongrel dogs exposed to 1 MVp. X-rays[7] a pre-irradiation injection of TAB probably increases the LD_{50} by a factor of 1·3–1·4. This is not so great a protective factor as is estimated for a combination of AET and PAPP in dogs[8], but TAB is one of the few substances which protects animals larger than laboratory rodents.

The mechanism by which TAB protects, and the mechanism by which endotoxin effects such marked chan[illegible] in the number of circulating granulocytes and platelets during the second post-irradiation week are not known. TAB given before exposure may produce population shifts in bone marrow compartments which result in an increased surviving fraction of precursor cells. Some evidence for an increased surviving fraction of colony-forming units (C.F.U.) has been obtained in mice given endotoxin 24 h before irradiation[11]. Endotoxin produced a twenty-fold increase in the number of C.F.U. detected in the spleen 8 days after irradiation. However, this increase does not necessarily indicate an increased surviving fraction alone, for the increased numbers may be influenced by the rate of migration of C.F.U. to the spleen[12]. Investigations of the extent to which the numbers of C.F.U. may be related to endotoxin protection are in progress. In dogs treated with TAB after irradiation, the diminished rate of fall in granulocytes during the second post-irradiation week may indicate an increased production and/or release of granulocytes into the circulation. Therefore, TAB given either before or after irradiation may somehow influence production, differentiation, and/or release of granulocytes.

The protective effect of TAB may be attributed to 'haematopoietic recovery' and the transitory rise in granulocytes and increased numbers of platelets. Since the mean survival time of saline-treated decedents is ~19 days, increased numbers of granulocytes and platelets during the second week might be propitious in combating infection and haemorrhage during a critical post-irradiation phase. However, the present results show that post-irradiation administration of TAB influences granulocyte-levels during the second week, although this treatment did not significantly reduce mortality. The question therefore arises as to whether the difference in granulocyte numbers resulting from pre- and post-irradiation injection is sufficient to account for the presence and absence, respectively, of protective effects of TAB. On the other hand, based on the granulocyte-levels in animals treated after irradiation, some beneficial effect of TAB on survival might be predicted; perhaps the early toxicity resulting from the combination of radiation and TAB may have some detrimental effect.

It is noteworthy that the effects of TAB on post-irradiation granulocyte-levels, that is, the rise or at least the slower rate of fall during the second week, coincides temporarily with the "abortive recovery or rise" in granulocytes which has been reported to occur spo[illegible]taneously in several species including man[13,14]. Thus, the TAB given either before or after irradiation may somehow influence the abortive recovery which has been attributed to haematopoietic precursor cells that complete only a

few divisions after irradiation[13,14]. Investigations of the interactions between TAB and the haematopoietic system are continuing.

Influence of Aminoethylisothiouronium Bromide·hydrobromide and Hypoxia on Recovery from Radiation Injury in Mice

AMINOETHYLISOTHIOURONIUM bromide·hydrobromide (AET) and hypoxia appear to act as radiation dose reducers; that is, to obtain the same biological response to radiation, higher doses are required in the presence of these agents than in their absence. The ratio of the doses required to elicit the same response in the presence and in the absence of the protectant (protection ratio) is about the same for radiation-induced mortality, changes in the various elements of the haematopoietic system, and changes in spleen, thymus, and body-weights[1,2]. The constancy of the protection ratio and recent cell culture studies[3] imply that radiation injury produced under the two conditions is equivalent. Recent investigations in this laboratory, however, have suggested that the radiation injury may not be completely equivalent. In sheep, pentobarbital anaesthesia and assumed attendant hypoxia resulted in a mortality protection ratio of 1·4. However, recovery at 30 days as measured by the split-dose technique was significantly less in the anaesthetized group than in animals irradiated without anaesthesia[4,5]. The present experiments with AET and hypoxia were conducted to determine the influence of protectants on initial injury and recovery from this injury. The term 'recovery' is used here to indicate the gradual return to normal radiosensitivity following a sub-lethal dose.

The radiation source was a Westinghouse 250 kVp. machine operated at 15 m.amp; the filtration consisted of 0·5 mm copper and 1·0 mm aluminium; the half-value layer was 1·4 mm copper. *CF* No. 1 female mice, 90–120 days old, were placed on a rotating turntable in 'Lusteroid' tubes and exposed at ~30 rads/min at a distance of 92 cm from the focus. LAF_1 male mice, 5 weeks old, were placed in a specially constructed 11 × 17 × 28 cm gassing chamber divided into 6 × 6 cm compartments and exposed at 100 rads/min without rotation; the distance from the focus was 51 cm. Exposures were converted to rad doses using established factors of 1·2 and 1·5 for the turntable and gassing chamber configurations, respectively. After irradiation, all animals were maintained ten in a cage on pine shavings and permitted standard mouse chow and tap water *ad libitum*. The tap water in the drinking bottles was acidified to *p*H 2·6 with hydrochloric acid to retard microbial growth. The number of animals dying was checked daily after the irradiation treatment and the $LD_{50/30}$'s calculated.

The experimental method was that of the split-dose technique wherein the animals are first given a conditioning radiation dose and afterwards divided into groups and exposed to graded challenge doses for determination of the $LD_{50/30}$ at different times after the conditioning dose. The extent to which the conditioning dose and the $LD_{50/30}$ exceeds the single dose LD_{50} indicates the amount of recovery (in rads) from the conditioning dose. The difference between the conditioning dose and the recovery (in rads) is the remaining injury and is expressed as a percentage of the conditioning dose in this report.

In experiments with AET using *CF* No. 1 mice, the agent, buffered to *p*H 7·2, was administered intraperitoneally at a concentration of 275 mg/kg 15 min before the first exposure. Challenge doses were later given without AET.

In the hypoxia studies with LAF_1 mice, both the conditioning and challenging doses were given under hypoxic conditions. Hypoxia, at the time of irradiation, was produced by placing the animals in a gassing chamber in an atmosphere of 95·8 per cent nitrogen and 4·2 per cent oxygen. The oxygen-level was controlled by mixing air and nitrogen using flow meters and measuring the effluent air from the chamber with a calibrated Beckman *C*-2 oxygen analyser. For exposure under non-hypoxic conditions, LAF_1 mice were placed in the gassing chamber and exposed to the conditioning and challenging doses in an atmosphere of air.

The radiation protection ratio for 275 mg/kg of AET was 1·65 based on the $LD_{50/30}$ of 1,270 rads (95 per cent C. I. of 1,229–1,308) for protected CF No. 1 mice and 775 rads (95 per cent C. I. of 758–791) for non-protected mice. The protection ratio for the 4·2 per cent oxygen atmosphere was 2·03 based on the $LD_{50/30}$ of 1,710 rads (95 per cent C. I. of 1,692–1,745) for protected animals and 846 rads (95 per cent C. I. of 831–863) for non-protected animals. About 2 per cent of the mice died from acute AET toxicity and 5 per cent of the mice died during irradiation in the 4·2 per cent oxygen atmosphere. These animals were not included in the LD_{50} determinations. The slopes of the radiation dose-response curves for protected animals do not differ significantly from the slopes for non-protected animals.

The influence of AET on the pattern of recovery is shown in Fig. 1. The curves are for animals conditioned with 854 rads in the presence of AET or with 514 rads alone. These exposures represent approximately 2/3 of the LD_{50} for treated and control mice. Based on the protection ratio for AET, the initial injury in the AET-protected group should be approximately equivalent to that in the non-protected group, namely, 514 rads. Therefore, this value was used as the basis for the determination of the percentage of remaining injury for both groups. The 2- and 24-h points on the AET curve indicate greater injury, 114 per cent, than is assumed for 0 time. Whether or not these values are significantly different from 100 per cent injury is uncertain. Nevertheless, the curves show that the rate of return toward normal radiosensitivity is markedly different in the two groups.

Recovery was evaluated in animals given both the conditioning and challenging dose either in air or under hypoxic conditions. Mice were conditioned with 1148 rads in a 4·2 per cent oxygen atmosphere or with 563 rads in air (approximately 2/3 of the LD_{50} determined for the respective gas mixtures). Based on the protection ratio, the initial injury in the two groups should be equivalent, and the pattern of recovery should be comparable. The curves presented in Fig. 2 indicate a marked difference between the groups in the pattern of recovery during the first 3 days.

In non-protected mice, recovery from radiation injury, as measured by the split-dose technique, proceeds rapidly during the first few days. In contrast, mice protected with AET or hypoxia exhibit a different pattern of recovery,

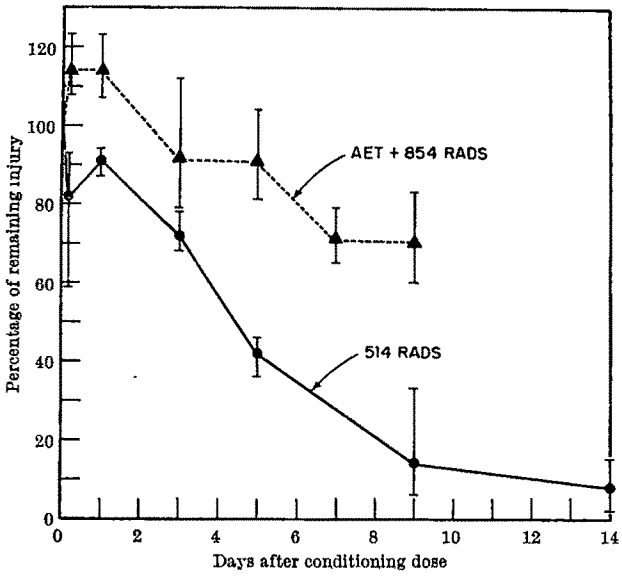

Fig. 1. Influence of AET on recovery in *CF* No. 1 mice

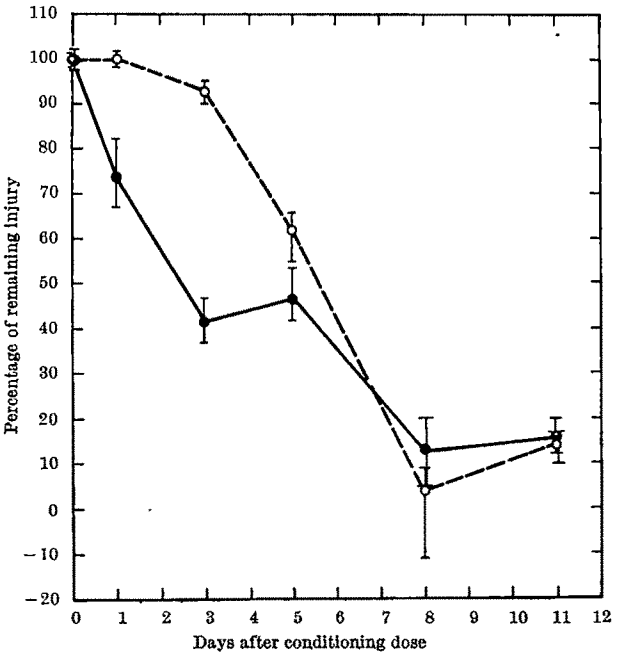

Fig. 2. Influence of hypoxia on recovery in *LAF* mice: ●, in air; ○, in hypoxic conditions

although the initial injury was theoretically equivalent to that in non-protected controls. In protected mice there is an initial delay of at least 24 h before the animals show significant recovery. Beginning at 3 days, recovery proceeds rapidly in the hypoxic group at a rate comparable with the controls, but in the AET group rapid recovery does not begin even by 7 days. Assuming that the pattern of recovery from quantitatively and qualitatively equivalent initial injury should be similar, the present results indicate that the initial injury in the protected and non-protected groups is not equivalent.

The differences in the patterns of recovery might be attributed to: (*a*) differential protection in various physiological systems[6]; (*b*) comparable injury but inherent differences in tissue repair potentials[7]; (*c*) qualitative differences in the injury sustained under different exposure conditions[8–11]; (*d*) an inhibitory effect of the protective procedures on recovery. We are at present attempting to determine which of these effects is responsible for the differences.

The influence of hypoxia on recovery, as shown both in cell cultures[9,11] and now in mice, is relevant to radiotherapy providing these findings are applicable to megavoltage radiations and to tumours. If the damage sustained in tumours under anoxic conditions is such that recovery is impaired, fractionated irradiation would result in greater additivity of injury in anoxic cells than in oxygenated cells. In effect, fractionation would reduce the anoxic protection ratio. This effect is shown by the present data when two fraction protection ratios are calculated by adding the conditioning dose and the LD_{50}'s. When fractions were separated by 1, 3, or 5 days, the protection ratios were 1·74, 1·54, and 1·88, respectively; the single dose protection ratio is 2·03.

In summary, the present data indicate that mice protected by AET or hypoxia show a greater sensitivity to a second exposure than would be expected on the basis of the protection ratio determined from acute lethality studies. Recovery is impaired when radiation injury is sustained in the presence of AET or under hypoxic conditions.

This investigation was supported through funds provided by the Bureau of Medicine and Surgery, U.S. Navy Department and the Defense Atomic Support Agency.

Direct and Indirect Effects of Radiation: their Relation to Growth

Holsten, Sugii and Steward[1] have recently added the colony-forming ability of single, isolated carrot cells to the spectrum of biological systems in which heavy X- or γ-irradiation of the carbohydrate component of the growth medium results in the production of a cytotoxic, growth-inhibiting substance in that medium. Similar demonstrations of this effect were reported by Molin and Ehrenberg[2] for a bacterial species, and by Berry, Hills and Trillwood[3] for two strains of mammalian cells grown *in vitro*. From their own results, however, Steward *et al.* have implied a potential biological hazard to man, by the supposition that radiation effects can be transmitted indirectly to cells (perhaps at times long after the actual irradiation) by stable, toxic radiolysis products derived from irradiated sugars. This supposition seems untenable. Even in their own very radio-resistant biological system, Steward *et al.* found quantitative differences between the growth inhibition produced by direct irradiation of the biological material, and that produced by the cytotoxic radiolysis products in irradiated growth medium. In mammalian cells, this quantitative difference is dramatic; radiation doses of the order of thousands of rads delivered to the carbohydrate-containing part of the growth medium were necessary to reduce cell growth even marginally[3,4], while

direct X- or γ-irradiation of mammalian cells *in vitro* with doses of the order of only tens of rads is sufficient not only to reduce the rate of cell growth, but also to produce cell reproductive death (see, for example, Puck *et al.*[5]). There is, as yet, no evidence that the cytotoxic effects of irradiated carbohydrates, and the toxic effects of ionizing radiation are in any way similarly produced at the cellular level.

Secondly, in drawing "obvious implications for the radiation sterilization of food", Steward *et al.* overlook the difference between their *in vitro* situation, in which the biological material is grown in a heavily-irradiated medium, and the *in vivo* situation for the whole animal (or human being) where ingestion of any potentially toxic materials by no means assures their absorption from the gastro-intestinal tract, or their transportation in a toxic form to any vulnerable sites within the body[6]. The only relevant test for *in vivo* toxicity is the birth-to-death study of health, longevity and reproductive function in large numbers of animals fed throughout their lives on irradiated foodstuffs (see, for example, Radomski *et al.*[7]). The necessity for such tests has already been clearly recognized in many countries[8], including the United Kingdom[9].

While some of these comments may seem obvious, we feel that they are necessary in the light of the wide publicity which the summary conclusions from the work of Steward *et al.* have received in the popular Press in Britain, and in the United States.

Breakdown of Ribonucleic Acid in *Escherichia coli B* after X-irradiation

The influence of ionizing radiation on the growth and metabolism of bacteria has been the subject of many reports. One of the most significant effects of X-irradiation is the degradation of a part of deoxyribonucleic acid (DNA) in bacterial cultures[1,2]. It was therefore interesting to examine whether the radiation damage of DNA is accompanied by an alteration of the synthesis of ribonucleic acid (RNA) in bacteria exposed to irradiation. Experiments of this kind by Frampton[3] have shown a depression of RNA synthesis in *Escherichia coli B/r* after exposure to X-irradiation. His analyses of cell-free extracts by ultracentrifugation in sucrose density gradients indicated a decline in the synthesis of 50 *S* ribosomes. In this paper we are going to describe experiments showing a breakdown of a part of RNA synthesized in a growing population of bacteria before or shortly after the irradiation.

We used *Escherichia coli B* in all our experiments. In a typical experiment the bacteria were grown in a mineral medium containing glucose at 37° C. Adenine-8-^{14}C (specific activity 53·5 mc./mmole) was added to an exponentially growing culture of about 3×10^8 cells per ml. to yield a final concentration of 4×10^{-7} M. The bacteria were able to incorporate more than 90 per cent of radioactivity in 15 min. Forty min after adding the isotope, the culture was cooled to +4° C; one half of it was irradiated with 16,000 r., and the other half was kept as the control. Such a dose of X-irradiation has always given a survival of about 1 per cent, and a marked degradation of DNA during subsequent incubation[2].

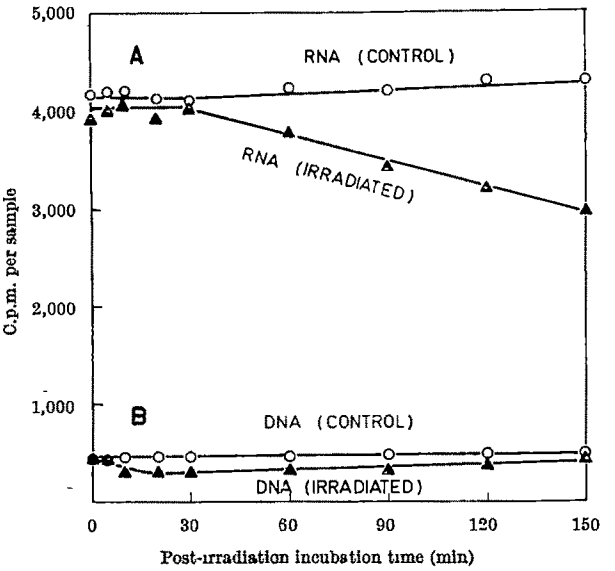

Fig. 1. Breakdown of ribonucleic acid (*A*) and deoxyribonucleic acid (*B*) in *Escherichia coli B* exposed to 16,000 r. of X-irradiation. The cells were labelled with adenine-8-^{14}C 40 min before irradiation

After the irradiation, both cultures were incubated at 37° C; 0·5 ml. samples were taken at various times and precipitated with 5 per cent trichloroacetic acid. The precipitates were collected on 'Millipore' filters, washed with 5 per cent trichloroacetic acid, and the radioactivity in both DNA and RNA measured in a window-less gas-flow counter. The activity of DNA was measured in parallel 0·5 ml. samples after hydrolysis of RNA with 0·3 N potassium hydroxide[4]. Radioactivity of RNA was computed from the difference of radioactivities of total nucleic acids and DNA. The results of such an experiment are presented in Fig. 1. It can be seen that a part of the RNA in an irradiated culture begins to break down after 30 min of incubation. The loss of radioactivity is linear during the following 120 min. At the end of this period the breakdown affects about 25 per cent of the radioactivity originally present in RNA.

It should be emphasized that this breakdown of a part of the RNA is accompanied by a significant, although somewhat depressed, net synthesis of RNA. This increase in the RNA content, demonstrated in similar experiments using the orcinol method[5], has always run parallel with the increase in turbidity of irradiated cultures.

Fig. 1 also shows that the loss of radioactivity from DNA during the first minutes after irradiation is 25 per cent, which is in good agreement with results on the degradation of DNA (ref. 2).

The breakdown of RNA depends on the dose of irradiation, as shown in Fig. 2. At doses up to 16,000 r., the breakdown is a linear function of the dose; at higher doses, a saturation can be observed. It is characteristic that, at all doses, the breakdown begins 30 min after irradiation and is linear during the next 120 min.

Since the breakdown of RNA described in the preceding paragraphs refers to the RNA synthesized before irradiation, it was of interest to find out whether the RNA

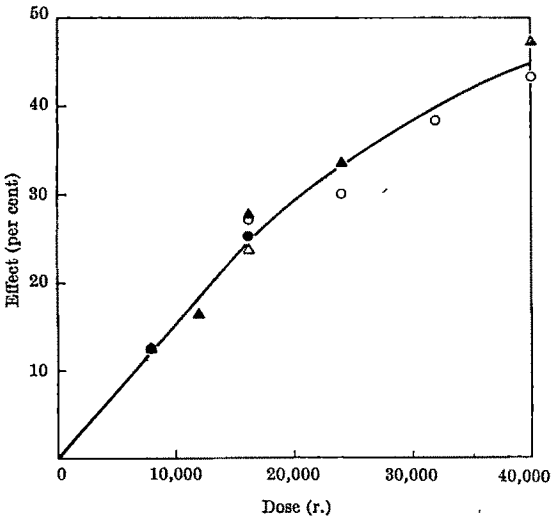

Fig. 2. Dose-effect curve for the breakdown of ribonucleic acid in *Escherichia coli B* exposed to X-rays. RNA broken down after 150 min of post-irradiation incubation is plotted against the dose of X-irradiation. RNA was labelled by adding adenine-8-^{14}C 40 min before irradiation. Various symbols are used for the values obtained in four independent experiments

synthesized after irradiation is similarly affected. In a series of experiments similar to that already described, adenine-8-^{14}C was added to the cultures at various times after irradiation with 16,000 r. The results show that the breakdown of RNA labelled immediately after irradiation begins at the same time, and at the same rate as in the experiment with the RNA labelled 40 min before irradiation. RNA labelled 40 min after irradiation showed a considerably lower rate of breakdown. We did not find any loss of radioactivity from RNA labelled 60 min after irradiation.

The radioactive products of RNA breakdown are found in the incubation medium as fragments of low molecular weight. This agrees to a great extent with the results of Billen[6], who found a release of the cellular constituents from irradiated *Escherichia coli B/r* incubated in phosphate buffer and glucose at 37° C. These were nucleic acid fragments, varying in size from free bases to oligo nucleotides. In our experiments we have shown that the material released originates from the labelled RNA. The cells were not able to re-incorporate these fragments into their nucleic acids. At the same time the irradiated cells retained their ability to incorporate added adenine-8-^{14}C. One hour after irradiation the rate of incorporation was only a little reduced compared with the control.

These experiments were performed with the aim of demonstrating a possible connexion between the degradation of DNA caused by X-irradiation, and presumable similar effects on RNA. The fact that the RNA synthesized before irradiation can be broken down, however, excludes a transmission (or copying) of the radiation-induced damage from DNA to RNA. On the other hand, RNA subject to post-irradiation breakdown does not necessarily have to be synthesized before irradiation, since RNA labelled shortly after irradiation shows the same effect.

To clarify the nature of the RNA broken down, we performed preliminary analyses of cell-free extracts on sucrose density gradients. Under our conditions 40 min after the addition of adenine-8-^{14}C 54 per cent of radioactivity was found in 50*S* ribosomes, 30 per cent in 30*S* ribosomes, and 16 per cent in 4*S* RNA. Taking into account that the loss of radioactivity from RNA is 25 per cent after the dose of 16,000 r., and about 50 per cent at 40,000 r., it can be concluded that the ribosomal RNA must represent a considerable fraction of the RNA which is degraded. More detailed experiments are still in progress.

We thank Mr. D. Jović for his assistance.

BIOLOGY

Visual Orientation and Feeding in Seals and Sea Lions

At least some, and perhaps most, pinnipeds of the families Phocidae and Otariidae are nocturnal feeders[1]. The eyes of these predators, being sensitive to very low light intensities[2], are suited for use at night and in deep water. During the day the visual acuity of the California sea lion (*Zalophus californianus*) allows this animal to discriminate a size difference ratio as small as 1·06 : 1 (ref. 3). A great deal of vocalizing occurs among pinnipeds, both above and below the surface of the water[1,4–6]. This fact, along with experimental work such as that of Mohl with the harbour seal (*Phoca vitulina*)[7], indicates that hearing is generally well developed. Poulter suggested that the California sea lion, and probably other species, is able to capture prey in darkness by utilizing an echo-ranging sense similar to that known to occur among cetaceans[4]. However, subsequent work[5,6] has failed to support Poulter's theory. Nevertheless, as "individuals totally blind but in a good state of health have been reported"[1], the possibility that such a sense may be developed when needed should not be dismissed lightly.

While observing behaviour in fishes during the past ten years, I have spent many thousands of hours underwater at all hours of both day and night. This experience has provided me with some insight into factors likely to influence the activity of mammals underwater which may have been overlooked by more terrestrially oriented students of mammalian behaviour.

Poulter was impressed by the ability of the sea lion to locate bait which he presented after it had become "so dark that the pieces of fish, and much of the time the animals, were not visible to the human eye". On picking up vocalizations by the sea lions in "a series of short pulses which are similar in many ways to the sonar pings of the porpoise", Poulter concluded, "Since the animals will pick up pieces of fish thrown into the tank just as quickly under the darkest conditions mentioned above as they do in daylight, I believe these sounds to be echo ranging signals of a complex and sophisticated nature".

The ability of the sea lion to locate bait under the conditions of darkness described by Poulter seems of questionable significance in an argument for an echo ranging ability in this animal. As sea lions possess an extensive tapetum lucidum[2], they presumably have a visual sense far more sensitive to low light intensities than that of humans. But quite apart from this fact, while it was too dark for a human looking down into the tank to distinguish the bait, and often the animal, the sea lion was below the surface of the water looking up at the bait from below. When located beneath the surface as light diminishes at dusk, I have found that I can readily distinguish an object in the water above me, silhouetted against the relatively light surface, long after an observer above the water is unable to see anything but darkness below. While diving in clear water at night I have been

able to distinguish objects above me, using the surface as a contrasting background, when the only source of illumination is starlight. This ability must be considerably more striking in a creature possessing the visual capacities of the seal or sea lion.

An observation made by Bonnot[8] suggests that the California sea lion may indeed take advantage of the relatively light surface in locating prey at night. Bonnot observed a sea lion feeding at night on flying fishes which were milling about under a night light next to his vessel. The sea lion consistently approached the area, swimming on its back, at a depth of approximately 30 ft. On reaching a point directly below the milling fish, the sea lion shot straight up and almost invariably succeeded in capturing a fish. Bonnot recorded the capture of at least six flying fish, with each attack following the pattern described here. Although the presence of the night light here created an atypical nocturnal situation, the unvarying manoeuvre performed by the sea lion in securing its prey suggests this to be a regular hunting pattern.

Captive sea lions and harbour seals at the U.S. Naval Missile Center, Point Mugu, California, also approach targets and baits by swimming in on their backs from below. Even when targets were lowered to a depth of 40 ft., a trained sea lion made its approach only after first descending to a depth greater than that of the target, and then shooting up after swimming in under the target from below. Limited observations at a depth of 240 ft. indicated that the same approach to a target is made at that depth[9].

Such a manoeuvre is advantageous for a predator, not only because its prey is thus viewed against the lighter water above, but also because its attack, being launched from the darker water below, is less readily seen by the prey.

Some predatory fishes use a similar tactic. In the Gulf of California, feeding intensity in the leopard grouper (*Mycteroperca rosacea*) reaches a peak just prior to dawn and shortly after sunset when the groupers concentrate under schools of flatiron herring (*Harengula thrissina*). In spite of the fact that the sky is still quite light at this time, relatively little light penetrates into the water, and from the herring's position near the surface the groupers below are very difficult to see. However, from the grouper's position below, the herring stand out sharply against the light surface. Feeding by the grouper under these conditions is consummated with a sudden rush up into the herring school[10].

It is possible that the prey of these animals are particularly vulnerable to attack from below for reasons other than those given here. For example, an approach from this direction may take advantage of the largest 'blind spot' in the visual field of the prey.

Feeding at night in phocids and otariids may also be aided by bioluminescence. The diet of the northern fur seal *Callorhinus ursinus* during its migrations on the high seas is composed largely of lantern fish and squid[11]. The lantern fish is well known for its luminescent characteristics. During the day the lantern fish and squid live at considerable depths, but rise close to the surface at night where they are preyed on by the seals.

In many areas of the sea at night, a moving object is readily observed due to the luminescence of many minute planktonic organisms, mostly protozoans, which light up when disturbed. These organisms are often so numerous that while making observations underwater I have been able to identify, to species, fishes which swam actively among them. This was not because the fish itself was illuminated, but rather because there were so many minute luminescent organisms about the fish that its form was essentially traced out in tiny flecks of light. Under such conditions, a feeding seal or sea lion might follow the luminescent trail of its fleeing prey in making the capture. Of course, a predator operating under such conditions would experience difficulty catching its prey unawares because its predatory manoeuvres would also be advertised by the luminescent organisms.

Differential Reaction of *Lolium perenne* Genotypes to Certain Herbicides

THE rapid progress in weed destruction made possible simply by introducing new chemicals has resulted in a concentration on obvious and gross effects. Examples of the selective toxicity of various chemicals between different plant genera and between different species of the same genus[1] have been widely reported. Much less frequently cited are differential responses between varieties of one species. In potatoes, variation in varietal reaction to pre-planting application of trichloroacetic acid (TCA) has been noted[2] and large differences in varietal susceptibility to 2 : 4-dichlorophenoxyacetic acid (2,4D) and 2-methyl-4-chlorophenoxyacetic acid (MCPA)[3] have been found. Hayes[4] has demonstrated the differential response of barley to DDT, susceptible varieties being killed by DDT application. Commercial varieties of sugar-cane differ in physiological tolerance to dalapon[5]. Fiddian[6] gave evidence of differential susceptibility of cereal varieties to some commonly used herbicides, variation occurring in amount of leaf scorch, growth deformity, ripening retardation, ear malformation and spikelet sterility.

In grasses, differential tolerances to various chemicals between species have been recorded. For example, King and Davies[7] have shown that of the common grasses differing in their response to dalapon, *Lolium perenne* and *Festuca* spp. are relatively resistant, while *Nardus stricta* and *Molinia caerulea* are susceptible even to quite low dose rates. The time of season at which the dose is applied and the age of the plants when treated affect species reaction. Within varieties, individual cocksfoot seedlings apparently resistant to dalapon were found by Cooper[8].

Sensitivity of *Lolium perenne* genotypes to various herbicides has been investigated at the Plant Breeding Station, Loughgall, North Ireland, with the view of initiating heritability studies. (The help of Dr. D. W. Robinson, formerly of the Horticultural Centre, Loughgall, is gratefully acknowledged.)

Four genotypes—512, 3002, 3136 and *S*2412—and six herbicides—MCPA, MCPB, mecoprop, dalapon, simazine and diquat—were included in the experiment. In a split-plot randomized-block lay-out of three replications herbicide application constituted the major plots and genotypes the sub-plots.

The genotypes were selected as having an identical date of ear emergence to ensure that, so far as possible, all would be at an equivalent physiological stage of growth

at the time of treatment. The clones were tillered on the same day and plantlets, each made up of ten tillers, were planted in the field in March 1961. The plantlets were placed 1·5 ft. apart in rows 1·5 ft. apart. In each sub-plot a genotype was represented by a single row of seventeen plantlets. The entire trial was surrounded by a border row. Compound fertilizer (N, 15 : P, 10 : K, 10) was applied to all plots at a rate of 3 cwt. per acre. A logarithmic sprayer was used for the application of herbicides. The 4·5-ft. spray boom had one nozzle directly above each genotype row and was carried at 1·5 ft. above ground-level. In each sub-plot the first two plants were shielded from application to act as controls and the sprayer allowed steadily to empty over the next twelve plants. The fifteenth plant was used as a buffer to the last two, which were left as unshielded controls. The peak dosages in lb. per acre of active material were as follows: MCPA, MCPB and mecoprop 8, dalapon 20, simazine 6, diquat 4. Ten days after all plants had been cut back uniformly to remove heads spraying was carried out on July 8, 1961, and 3 weeks later plants were cut with hedge shears 3 in. from ground-level and the mean green weight of each adjacent pair of plants recorded.

The mean yield of the four genotypes, which can be considered to represent the general reaction of *Lolium perenne*, is given in Table 1.

Table 1. MEAN YIELDS OF FOUR *Lolium perenne* GENOTYPES SUBJECTED TO VARIOUS CONCENTRATIONS OF SIX HERBICIDES

Herbicide	Mean green weight of adjacent plants (gm) Percentage of peak dosage applied 73·8	47·5	30·0	18·8	12·5	7·5	Unshielded control	Shielded control
MCPA	113·2	126·7	122·1	142·1	123·3	125·8	123·9	128·3
Mecoprop	128·7	130·0	137·7	144·6	143·3	141·6	141·2	144·2
MCPB	142·1	148·7	152·1	144·2	137·1	137·9	136·6	139·6
Dalapon	12·1	28·3	45·4	72·5	106·6	127·5	134·2	140·4
Simazine	23·3	24·2	33·7	43·8	50·8	61·6	132·8	136·7
Diquat	18·3	17·9	34·1	39·6	46·2	60·4	132·5	136·2

MCPA, MCPB and mecoprop (synthetic growth regulators reported not to harm cereals and other graminaceous crops) had no significant effect on yield. Dalapon, a translocated herbicide toxic to grasses, gave a gradual reduction in yield with increased dosage. Diquat and simazine, characterized by their high toxicity to a large range of plants, reduced yield by more than 50 per cent at even the lowest dosage, further reduction proceeding gradually with increase in dose rate.

No genotypic differences were evident when the yields of the four genotypes in the MCPA, MCPB and mecoprop treatments were examined individually, but very obvious differential effects occurred in the dalapon, simazine and diquat treatments. The magnitude of these effects was so great that no formal statistical analysis was considered to be necessary.

The concentration at which death-point was reached varied with genotype. Simazine (Fig. 1) while causing the death of genotype 3002 at 18·8 per cent peak dose (PD), 3136 at 30 per cent PD and 512 at 73·8 per cent PD affected *S*2412 relatively little, almost half of its normal yield still being found at 73·8 per cent PD. The slope of the curves is indicative of further differential reaction, three of the genotypes rapidly succumbing to even the lowest concentration of simazine while *S*2412 was almost unaffected at these levels of application.

Dalapon killed 3136 at 30 per cent PD, 3002 and 512 at 73·8 per cent PD, while *S*2412, little affected by even 18·8 per cent PD, was still alive with about 25 per cent of normal yield at 73·8 per cent PD. A different reaction was obtained with diquat which, while reducing yield of *S*2412 at 73·8 per cent PD to a level similar to that produced by dalapon at 73·8 per cent PD, did not kill any of the genotypes completely. The relative sensitivity of 3002 to even 7·5 per cent PD of diquat compared with that of the other genotypes revealed further differential reaction.

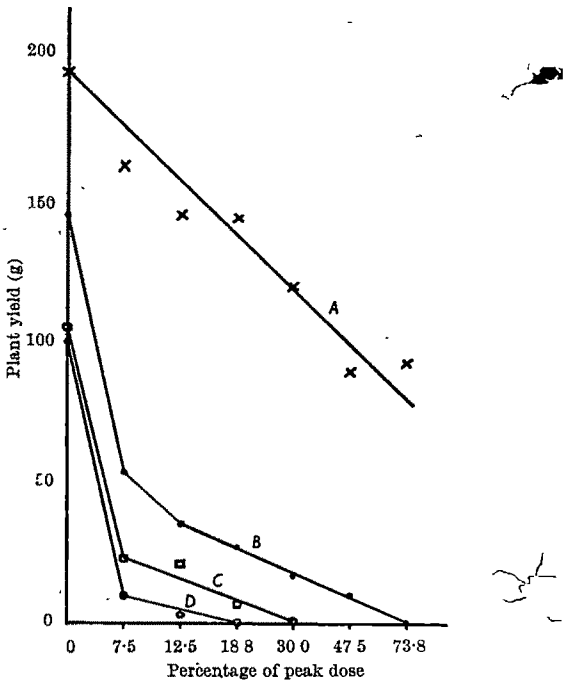

Fig. 1. Effect of various concentrations of simazine on the herbage yield of four *Lolium perenne* genotypes. *A*, *S*2412; *B*, 512; *C*, 3136; *D*, 3002

The agronomic value of grass cultivars based entirely on genotypes resistant to recognized 'grass-killers' could be far reaching. For example, pastures sown with such cultivars could be effectively renovated without ploughing, and contaminant rogues and weeds could be removed by spraying from crops destined to produce certified seed. Should resistant genotypes be found in the species normally sown in lawns the possibility of a simple management for the perfect lawn can be envisaged.

Stimulation of Flowering in Certain Short-day Plants by Abscisin

ALTHOUGH day-length is known to control flowering in some plant species, and a variety of vegetative responses, including dormancy, runnering and tuberization, in other species the relationship between these different types of photoperiodic effect is obscure. Evidence has been presented that the induction of dormancy in woody plants in response to short days involves the newly discovered growth-regulator, abscisin II ('dormin')[1], and it has been possible to induce the formation of resting buds by application of endogenous inhibitor in birch[2]. Evans has recently reported the inhibition of flowering in the long-day plant, *Lolium temulentum*, by abscisin[3]. Thus it is pertinent to investigate whether abscisin II will stimulate flowering in short-day species. The availability of synthetic abscisin[4] has made it possible to carry out a range of experiments on this problem.

The following experiments have been carried out with the short-day species, *Pharbitis nil*. Scarified seeds were sown in pans of vermiculite and maintained under con-

tinuous illumination from fluorescent lamps at 20° C. When the plants had formed 1–2 leaves and were 8–10 cm high they were removed and their roots washed free of vermiculite. Each seedling was then placed with its roots in a test-tube containing either a solution of synthetic abscisin (a racemic mixture of two enantiomorphs) at a concentration 4 p.p.m. or water alone, and the seedlings were allowed to remain in the tubes under continuous illumination for 7 days. The seedlings were then planted in soil in pots and transferred to a heated greenhouse under 18 h photoperiods. Macroscopic flower buds were visible after 4–5 weeks. The results of three experiments of this type are shown in Table 1.

Table 1. EFFECT OF ABSCISIN ON FLOWERING IN *Pharbitis nil*

	Treated with abscisin		Water controls	
	Vegetative	Flowering	Vegetative	Flowering
Experiment 1	5	7	12	0
Experiment 2	7	18	11	4
Experiment 3	2	10	25	0
Total	14	35	48	4

It is seen that an average of 70 per cent of the seedlings treated with abscisin flowered, whereas only 8 per cent of the untreated control plants did so.

Experiments were also carried out with seedlings of *Chenopodium rubrum*, seed of which was sown on filter paper in Petri dishes. The seedlings were maintained under continuous illumination at 20° C and were supplied with Hoagland's No. 1 nutrient solution (half strength) on alternate days. After 4 weeks, the seedlings were transferred to filter paper in small crystallization dishes, and were supplied with an aqueous solution of abscisin (4 p.p.m.) or with water alone, for 7 days. The seedlings were then continued under the same conditions and supplied with Hoagland's solution on alternate days. Growth was slow under these conditions, but after 6 weeks a high proportion of the seedlings treated with abscisin produced flowers (Table 2). Similar results were obtained in a repeat experiment.

Table 2. EFFECT OF ABSCISIN ON FLOWERING IN *Chenopodium rubrum*

	Treated with abscisin		Water controls	
	Vegetative	Flowering	Vegetative	Flowering
Experiment 1	41	23	49	0
Experiment 2	17	33	26	0

Further experiments have been carried out with larger plants of *Chenopodium rubrum* grown in pots in a greenhouse, and with other short-day species, including soya-bean c.v. 'Biloxi', *Xanthium pennsylvanicum*, and tobacco c.v. 'Maryland Mammoth', in which abscisin was applied at concentrations of 5 p.p.m. using various methods of application, namely: (1) by spraying on the leaves; (2) by feeding through a lip of tissue cut in the stem; (3) by application to the roots of plants grown in sand. No flowering responses were obtained with any of these treatments with these species.

Experiments have also been carried out with plants of blackcurrant, using partially purified endogenous growth-inhibitor extracted from the leaves of other blackcurrant plants grown under short-days. The extraction and purification procedure was similar to that described elsewhere for inhibitors extracted from sycamore and birch leaves[5]. The experimental blackcurrant plants (grown from cuttings) were about 60 cm in height and were grown in pots in a warm greenhouse under 18 h photoperiods. The inhibitor solution (containing the activity from 10 g dry weight of leaves per 1 ml. of water, with 0·01 per cent 'Nonidet *P*42' added as a wetting agent) was sprayed on the apex and leaves in the upper parts of thirty plants. A further thirty plants sprayed with water were used as controls. The treatments were applied for 30 days. The plants were then allowed to remain under long days for a further 60 days, when the axillary buds of each plant were sectioned for examination. It was found that fifteen of the plants treated with inhibitor had initiated clearly recognizable flower primordia, whereas all the control plants remained vegetative.

A further experiment was carried out with blackcurrant, using synthetic abscisin II. Pot grown plants maintained under long days in a heated greenhouse were treated with abscisin at a concentration of 5 p.p.m., applied through a lip in the stem for 15 days and sprayed on the leaves for a further 5 days. Examination of the axillary buds 5 weeks after the cessation of treatment showed that six out of nine plants treated with abscisin had initiated flowers, whereas none of the six control plants had done so.

Thus abscisin II appears to be effective in stimulating flowering in the short-day species *Pharbitis nil*, *Chenopodium rubrum* and blackcurrant, but attempts to induce flowering in other short-day species have so far been unsuccessful.

We thank 'Shell' Research, Ltd., for a supply of the synthetic abscisin II used in this investigation and also for the provision of a support grant. Acknowledgements are also made to Prof. S. L. Imamura for kindly supplying seed of *Pharbitis nil*.

ENTOMOLOGY

'Paper Factor' as an Inhibitor of the Embryonic Development of the European Bug, *Pyrrhocoris apterus*

WE have already described a fortuitous combination of events which led to the discovery that American newspapers and other paper products contain a potent analogue of the juvenile hormone of the European bug, *Pyrrhocoris apterus* L. (Heteroptera ; Pyrrhocoridae)[1]. When reared in contact with 'active paper' or when exposed to surfaces impregnated with extracts of the 'paper factor' (PF), fifth-stage *Pyrrhocoris* larvae undergo one or more supernumerary larval moults and finally die without completing metamorphosis or attaining sexual maturity. This same result is observed when 1 μg of partially purified PF is topically applied to young fifth instar larvae[1,2].

The purpose of this communication is to report additional experiments in which PF was tested on *Pyrrhocoris* eggs and adults.

When newly laid eggs were collected from normal, untreated females and placed in contact with active paper, we were astonished to find that few, if any, of them hatched. A typical experiment is summarized in Table 1. It will be observed that, of the 150 eggs exposed to PF, only six completed embryonic development. Experiments of this type have been repeated many times and always with the same result. For example, when 800 freshly deposited eggs were placed on filter paper impregnated with 0·5 mg PF, only four completed embryonic development.

We would emphasize that this inhibition of embryonic development was observed only in experiments performed on *Pyrrhocoris* eggs. For example, PF did not have any

Table 1. EFFECT OF 'PAPER FACTOR' ON THE EMBRYONIC DEVELOPMENT OF THE EGGS OF *Pyrrhocoris apterus*

Exposure to:	No. of eggs	Results: Normal development	Results: Arrested development
Inactive paper (Whatman's No. 1 filter paper)	50	50	0
Active towelling (Scott, Brand 150)	50	6	44
Whatman's filter paper impregnated with 1 mg PF	50	0	50
Microdrop of acetone solution of PF	50	0	50

detectable effect on the eggs of numerous other species of laboratory insects, including two other species of Heteroptera, *Oncopeltus fasciatus* (Lygaeidae) and *Rhodnius prolixus* (Reduviidae). This finding is in accord with conclusions derived from previous experiments performed on larvae—namely, that PF is an effective analogue of the juvenile hormone of *Pyrrhocoris*, but is completely inert for most other species[1,2].

Detailed investigations of *Pyrrhocoris* eggs revealed that, after exposure to PF, embryonic development was initiated and progressed in an apparently normal manner to at least the formation of the germ band. At some later stage, development stopped with the still living embryo short of completion.

The most affected eggs contained a small disk of embryonic tissue afloat on a mass of unincorporated yolk. In somewhat more advanced cases, the embryonic mass showed the rudiments of certain appendages but not of others. Sometimes parts of appendages had formed in the absence of the remainder. Embryos that attained a more advanced status showed rudimentary legs and antennae which were closely appressed to the body surface. The entire, living embryo was, in fact, reminiscent of a miniature lepidopteran pupa. The most advanced embryos were covered with a thin, transparent cuticle overlying epidermal cells in which a red pigment had been synthesized. Hairs and setae were absent and only traces of the compound eyes could be recognized. In some cases, the chorion ruptured at the normal time and the bizarre, non-motile (but still living) creatures were aborted from the eggs.

When PF was topically applied to freshly oviposited eggs, development was blocked at a more uniformly early stage than when eggs were simply placed in random contact with active paper. This implies that the stage at which embryonic development is blocked is related to the uptake of PF.

Freshly laid eggs are maximally sensitive to PF. When eggs were incubated at 25° C for 1 or 2 days and then treated with PF, embryonic development was always less affected. After 4 days of preliminary incubation, the eggs were virtually insensitive to PF, even when high doses were topically applied.

These findings suggested that the eggs might be sensitive to PF while still in the ovary or oviducts. To test this possibility, each of six freshly moulted adult females was treated with a topical application of 200 μg of partially purified PF. The animals were then reared in individual Petri dishes together with adult males. At daily intervals the eggs were collected, counted and incubated at 25° C.

Without exception, the eggs behaved as if they had been directly exposed to PF; that is, development proceeded to a certain stage and then stopped. This implies that, after topical application to adult females, PF is absorbed, translocated to the reproductive tract, and somehow brought into association with the eggs.

We have previously demonstrated the ability of PF to block the metamorphosis or sexual maturation of *Pyrrhocoris* larvae[1,2]. We now see that, for *Pyrrhocoris* eggs either before or immediately after oviposition, PF is an effective and selective ovicide. These findings should encourage a search for juvenile hormone analogues which have similar effects on specific insect pests[3].

The ability of PF to block the metamorphosis of *Pyrrhocoris* is just what would be anticipated on the basis of present knowledge of the mode of action of juvenile hormone[4–6]. As has been pointed out elsewhere[4,5], nearly all the effects of juvenile hormone can be accounted for in terms of its ability to block the derepression, transcription, or utilization of fresh genetic information. Therefore, only in the absence of juvenile hormone can the cells and tissues undertake the new synthetic acts which are prerequisite for metamorphosis but not prerequisite for larval growth. Though the role of hormones in embryonic development is little understood[7–11], this same theory of the action of juvenile hormone can obviously account for the ability of PF to block the metamorphosis of an egg into a *Pyrrhocoris* larva.

This work was supported, in part, by a grant from the National Science Foundation.

Effect of Removal of the Frontal Ganglion on Corpus Allatum Function in *Locusta migratoria migratorioides* R. & F.

REMOVAL of the frontal ganglion from young adults of *Locusta migratoria* L. prevents normal growth and sexual maturation; the operation is thought to interfere with the activity of the cerebral neurosecretory system[1]. It is possible, however, that the removal of the frontal ganglion affects the activity of the corpora allata which are also essential for maturation in locusts[2,3]. This possibility has been investigated using adults of *Locusta migratoria migratorioides* R. & F.

The frontal ganglion was removed from each of ten newly emerged females, and a further ten newly emerged females were subjected to a sham operation. The insects were reared with males, under conditions described elsewhere[3], for 14 days after which time the survivors were weighed, killed, their ovaries examined, and the volume of their corpora allata measured using Staal's technique (Table 1).

Table 1. FRONTAL GANGLION REMOVAL IN *L. m. migratorioides*.
The mean weights, terminal oocyte lengths, and volumes of the corpora allata of the operated and sham-operated females

	Operated females	Sham-operated females	Comparison of means
Number of locusts	7	8	
Mean weight (g) ± *S.E.*	1·476 ± 0·077	3·020 ± 0·034	$P = < 0·001$
Mean terminal oocyte length (mm) ± *S.E.*	1·21 ± 0·101	6·31 ± 0·263	$P = < 0·001$
Mean corpus allatum volume (arbitrary units) ± *S.E.*	15·8 ± 0·86	34·6 ± 2·15	$P = < 0·001$

The inhibitory effect of the operation on growth and sexual maturation[1] is confirmed, but in addition a new relationship has been established. Removal of the frontal ganglion prevents the increase in corpus allatum volume which normally precedes and accompanies maturation. The effects of the operation are very similar to those observed in adult females of *Schistocerca paranensis* after cautery of the cerebral neurosecretory cells[3]. There may not be a positive relationship between corpus allatum volume and secretory activity in *L. m. migratorioides*, but since the accessory sex glands of the operated females lack secretion it is unlikely that the small corpora allata are active. Additionally Staal has shown that in nymphs of *L. m. migratorioides* corpora allata which are prevented from increasing in volume secrete only at a minimal level.

Clarke and Langley suggest that removal of the frontal ganglion prevents the production and/or release of media neurosecretion from the cerebral neurosecretory system. This withdrawal of neurosecretion may be direct

responsible for the suppression of growth of the corpora allata observed in this work. Indeed in nymphs of *L. m. migratorioides*, small denervated corpora allata grow if placed in contact with the corpora cardiaca[4]. However, median cell neurosecretion has not been identified within the corpora allata of locusts. Furthermore, Girardie has shown that destruction of the cerebral neurosecretory cells causes activation of the corpora allata in nymphs of *L. migratoria*[5].

There is another explanation for the suppression of corpus allatum growth after removal of the frontal ganglion. In *Calliphora erythrocephala* the activity of the corpus allatum can be regulated by varying concentrations of metabolites in the haemolymph[6]. If a similar mechanism exists in locusts, the corpora allata of the operated insects may be expected to remain small since the concentrations of haemolymph metabolites are low following removal of the frontal ganglion[7].

This work is being carried out during the tenure of a research fellowship from the Science Research Council.

VIROLOGY

Small Deoxyribonucleic Acid-containing Viruses (Picodnavirus Group)

THE picornavirus group was established in accordance with the decision of the International Subcommittee on Virus Nomenclature for classifying the major groups of viruses on the basis of common biochemical and biophysical properties[1]. Picornaviruses contain ribonucleic acid and protein, are insensitive to ether, and are extremely small in size (15–30 mμ in diameter). The capsids of those members of the group the symmetry of which has been studied appear to display cubic symmetry of the icosahedral pattern[2]. Members of the group derived from humans and lower animals are recognized. Certain plant viruses and the recently isolated RNA-containing bacteriophages have properties which suggest that they might be classified as picornaviruses. The cubic symmetry of the picornaviruses which have been studied is consistent with a capsid constructed from thirty-two morphological sub-units positioned at the vertexes of a rhombic triacontahedron[2] (Fig. 1*a*).

A number of DNA-containing viruses of the same size as the picornaviruses have recently been found, which by analogy might be considered as 'picodnaviruses'. The capsids of one of the small DNA animal viruses appear to be structurally similar to those of the picornaviruses. Vasquez and Brailovsky[3] recently proposed icosahedral symmetry for the Kilham rat virus (RV) based on a hexagonal outline in the electron microscope and a probable capsomere count of thirty-two. The structural symmetry of this virus with a 20 mμ diameter was best represented by the Archimedean dual solid, the pentakis dodecahedron (Fig. 1*b*). Vasquez and Brailovsky believed that the closely related hamster osteolytic *H* viruses (*H*1, *H*3) in all probability presented a similar fine structure.

Members of the hamster osteolytic group of viruses (*H*1, *H*3) are again of very small size (about 20 mμ in diameter). All serotypes produce intranuclear inclusions containing DNA demonstrable by cytochemical staining techniques. Recently Cheong *et al.*[4] have studied the nature of the DNA of the *H*1 prototype virus after purification in a caesium chloride density gradient. They concluded from their biochemical data that the virus consisted of a protein capsid containing a DNA core making up 25 per cent of the complete virion. Green and Karasaki[5] have partially purified *H*1 virus by precipitation at *p*H 4 and have detected evidence of sub-unit structure on the 23 mμ diameter capsid in the electron microscope.

The rat virus *X*14 is serologically related to the *H*3 group of hamster osteolytic viruses. Payne *et al.*[6] banded *X*14 virus at a density of 1·40–1·43 in caesium chloride and examined the virus particles in the electron microscope. The particles were polyhedral in shape and approximately 20 mμ in diameter. The replication of *X*14 was inhibited by 5-fluoro-2′-deoxyuridine[7], thus suggesting that the virus contained DNA, and it has been shown recently by acridine orange staining that the DNA of *X*14 virus occurs in the single-stranded form[8]. This would seem to be the first animal virus to be reported to contain DNA of this type. The fine structure and morphology of the *X*14 virus (Fig. 1*c*) are indistinguishable from RV and from human picornaviruses.

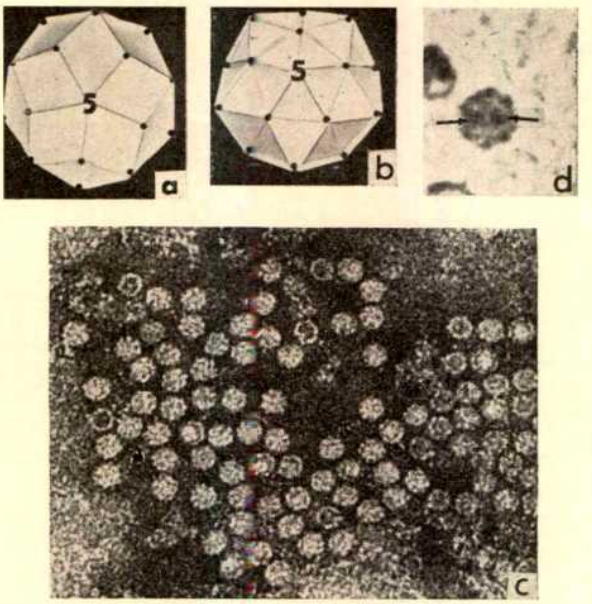

Fig. 1. *a*, Model of a rhombic triacontahedron viewed along a five-fold axis of symmetry. This convex polyhedron belongs to the icosadeltahedral class with triangulation (*T*) number equal to 3. *b*, Model of a pentagonal dodecahedron viewed along a five-fold axis of symmetry. This polyhedron also belongs to class $T = 3$ but demonstrates concavities. *c*, Group of *X*14 virus particles negatively stained with 2 per cent phosphotungstic acid (× *c*. 150,000). *d*, Photographic reversal of a favourably oriented ASV particle from adenovirus *SV*15 negatively stained with 2 per cent ammonium molybdate. Particle is viewed along a two-fold axis of symmetry. Two five-fold axes (black arrows) and six peripheral sub-units are seen. (× *c*. 455,000)

Small 20-mμ particles containing DNA and morphologically similar to *X*14 have recently been observed in preparations of a number of adenoviruses of man and animals[10–13]. Detailed investigation of the particles prepared from simian adenovirus *SV*15 stocks by genetron treatment and density gradient centrifugation revealed that the small particles did indeed possess icosahedral symmetry with as few as twelve morphological sub-units on the capsid[10] (Fig. 1*d*). Under certain conditions, these 20-mμ particles are able to replicate when inoculated into susceptible cell cultures. Both mature adenovirus particles (70 mμ in diameter) and 20-mμ particles are recovered in the material collected. The 20-mμ particles do not occur in the absence of the adenovirions. The particles were banded in a caesium chloride density gradient at 1·43 g/cm³. The band, when fixed and stained with acridine orange, yielded a yellow-green fluorescence consistent with the presence of a double-stranded DNA. The staining reaction was prevented by prior digestion with pepsin and DNase. However, subsequent experi-

Table 1. PHYSICAL AND CHEMICAL PROPERTIES OF SMALL DNA VIRUSES (PICODNAVIRUSES)

Virus	Nucleic acid	Particle diameter (mμ)	Ether resistance	Capsomere diameter (Å)	Buoyant density in caesium chloride	Refs.
RV	DNA	20	+	20	1·38	3
*X*14	Single-stranded DNA	22	+	?	1·40	6,7,8,9
*H*1	DNA	23	+	40	1·39	4,5
Adeno satellite virus from *SV*15	Single-stranded DNA	20	+	35–45	1·43	11,13,19
Adeno satellite virus from human adeno 7	Single-stranded DNA	20	+	?	1·41	10,12,19
φ*X*174	Single-stranded DNA	22	+	70	1·43	16,17,18

ments have shown that the reaction is readily susceptible to DNase digestion even without fixation or pepsin treatment. This is indicative that in addition to the 20-mμ particles a very accessible DNA, possibly even free, but inactive, double-stranded adenovirus DNA, was captured and banded with the small particle fraction. The presence of many degraded adenovirions and free capsomeres in the *SV*15 stocks from which this material was prepared is consistent with this interpretation. When freshly prepared *SV*15 material was monitored in the electron microscope and when only material free from morphological evidence of adenovirus degradation was used, the subsequent bands at 1·43 g/cm³ gave clear 'flame red'-staining and the DNase susceptibility characteristic of single-stranded DNA.

Atchison *et al.*[13] have investigated similar small DNA-containing particles with hexagonal profiles associated with the simian adenovirus *SV*15. These particles were not related antigenically to the adenovirus, but replication of the particles in tissue culture was achieved only when they were inoculated simultaneously with adenovirus. The particles were insensitive to ether.

Similar small virus-like particles containing DNA have been found associated with human adenoviruses[10,12,19]. Again these particles do not appear to be able to replicate unless adenovirus is present. Staining reactions with acridine orange indicate that these particles, like the *X*14 virus, contain single-stranded DNA. The particles, like the *H* viruses, are insensitive to ether but, unlike them, appear incapable of autonomous replication.

Atchison *et al.*[13] suggested that the small particles should be referred to as 'adeno-associated' virus. However, since they behave like the previously described satellite virus of plants[14,15] (in that they are unable to replicate autonomously and their replication is dependent on the presence of a larger virus), the particles should be more fittingly referred to as 'adeno-satellite' virus (ASV). The numerous recent reports on the occurrence of 20-mμ particles containing DNA have prompted us to comment on their structural similarity to the picornaviruses. Certain plant viruses have properties similar to those of the picornaviruses of man and lower animals. Turnip yellow mosaic virus is an example of a small RNA plant virus capable of autonomous replication in a susceptible host. The satellite tobacco necrosis virus (TNSV) is a defective small RNA virus of plants[14,15]. The adeno-satellite viruses are defective DNA viruses of human or monkey origin. Many of their properties are analogous to those exhibited by the satellite tobacco necrosis system.

Selected biophysical and chemical properties of some small DNA virions are shown in Table 1. It should be noted that the buoyant densities of these viruses (approximately 1·40 g/cm³) are greater than those of picornaviruses (1·34) and papovaviruses (1·32).

The staining reactions with acridine orange and relevant enzyme susceptibility patterns of selected DNA virus preparations are shown in Table 2. The yellow-green staining reactions of the purified adenoviruses free from satellite particles are consistent with a double-stranded DNA. On the other hand, the staining reactions of the adeno-satellite viruses and of the *X*14 virus are consistent with a single-stranded molecule. Similar staining reactions were demonstrated by a purified preparation of the well-defined single-stranded bacteriophage φ*X*174. It is probable that the DNAs of RV and of the *H*1 viruses will also be found to exhibit a single-stranded secondary structure.

Table 2. STAINING REACTIONS OF CARNOY-FIXED SMEARS OF SELECTED DNA VIRUS PREPARATIONS

Virus	Staining reactions with 0·01 per cent acridine orange	Enzyme susceptibility RNase	Enzyme susceptibility Pepsin + DNase
φ*X*174	flame red	–	+
*X*14	flame red	–	+
ASV from simian adenovirus *SV*15	flame red	–	+
ASV from adenovirus 7	flame red	–	+
Simian adenovirus (*SV*15)	yellow-green	–	+
Human adenovirus 7	yellow-green	–	+

Inhibiting Effect of Increasing Body-weight on the Lethal Response of DBA/1 Mice to Vaccinia Virus Infection

IN a previous publication[1] I considered the response of mice of different ages to experimental vaccinia infection; the high degree of resistance of adult mice to this virus, as well as the fact that vaccinia is highly lethal for new-

Table 1. EFFECT OF INCREASING BODY-WEIGHT AND/OR INCREASING AGE ON THE RESISTANCE OF *DBA*/1 MICE TO VACCINIA INFECTION

Infective particles*	Average body-weight of mice‡	Age of the mice in days when inoculated†

* Levaditi neurovaccinia grown in rabbit testes.
† Surviving mice/inoculated
‡ The average body-weight of the mice from each litter was calculated from the total weight of the litter.
§ More than one litter included. The average number of offspring in *DBA*/1 litters is ordinarily five.

born mice. It was also demonstrated that the young mice (non-inbred albino) became resistant to increasingly higher doses of virus as they aged.

The present findings, however, indicate that resistance to vaccinia infection in young mice is determined by their body-weight rather than by their age. The acquisition of resistance to viral infection during the first weeks or days of life has been demonstrated in a variety of systems and it is generally attributed to the effects of increasing age. In some systems, however, it is difficult to establish the precise age at which resistance actually begins. In such systems resistance develops gradually during a comparatively long period of time against increasingly higher doses of virus. This suggests that the very first signs of resistance will scarcely be noticeable as they probably involve the response of the host to minimal doses of virus.

The gradual development of resistance as a dose-dependent phenomenon was clearly demonstrated in experiments in which several strains of Coxsackie virus were titrated in baby mice of different ages[2]. The infective titre of all the strains tested declined gradually in increasingly older hosts until the lowest dilution became non-pathogenic for mice 33–35 days old. In the course of these experiments, it was also noted that differences in body-weight among mice of the same age influenced the host response to viral infection.

The gradual development of resistance was also observed in the experiments with mice infected with vaccinia virus referred to previously[1]. The virus titre declined from 10^5 in newly-born animals to 10^3 in the 1-week-old mice and to $< 10^1$ in the 3-week-old mice. At 4 weeks of age the mice were 100 per cent resistant to the highest virus dose used ($7{\cdot}5 \times 10^6$).

Other examples of dose-dependent host response to viral infection are those in which newly isolated viruses, notably viruses with neoplastic properties, acquired the ability of infecting increasingly older hosts, as well as initially resistant strains or species, when their virulence and/or replicating capacity was increased by repeated animal passage.

From this it appears that differences in the response to certain viral infections among young animals of different age, strain or even species can be overcome by increasingly higher doses of virus and are, therefore, of a quantitative as well as of a qualitative nature.

During recent investigations, a comparison was made between the response to vaccinia infection of baby mice of two strains, non-inbred albino and inbred *DBA*/1, and it was observed that susceptibility to the virus persisted in the latter mice for a considerably longer period of time than in the albino strain.

However, the longer lasting susceptibility of the *DBA*/1 mice to vaccinia infection was apparently due to the fact that these mice are much smaller than the albino mice. Thus, whereas mice from a 23-day-old *DBA*/1 litter weighed on average as little as 3·7 g and were 100 per cent susceptible to the virus, mice from a 12-day-old mouse litter weighed on average as much as 8·5 g and were 100 per cent resistant to the same dose of virus.

It was next determined that the range of body-weight is considerably wide among litters of the same age in both strains but that it stayed within a much lower level until much later in life in the *DBA*/1 than in the albino strain. The average body-weight of 12-day-old mice from albino litters was found to be 4·0–8·5 g, whereas for 23-day-old mice of *DBA*/1 litters it was 3·3–7·5 g. In view of this finding, *DBA*/1 mice were used in the present experiments in order to determine the effect of increasing body-weight in relation to increasing age on the development of resistance to vaccinia infection.

First litters were used of *DBA*/1 mice conceived and born in our laboratory from parents obtained from the Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine. Mice of different body-weights were inoculated at various ages in the fat pad between the scapulae, with 0·05 of a 1 : 10 saline extract of rabbit testes infected with Levaditi neurovaccinia. The dose of virus was about 5×10^5 particles infective for rabbit skin. The average body-weight of the mice was calculated from the total weight of the litter, except when obvious differences in size were observed. Each litter was weighed immediately before inoculation. Autopsies were performed periodically to determine the presence of typical lesions. Deaths occurring either within 48 h or after 15 days of virus inoculation were not recorded as due directly to vaccinia infection.

The results of these experiments are summarized in Table 1. From top to bottom the data indicate the effect of body-weight on the development of resistance to vaccinia infection: from right to left, the effect of increasing age.

It will be noted here that the degree of resistance has been estimated in each group of mice by the percentage of survivals without reference to the incidence of illness among the survivors. Death as well as illness was apparently induced in the present experiments by necrotic lesions in the lungs. The type of lesions induced by vaccinia in young mice varies, depending on the degree of susceptibility of the host and/or the virus dose. The organ distribution and pathology of these lesions have been described elsewhere[1].

The results in Table 1 indicate that increasing body-weight and increasing age compensate for each other in influencing the development of resistance to vaccinia infection in mice, as they exert such an influence in a quantitatively inverse relationship. The greater the body-weight, the younger the animal becomes resistant to the virus. Conversely, the lower the body-weight, the longer it takes for the animal to become resistant. It will be seen that, whereas the mice weighing 6·0–6·8 g were already resistant at the age of 10 days, those weighing 5·2–5·5 g did not become resistant until they were 15–17 days old, and those weighing 4·2–4·8 g until they were 18–20 days old.

These findings indicate that under the present conditions small differences in body-weight seem to have a decisive effect on the response of the mice to vaccinia infection. Thus, whereas most of the 20-day-old mice, which weighed an average of 4·3 g, were resistant to the virus, the mice weighing an average of 3·7 g were still virtually 100 per cent susceptible at the age of 23 days. The long-lasting susceptibility of vaccinia infection of the latter mice is apparently related to their abnormally small size. However, this class of mice, which occurred

in 10–15 per cent of the litters, do not seem to be otherwise abnormal. They are physically well proportioned, as they look rather like miniatures of their normal size counterparts. They are as quick and lively, if not more so, than mice of the same age weighing twice as much. They develop a good set of teeth with which they feed themselves eagerly and bite vigorously when handled for inoculation.

We are trying to determine how long these mice remain susceptible to the virus or fail to reach normal growth. We are also interested in determining how early in life differences in body-weight are apt to influence the response of the mice to vaccinia infection. This information might provide some insight into the difficulties often encountered when attempting to isolate in new-born animals viruses present in the inoculum in unknown amounts. With the virus dose used in the present experiments the 10-day-old mice were the youngest to become resistant to the virus (see Table 1) under the influence of increasing body-weight. With lower doses of virus similar findings have been observed in younger mice. Seven-day-old mice, which on average weighed 4·7 g, survived inoculation with 5×10^3 vaccinia infective particles, whereas 17-day-old mice, which on average weighed 3·3 g, were 100 per cent susceptible to the lethal effects of the same virus dose.

It would seem possible from these findings that differences in the response to experimental viral infection among young animals of the same age and strain as well as of different strains or species might be related from birth to differences in their level of growth. Furthermore, that the age of young hosts is no accurate indication of their probable response to experimental viral infection unless it is correlated with their body-weight.

CYTOLOGY

Chromosome Numbers of *Elaphoglossum* and *Hymenodium*

THE fern genus *Elaphoglossum* is one of the largest in the family Aspidiaceae. Moreover, some taxonomists would like to place it in a separate family, Elaphoglossaceae[1]. Of more than four hundred species of *Elaphoglossum*, most are to be found in tropical America. Some of the species deviate so much from the type of *Elaphoglossum* that they have been separated from the genus, and one of them is the species *Elaphoglossum crinitum*, which has been renamed *Hymenodium crinitum* by Fée and *Dictyoglossum crinitum* by J. Smith. Copeland, however, prefers the name *Elaphoglossum crinitum*[2].

Only very few species of the genus *Elaphoglossum* have been studied cytologically. *Elaphoglossum hirtum* (Sw.) C.Chr., $n = 82$; *E. krajinae* Biswas, $n = 41$; and *E. spathulum* (Bory) Moore, $2n$ = about 160, were studied by Manton and Sledge[3]. Two other species, *E. conforme* Sw., $n = 82$, and *E. latifolium* Bett., $n = 82$, were studied by Bir[4]. All these species seem to have the basic chromosome number of forty-one, although most of them are polyploids.

Material for the present study was collected from El Verde rain-forest in the eastern part of Puerto Rico, in August 1964. The herbarium specimens were identified by Dr. R. Woodbury, of the Agricultural Experiment Station at Rio Piedras. Sporangia were fixed in acetic alcohol (1 : 3) and stained in acetic–iron–haematoxylin solution. The chromosomes were counted at the late meiotic prophase and first metaphase stages.

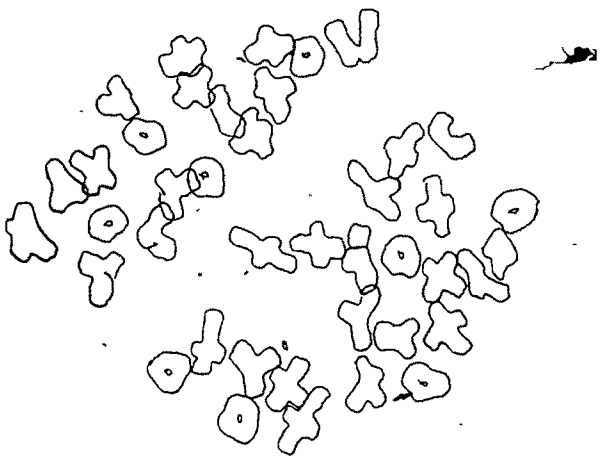

Fig. 1. Diakinesis of *Elaphoglossum flaccidum* (Fée) Moore, $n = 41$. Aceto-iron-haematoxylin squash (× *c.* 2,000)

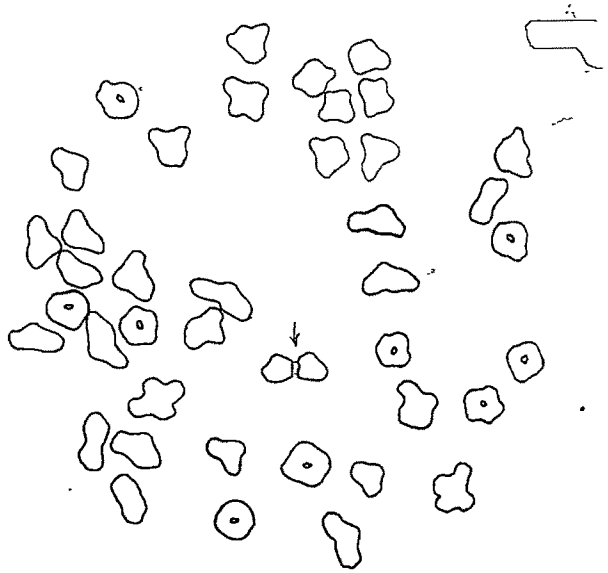

Fig. 2. Prometaphase I of *Hymenodium crinitum* (L.) Fée, $n = 41$ (forty bivalents and two halves of a bivalent). Aceto-iron-haematoxylin squash (× *c.* 2,000)

In both species of *Elaphoglossum* investigated, *E. flaccidum* (Fée) Moore, and *E. firmum* (Mett.) Urban, forty-one bivalent chromosomes were counted. But in the meiosis of *Hymenodium crinitum* (L.) Fée, the chromosome number often seems to be forty-two. Careful investigation of meiosis, however, reveals that the chromosomes of one bivalent very often part company as early as diakinesis. Actually the true number of chromosomes is forty bivalents and two halves of a bivalent, which is the same as in the *Elaphoglossum* species now studied. Another obvious similarity between the meiotic chromosomes of *Elaphoglossum* and *Hymenodium* seems to be the relatively large number of ring bivalents.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, April 18

OPERATIONAL RESEARCH SOCIETY (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 4.30 p.m., Forum on "O.R. and Accountancy".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. C. Claydon. "Electricity for Grain Drying".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.E.–I.E.R.E. COMPUTER GROUPS (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Computer Bulk Storage".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Annual General Meeting, followed by Dr. B. J. Heywood: "Hydroxybenzonitrile Herbicides" (Chairman's Lecture).

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"The Days of Whiskey Gap" and "City of Gold" (films).

Tuesday, April 19

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. G. F. Turnbull and Mr. B. E. Jones: "A High Input Impedance Clip-on A.C. Voltmeter": Mr. E. Rawlinson, Mr. P. H. King and Mr. P. K. Richardson: "Automatic Corona Loss Measuring Equipment".

INSTITUTE OF SCIENCE TECHNOLOGY, LONDON BRANCH (in the Surgical Lecture Theatre, New Guy's House, St. Thomas' Street, London Bridge, S.E.1), at 6.30 p.m.—Mr. J. C. Gazet: "Surgery in the Sixties".

Tuesday, April 19—Wednesday, April 20

BRITISH SOCIETY OF SOIL SCIENCE (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 10.30 a.m. daily—Meeting on "Soil Moisture—Physical and Biological Aspects".

Tuesday, April 19—Thursday, April 21

INSTITUTE OF METALS (at Church House, Great Smith Street, London, S.W.1)—Spring Meeting.

SOCIETY OF ENVIRONMENTAL ENGINEERS (at Imperial College, London, S.W.7)—Symposium on "Environmental Engineering and Its Role in Society".

Wednesday, April 20

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. T. Coley, Mr. L. F. Rutishauser and Mr. H. M. Ashton: "A New Laboratory Test for Predicting Low Temperature Operability of Diesel Fuels".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. B. M. Cobbe: "The West London Area Traffic Control Experiment".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 6 p.m.—Mr. B. D. Armstrong: "Automatic Landing".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, ELECTRO-ACOUSTICS GROUP (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Mr. P. J. Baxandall: "Low Distortion Transistor Audio Amplifiers—Some Important Design Characteristics".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—FOOD ENGINEERING PANEL (at R.S.H. Headquarters, 90 Buckingham Palace Road, London, S.W.1), at 6.15 p.m.—Annual General Meeting, followed by Dr. E. H. T. Hoblyn, M.B.E.: Chairman's Address.

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the Society for Analytical Chemistry, at the College of Technology, Park Street, Luton), at 6.45 p.m.—Dr. D. T. Lewis: "Recent Investigations at the Laboratory of the Government Chemist".

Thursday, April 21

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. D. Rees: "The Birational Geometry of Local Rings".

ASLIB (at 3 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. J. L. Dolby and Mr. M. B. Line: "University Libraries and the Information Needs of the Research Worker".

INSTITUTE OF PETROLEUM, ECONOMICS AND OPERATIONS GROUP (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. K. Mackrell: "Review of the Year".

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. H. E. Pearson: "Satellite Communication" (Silvanus P. Thompson Lecture).

OIL AND COLOUR CHEMISTS' ASSOCIATION, LONDON SECTION (at the Criterion-in-Piccadilly, London, W.1), at 7 p.m.—Annual General Meeting.

TELEVISION SOCIETY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 7 p.m.—Prof. W. D. Wright. "The Implications for Television of Modern Thinking on the Visual Process" (Fleming Memorial Lecture).

Thursday, April 21—Friday, April 22

BIOCHEMICAL SOCIETY (at University College, Gower Street, London, W.C.1)—Annual General Meeting. Symposium on "Instrumentation in Biochemistry". Prof. F. Lynen: "The Role of Biotin-Dependent Carboxylations in Biosynthetic Reactions" (Third Jubilee Lecture). Small exhibition of instruments.

Friday, April 22

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 10 a.m.—Colloquium on "Electrical Services in System Building".

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on "Physical Origin of Magnetization in Rocks".

SOCIETY OF CHEMICAL INDUSTRY, FINE CHEMICALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting, followed by Dr. D. S. Morris: "Coarse Chemistry and Fine Chemicals" (Chairman's Address).

Monday, April 25

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "Breakdown of Large Air-gaps and Effect of Voltage Wave Shape" opened by Dr. F. D. A. Boylett and Dr. D. F. Oakeshott.

PLASTICS INSTITUTE, LONDON SECTION REINFORCED PLASTICS SUB-GROUP (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. P. Lynch: "The Advances of Hot Press Moulding in the U.K."

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Prof. S. Thorarinsson: "An Island is Born".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned.

LECTURER IN THE DEPARTMENT OF PHILOSOPHY—The Registrar, The University, Leicester (April 20).

LECTURER (preferably with a research interest in numerical analysis, astrophysics or fluid dynamics) IN APPLIED MATHEMATICS—The Registrar, King's College (University of London), Strand, London, W.C.2 (April 22).

ORGANIC CHEMIST (with experience in isolation of natural products) for research on coffee berry disease—The Secretary, Wye College (University of London), near Ashford, Kent (April 22).

ASSISTANT EXPERIMENTAL OFFICER (with a degree or equivalent in botany, chemistry, agriculture or related subject) to assist with work on the extraction and purification of plant hormones and the study of their physiological properties—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (April 23).

ASSISTANT LECTURER IN ORGANIC CHEMISTRY—The Registrar, The University, Manchester, 13, quoting Ref. 79/66 (April 23).

CHAIR OF PURE MATHEMATICS—The Registrar, University College of Swansea, Singleton Park, Swansea (April 23).

LECTURER or ASSISTANT LECTURER (climatologist, preferably with an interest in biogeography) IN THE DEPARTMENT OF GEOGRAPHY—The Secretary, The University, Southampton (April 23).

LECTURER (preferably with some research or industrial experience) IN THE DEPARTMENT OF METALLURGY—The Registrar, University College of Swansea, Singleton Park, Swansea (April 23).

ASSISTANT LECTURER IN STATISTICS, preferably in Mathematical Statistics, or Probability Theory—The Registrar, The University, Hull (April 25).

TEACHING FELLOW/DEMONSTRATOR (graduate, preferably with an honours degree in rural science, agriculture, or science with specialization in plant science) IN AGRONOMY at the University of New England, Armidale, New South Wales, Australia—The Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 25)

LECTURER IN THEORETICAL CHEMISTRY—The Secretary of the University Court, The University, Glasgow (April 27).

ASSISTANT LECTURER (with an honours degree in pharmacy and an interest in phytochemistry) IN PHARMACOGNOSY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (April 29).

LECTURER (honours graduate in pharmacy or an equivalent qualification, an interest in organic chemistry and experience of the application of modern analytical methods to the solution of pharmaceutical, chemical and biochemical problems) IN PHARMACEUTICAL CHEMISTRY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (April 29)

DIRECTOR OF THE UNIVERSITY COMPUTING CENTRE; and a LECTURER IN THE UNIVERSITY COMPUTING CENTRE—The Registrar, The University, Leicester (April 30).

LECTURER and an ASSISTANT LECTURER IN THE DEPARTMENT OF BIOCHEMISTRY, Queen's College—The Secretary, University of St. Andrews, Queen's College, Dundee (April 30).

LECTURER (graduate in metallurgy or physics) IN PHYSICAL METALLURGY—The Secretary, Sir John Cass College, Whitechapel High Street, London, E.1 (April 30).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF PHYSICS, University of Singapore—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 30).

LECTURER (Electrical Theory) (with an electrical engineering degree and postgraduate experience in industry or in research) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING, University College, Nairobi, University of East Africa—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 30).

LECTURER or SENIOR LECTURER (with qualifications in the biological or physical sciences and particular interests in the methods of teaching science) IN SCIENCE EDUCATION in the School of Education, University of Zambia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (April 30).

LECTURER (with a special interest and research experience in plant pathology) IN BIOLOGY IN THE DEPARTMENT OF APPLIED MICROBIOLOGY AND BIOLOGY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (April 30).

LECTURERS (preferably with research experience in bacterial genetics or electron microscopy) IN GENETICS—The Secretary of the University Court, The University, Glasgow (April 30).

RESEARCH ASSISTANT (with a qualification, not necessarily a degree, in physics and/or chemistry) IN THE DEPARTMENT OF INORGANIC AND STRUCTURAL CHEMISTRY, for duties which will include the operation of electronic equipment for X-ray crystallography—Prof. H. Irving, School of Chemistry, The University, Leeds, 2 (April 30).

SENIOR LECTURER (Grade I) or LECTURER (Grade II) IN APPLIED MATHEMATICS—The Registrar, University Senate House, Tyndall Avenue, Bristol, 2 (April 30).

SENIOR LECTURER/LECTURER IN MATHEMATICS at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, April 30).

SENIOR LECTURER or LECTURER IN SYSTEMS AND CONTROL ENGINEERING; and a LECTURER IN AUTOMATIC CONTROL OR SYSTEM DYNAMICS, including vibration analysis—The Registrar, The University, Leicester (April 30).

CHAIR OF PLANT SCIENCE; CHAIR OF SOIL SCIENCE; and CHAIR OF AGRICULTURAL ECONOMICS IN THE FACULTY OF AGRICULTURE, University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, May 1).

RESEARCH ASSISTANT IN SOIL CHEMISTRY OR PLANT PHYSIOLOGY—The Reader in Soil Science, Soil Science Laboratory, The University, Oxford (May 1).

LECTURERS OR ASSISTANT LECTURERS (with qualifications in either sociology or social anthropology, and for one of the posts an interest in sociological aspects of developing countries or in organizational theory would be an advantage) IN SOCIOLOGY—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 88C (May 2).

LECTURER IN BIOCHEMISTRY OR ANIMAL PHYSIOLOGY IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY, The Royal University of Malta—The Inter-University Council, 33 Bedford Place, London, W.C.1 (May 3).

CHAIR OF GEOLOGY—The Registrar, The University, Hull (May 5).

CHAIR OF MECHANICAL ENGINEERING—The Registrar, The University, Manchester, 13, quoting Ref. 85/66 (May 5).

READER IN PHARMACOLOGY at Guy's Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 6).

ASSISTANT LECTURER (preferably with research interests and experience in aspects of the geography of Africa) IN GEOGRAPHY—The Registrar, The University, Sheffield (May 7).

ASSISTANT LECTURER (with a wide interest in cytology so as to be able to lecture to students of both departments) IN CYTOLOGY IN THE DEPARTMENTS OF BOTANY AND ZOOLOGY in the Faculty of Sciences—The Registrar, The University, Manchester, 13, quoting Ref. 84/66 (May 7).

LECTURER or ASSISTANT LECTURER IN MATHEMATICAL STATISTICS, to work with an existing group of five members of staff—The Registrar, The University, Manchester, 13, quoting Ref. 87/66 (May 7).

LECTURER (with a special interest in either electrical machinery or electrical power distribution systems) IN ELECTRONIC AND ELECTRICAL ENGINEERING—The Registrar, The University, Sheffield (May 7).

READER IN BIOLOGY at King's College—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 9).

THE H. W. HOOVER, JR., CHAIR OF MATHEMATICAL STATISTICS AND OPERATIONAL RESEARCH—The Registrar, University College of South Wales and Monmouthshire, Cardiff (May 9).

PROFESSOR IN MICROBIOLOGY; and a SENIOR LECTURER or LECTURER IN MICROBIOLOGY IN THE FACULTY OF AGRICULTURE, University of Natal, Pietermaritzburg—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, May 10).

CHAIR OF CELL BIOLOGY—The Secretary of the University Court, The University, Glasgow (May 13).

ASSISTANT LECTURER or a UNIVERSITY DEMONSTRATOR IN THE DEPARTMENT OF ZOOLOGY—The Secretary, The University, Edinburgh (May 14).

CHAIR OF BOTANY—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (May 14).

LECTURERS/SENIOR LECTURERS/READERS (3) IN THE DEPARTMENT OF MATHEMATICS, University of Tasmania—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 20).

LIBRARIAN (preferably science or engineering graduate with library experience) OF THE SCIENCE AND ENGINEERING LIBRARY, Haile Sellassie I University, Ethiopia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (May 22).

SENIOR RESEARCH FELLOW IN THE DEPARTMENT OF THEORETICAL PHYSICS, Research School of Physical Sciences, Institute of Advanced Studies, Australian National University (members of the department are working on theoretical nuclear physics, elementary particles and field theory and many-body problems)—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 27).

CHAIR OF BOTANY at the University of Tasmania—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 31).

LECTURER (with a postgraduate degree and preferably some experience of teaching biochemistry at university level) IN BIOCHEMISTRY at Lincoln College, University of Canterbury, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or the Registrar of the College (New Zealand and London, June 30).

SENIOR LECTURER or LECTURER (preferably with interests in the genetics of micro-organisms) IN GENETICS—The Secretary, The Queen's University, Belfast, Northern Ireland (June 30).

RESEARCH ASSISTANTS/STUDENTS (graduates or prospective graduates in zoology or physiology) in the following fields: physiology of aquatic adaptations in reptiles; limnology (especially underwater sound); soil zoology; parasites of fish and amphibia; ecology of ticks of British mammals; and insect sound—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

UPROAR ABOUT TEACHING

IF war is too important to be left to generals, can society continue to entrust education to the teachers? This is one of the many questions thrust on public attention in Britain by the confrontation at Easter between the Secretary of State for Education and Science, Mr. Anthony Crosland, and the National Union of Teachers. For what has been plain for years is now inescapable—the administration of primary and secondary education, and the terms of service of teachers, are too rigid for a society seeking to transform itself.

There were three main issues at the annual conference of the National Union of Teachers at which the disagreement between the profession and the British Government emerged with almost unprecedented abandon. First, there was the complaint that the Government has asked for a reorganization of the pattern of secondary education, and in particular for the replacement of selective by comprehensive schools, without providing the money to ensure that the job is done properly. Mr. Crosland's retort that the teachers themselves have not done what they might have done to awaken public support for public spending on education was fair comment, but no answer. There was also a dispute about the place of ancillary aids in the classroom. In the hope of mollifying the teachers with a vision of what might be, Mr. Crosland only maddened them by saying that the teacher of the future would be a superintendent of a host of teaching aids, some human and some mechanical. Finally, there was the familiar, but legitimate, complaint that teaching is a grossly impoverished profession. So it is, but the teachers themselves are partly to blame.

On reorganization and the cost thereof, the problem is not that the Minister wishes to go too far too fast, but that his thinking may not yet be radical enough. The pattern of secondary education in Britain evolved at the end of the nineteenth century, when few people went to university. It was a considerable pedagogical triumph that secondary schools should have found ways of giving a great many young people a valuable replica of the benefit they would have won from further education. But times have changed. Education after school has become a commonplace. Yet specialist sixth-form teaching in secondary schools remains the pride of British headmasters, the self-justification of a large part of the teaching profession, a determinant of the organization of secondary schools of all kinds and an exacerbation of the shortage of teachers. But—in its present form—is it really necessary? And is the curriculum elsewhere in the secondary schools that best suited to modern needs? At a time when even the French Government has carried through a reorganization of secondary schooling, it would be easier to feel that British disputes about reorganization were worth fighting if there were some evidence that the parties involved knew what secondary education is really for.

When it comes to guessing how innovations of technique could transform the craft of teaching, the angels are mostly on the Minister's side. The possibilities are exciting. There is a bright future for well-designed and well-tested programmed courses of instruction. Computers have a part to play. So also have television and other visual aids. Team teaching needs a thorough trial, and extra-mural activities (such as visits to countries abroad) have a valuable potential. Then there is no school in Britain that could not, for example, profit from the services of laboratory assistants skilled enough to participate in teaching. The promise of these and other innovations is not merely a better use of existing manpower, but a means of catering more sensitively than is at present possible for the increasingly diverse interests and abilities of students at schools. It is exceedingly tiresome that the National Union of Teachers, like many similar organizations in countries other than Britain, should be suspicious of these and other innovations, but it is only fair to add that the British Government has not yet seen fit to back Mr. Crosland's enthusiasm with the substantial sums of money that will have to be spent on development if schools are to make proper use of the new technology of education.

The teachers' distrust of innovation unfortunately seems to spring from arguments closely allied to frustration over terms of service. Their insistence that there is a special relationship between students and those teachers on whom the mantles of Dewey and Piaget have been solemnly laid fits so well with the strategy of labour scarcity pursued by the more primitive Trade Unions that even innocent observers are bound to wonder how much weight to give the argument. In fact, the Union has successfully fought for a nation-wide salary structure and in the process may have done the profession a disservice. One result is that it is difficult to reward really able people. Another is that teaching is less able than it might be to attract those who decide, in middle life, to forsake careers in industry or the armed services. And everybody would be better off if young people entering the profession could look forward to a progressively better salary without having to abandon the classroom for administration or some similar activity.

The teaching profession as a whole would also be much more healthy if it were less obviously cut off from the outside world. Part-time teachers should be welcomed, not only for the relief they bring to the shortage of teachers but also for the experience of the outside world they can import into the classroom. In the same spirit, it has become an urgent need that full-time teachers should be regularly relieved from their responsibilities in class, partly so as to keep up to date but also to refresh themselves intellectually. They must also be freed from the penny-pinching meanness that prevents many of them from being free agents in their classrooms.

These are issues too broad to be debated at annual conferences, and too separate from daily administration to play much part in the making of government decisions. Yet they are important, and they are alive. They deserve more serious attention than they have been given in recent years. There may, after all, be some merit in the suggestion of that otherwise eccentric body, the National Association of Schoolmasters, that the times call for a thorough re-examination of British education. What needs to be decided, of course, is not the payment to be made to schoolteachers, but what function they are to have in modern society and how they are best to be equipped to do their job. No doubt Mr. Crosland was

hoping, at Easter, that an outspoken declaration would jolly the profession along for a few months or so. The growls of discontent he left behind should have convinced him that this is a turning point in the history of British education, and that he should take the lead in finding out what should happen to it next.

TRIBOLOGY FOR ALL

IF you give a dog a good name, you have more hope of sanctifying him. This principle seems to have guided the British working party on lubrication which has now reported to the Department of Education and Science (*Lubrication*, H.M.S.O., 6*s*. 6*d*.). It is no excuse that the editors of the *Oxford English Dictionary* are said to have helped in coining the word 'tribology' for "the science and technology of interacting surfaces in relative motion and the practices related thereto". There is nothing wrong with the word, but only with the amalgam of pomposity and special pleading which had led the working party to undermine a good case by wild exaggeration.

The working party starts off on the wrong foot with the calculation that British industry could save some £515 millions a year by making full use of what is called tribotechnology. Obviously there are savings to be made—in reduced energy consumption, reduced lubrication costs, savings on spare parts and because properly designed and lubricated machinery should last longer. Better tribology could also reduce losses of industrial output caused by unexpected breakdowns. But is it sensible to suppose that industry could realistically hope to win all these benefits by better practice ? Or that it would be wise to try ? There may indeed be many circumstances when bad practice is cheapest and therefore best. As with fuel efficiency or the prevention of corrosion, it is necessary always to balance potential benefits against the costs of attaining them. The working party has naïvely forgotten this rule.

The report does not recover from this bad beginning. It says, for example, that only "a small minority" of the 200,000 technicians in the metal and engineering industries have a "working knowledge" of lubrication, but does not go through what would have been the valuable exercise of saying what a working knowledge should consist of. There is a lot in the working party's argument that there should be more lubrication research in Britain, and better liaison with and a more intimate involvement of the universities. Obviously it would also help a great deal if there could be more short courses for practising engineers and technicians. But it is hard to see what is intended by the recommendation that tribology should sometimes be "offered as an optional subject in the last year of engineering first degree courses". The working group has evidently fallen into the old fallacy of British education—the view that if a topic is thought to be important, it should be possible for a few specialists to study it to the exclusion of most other things. By recommending 'several' institutes of tribology, and "organized professional institution activities in the subject of Tribology", the working party repeats the error of trying to make a portentous speciality out of an activity so important that it should be a part of the equipment of all technologists. It is a relief to see that this report does not finish with the demand that there should be a Minister of Tribology, with a seat in the Cabinet.

CLASSIFICATION IN PSYCHIATRY

Personality and Personal Illness

By G. A. Foulds, in collaboration with T. M. Caine, and with the assistance of Anne Adams and Anna Owen. Pp. xi+344. (London: Tavistock Publications, Ltd., 1965.) 55*s*. net.

CLASSIFICATION is a painful subject in psychiatry. No one can do without it, and no one likes it. At times it has taken the form of multiple divisions and subdivisions, as in medicine generally; Boissier de Sauvages, using a Linnean model, recognized 2,700 types of disease. At other times excessive classification was denounced : Adolf Meyer, the outstanding psychiatrist of the United States, groaned at "veritable debauches of unwarranted systematization" and declared that hankering after premature groupings was "excusable in a naïve statistician but not in a modern clinician". The statisticians, among whom many psychologists may now be included, do not by any means regard themselves as naïve in this matter. They have grappled with the problem, and, as Dr. Foulds clearly shows, have contrived ingenious ways of setting about it. Their work has reached the stage at which there is contention about methods and interpretation. Dr. Foulds is a notable contributor to the subject, who has worked alongside psychiatrists and acquainted himself with their diagnostic procedures, but developed his independent approach.

Initially and throughout he emphasizes the difference between traits of personality and the symptoms and signs of illness. It seems an obvious point, but some psychologists who have worked in this area have overlooked it. He then says, quite rightly, that the system of diagnostic classification used by psychiatrists is logically inadequate, intermingling as it does classes defined by major cause with classes defined by manifest anomalies of behaviour, and with classes defined by course of development or even by adequacy of social compliance. The hotch-potch has its merits and its empirical justification, but Dr. Foulds, like many before him, would greatly prefer a more cohesive system. The product of his efforts in this direction makes up the main body of *Personality and Personal Illness*.

He starts from the premise that every mental illness is a disorder "of the person, not merely of the organism", and that it is characterized by a failure, of varying extent, to maintain mutual personal relationships. He comes to the conclusion that there is a continuum of increasing failure as one passes from normality to personality disorders, neuroses, psychoses, and at last to non-integrated psychoses (by which he means psychoses in which the patient has lost awareness of himself as agent). He has investigated the problem mainly by the use of two questionnaires. One, devised by his collaborator, T. M. Caine, measures a component in personality which he calls 'hysteroid-obsessoid'; the other is an inventory which deliberately does not cover traits but only the symptoms and signs that betoken illness. Using the scores on the questionnaire and this symptom-sign inventory as valid quantitative criteria for mental disorder and personality respectively, he shows that in his subjects the illness measure, that is, the inventory score, changed during treatment, and that personality measures did not change except in some patients who had lengthy 'community therapy' which altered some of their attitudes.

The work is technically well documented and argued—though the reader becomes a little tired of the scholastic flavour of some often repeated phrases. It throws some systematic light into a troubled area, and it examines faithfully the faults inherent in psychological methods of enquiry which do not distinguish between personality which is lasting and mental illness which may be transitory, nor between symptoms and the pathological or psychopathological process manifested through them. Some of Dr. Foulds's statements provoke dissent. He

says, for example, that "the presence of delusions and/or gross perceptual disorder constitutes the necessary and sufficient condition for psychosis"—where, then, does schizophrenia simplex belong? "An involutional melancholia with schizophrenic features is incomprehensible except to those who believe in a schizo-affective syndrome", he writes: and he holds that syndromes must be mutually exclusive, therefore there cannot be a schizo-affective syndrome but "it would, however, be possible for a particular individual to fall into both classes". Where psychiatrists have most trouble in classification, Dr. Foulds's scheme likewise tends to run aground; for example, in distinguishing the varieties of neurotic disorder.

There is, in the main, however, remarkable agreement between the findings arrived at here by the psychologist, determinedly systematic in his procedure, and those of the psychiatrist, using all the information he can and obliged to turn his diagnoses to practical account in each individual patient. Dr. Foulds, in a characteristic aside, says that until the structure of an experimental science of abnormal behaviour is complete, "psychiatrists should bear the confirmation of their observations with benign resignation".

AUBREY LEWIS

MANAGEMENT FOR METALLURGISTS

Management and Cost Control in the Metallurgical Industry

(Lectures delivered at the Institution of Metallurgists Refresher Course, November, 1964.) Pp. x+105. (London: Iliffe Books, Ltd., 1965. Published for The Institution of Metallurgists.) 25*s*. net.

MANAGEMENT and Cost Control in the Metallurgical Industry is comprised of lectures delivered at the Institution of Metallurgists in November 1964. The lectures were: "The Role of the Manager", by E. F. L. Brech; "Management and Cost Accountancy", by J. H. Spooner; "Industrial Relations", by Lord Geddes; and "A Project Officer's Diary", by R. L. Berry.

Mr. Brech attempted to distil his many years of experience as a management consultant into twenty-odd pages, including two appendixes entitled "A Definition of Management" and "The Theory of Management". The latter are a useful record, but until one has had experience it is difficult to turn the precise phrases into the flesh and blood of management in practice. It is bound to be true that the role of the manager varies between organizations, and particularly with the size of the organization and the extent to which technological advance has made an impact on it. It would have been helpful in addressing a group of technologists and scientists to discuss these points and to consider the presently changing role of management.

In the lecture "Management and Cost Accountancy", Mr. Spooner presented the results of twenty years' experience of the United Steel Companies in the development of their standard cost system. This talk gives a useful insight into the objectives of their cost control system and the means by which these are to a greater or lesser extent achieved. An audience of technologists would probably have been interested to hear more about the basic relationships underlying the cost structure of an industrial organization, since without this knowledge a manager is less able to interpret the true meaning of the data presented. Under what circumstances is it reasonable to assume that the total cost/output relationship is linear and the marginal cost per unit of product constant?

Lord Geddes's talk consisted of his presentation of the general case for the Trades Unions in industrial behaviour. This is a most valuable talk for the person with little experience of industrial relations in industry. The speaker managed to get away from the traditional 'two sides' approach to such problems and to explain the basic aims of Union activities. This talk should be read by those on both sides who are inclined towards a stereotyped view of the roles of management and Unions.

In the final talk, Dr. Berry, a director of I.M.I. Ltd., described the changing role of the manager as a particular project progresses from research, through development and pilot plant operation, to full-scale production. The talk suggests how the relationship of the project officer with other functions in the organization must develop, and how his role must change as increasing emphasis is placed on production. The research technologist who may transfer into production management by this route will find the talk most helpful. Dr. Berry not only signposted the route, but also the way in which the individual must change the emphasis that he puts on the qualities and abilities he possesses in order to become a good manager.

In summary, this is a mixed bag containing some useful material and some which would have been more so if it had been aimed more particularly at the needs of a specialist audience. The lack of obvious orientation is reflected in the discussions after the lectures which rapidly got down to the details of the subjects presented rather than retaining the broader overall perspective. Some bibliographies would have been helpful.

J. BANBURY

DETERMINATION OF NITROGEN

The Kjeldahl Method for Organic Nitrogen

By R. B. Bradstreet. Pp. viii+239. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 76*s*.

THERE can be little doubt that the methods most frequently used for the determination of nitrogen in organic substances are based on that originally described by J. Kjeldahl in 1883. Essentially the method involves the conversion of the nitrogen to ammonia by digestion with sulphuric acid, and titration of the ammonia. Speed and simplicity are the principal attractions of the method, but other useful features are its adaptability to multiple determinations and to aqueous solutions of nitrogenous substances, and its sensitivity to low levels of nitrogen. The defects are that many compounds, notably those in which nitrogen is linked to oxygen or to nitrogen, require special treatment which detracts from the essential simplicity, and there are a few types of compound which apparently fail to give correct values with any known modification of the method. Other methods for the determination of nitrogen, although usually applicable without modification to a wide range of substances, lack many or all of the attractive features of Kjeldahl's method. The combustion method of Dumas (1831), although accurate, is slow and complicated even in its micro-modification by Pregl (1912), nor is it of universal application, being unreliable with some heterocyclic compounds and unsuitable for materials containing trace amounts of nitrogen. The ter Meulen (1924) method, based on pyrolysis in a stream of hydrogen, overcomes these two latter objections but remains unattractively complex. The Kjeldahl method seems likely, therefore, to retain its popularity, and it is thus most important that both its potentialities and limitations be widely recognized.

Since the inception of the method, many investigations and modifications have been described, and the literature of the subject is vast and scattered. Thus it is often difficult especially for the inexperienced analyst to find the procedure most appropriate for the material under examination, and it is probable that many procedures in regular use are far from the best that could be devised.

The author of *The Kjeldahl Method for Organic Nitrogen* has set out to ease the task of the analyst by collecting in

monograph form as much as possible of the available information on the Kjeldahl procedure; and in this aim he has been very largely successful. The material is arranged in five main sections. After a short historical introduction, there is a chapter (74 pages) dealing with conditions affecting the sulphuric acid digestion of organic material, which considers, among other topics, acid requirements, effect of salt addition, oxidizing agents, catalysts, and reducing agents. The third chapter (50 pages) is concerned with digestion procedures appropriate to various types of material and also deals with sub-micro methods. In the fourth chapter (21 pages), methods for the determination of ammonia, with and without distillation, are considered. Finally, there is a useful classified bibliography of publications covering the entire period since the inception of the method.

The book is well documented with a numerical list of references at the end of each chapter and there is an adequate subject index, but the absence of an author index is, to say the least, irritating. References up to the year 1963 are listed.

Although there are few if any sins of commission, there are a few of omission. For example, the section dealing with procedures for soils is inadequate in that there is no reference to work later than 1937, and important contributions such as those by Alves and Alves in 1952 and Bremner in 1960 are not mentioned either in the text or in the bibliography. The subject of distillation apparatus would seem to merit more extensive treatment in the text than it has received, although it is well covered in the bibliography, but even here no reference could be found to the Hoskins distillation apparatus which is commercially available in the United Kingdom. Furthermore, there is no mention of adaptation of the Kjeldahl procedure to automatic analysis as described by Whitehead in 1961.

The text is clear and concise in style and the printing and binding are admirable. With only minor faults, this book brings together a mass of information on the Kjeldahl method and is undoubtedly worthy of careful examination by all investigators concerned with nitrogen in organic materials. One is, however, left with the thought that an extension of the book to include all methods for the determination of organic nitrogen would make it even more valuable; perhaps the author might consider this suggestion when a second edition becomes due.

R. I. MORRISON

JETS IN IDEAL FLUIDS

Theory of Jets in Ideal Fluids

By M. I. Gurevich. Translated from the Russian by Robert L. Street and Konstantin Zagustin. Pp. xvi + 585. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 120*s*.

ONLY the word 'jets' in the title of *Theory of Jets in Ideal Fluids* needs amplification, the other words need only emphasis. The author uses the term 'jet-flows' to include any flows with free streamlines, flows caused by hydrofoils and separated flows as well as the kinds of flow more ordinarily thought of as jet-flows, that is, flows from orifices. The book is certainly about theoretical investigations and exclusively about ideal fluids. The author's intention is clearly that of being a compiler of work carried out under the heading which is his title, work which is otherwise scattered in many journals. He disclaims, properly, the aim of being encyclopaedic but he does not always make clear the principles on which he has based his choice of material.

The book appeared in Russian in 1961. More than half of it deals with two-dimensional, steady, incompressible flow. This material is therefore a long account of the many ingonious uses of conformal transformation techniques and is very much for the hydrodynamicist rather than the engineer-scientist working with real fluids. After this long section the final four chapters deal, in sequence, with: unsteady flows; jets in compressible fluids (a topic which perhaps just steps outside the narrowest definition of ideal fluids); axisymmetric flows; and a very short section (26 pages) on heavy fluids and surface effects. From the purely visual point of view it is not an easy book to read. It is produced by photographic reproduction of a typescript original, with the result that apart from the use of upper and lower case letters there is no variety whatsoever of type-face. This monotony of visual impact is increased by the minimal use of headings.

The translators claim, as one of the particular strengths of the book, the comparison of theoretical results with experimental data. This claim is, unfortunately, not justified. There is very little indeed of such comparison and therefore very little assessment of the value of the work in relation to the flow of real fluids. This claim, it must be emphasized, is made by the translators in their preface and not (except perhaps by a most oblique implication) by the author in his preface.

All the flows discussed in the book are ones of which the kinematics are those of shear layers in real fluid flows. Of course there is no consideration of shear forces, the fluid by hypothesis being inviscid, but the flows themselves are all examples of flows with steep velocity gradients. It is just in such flows that viscous effects are of great importance. Where, also, the pressure gradient is adverse, the flow of a real fluid may not be even qualitatively similar to that of an ideal fluid. This situation does make the detailed results of questionable value. If the combined effects of pressure forces and shear forces in real fluids result in flows at least qualitatively the same as the flow patterns of the ideal fluids discussed here, then some features of these ideal flow solutions can be of value. More precisely, it can be the case that the ideal fluid flow results may give a satisfactory outer boundary condition to which the shear layer solution of real fluid flows can be matched. Also, for thin shear layers, the prediction of the pressure field may be satisfactory.

There is an extensive bibliography with many Russian references. The proof reading has been rather rough; a quick glance at the list of authors shows Lord Kelvin referred to as 'Lelvin' and Lighthill has been given one of his degrees (B.A.) as his initials.

R. G. TAYLOR

ANALYSIS OF THE FLYSCH

Sedimentary Features of Flysch and Greywackes

By S. Dzulyński and E. K. Walton. (Developments in Sedimentology, Vol. 7.) Pp. viii + 274. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 95*s*.

IT is easy to suppose that the authors of *Sedimentary Features of Flysch and Greywackes* had some difficulty in deciding on its title; and the layman could not appreciate that a previous volume in this series entitled *Turbidites* referred to the same group of rocks. This reflects a fundamental difficulty of definition. The name 'greywacke' is a petrographic term, enveloping a specific group of rock-types, which may loosely be defined as muddy sandstones. 'Flysch' describes an association of rock-types, now recognized as having genetic affinities, and as having been deposited in a particular tectonic environment—that of a deep trough in front of an advancing mountain chain. While many flysch sandstones are greywackes, they are not all; nor are greywackes confined to flysch. While a consensus agrees that turbidity currents are responsible for flysch, it must be conceded that this is not proved, that greywackes can originate by other processes, and that turbidity currents can operate in other environments than that envisaged for flysch. Nevertheless it must be admitted that there exists a genetic associa-

tion of rocks which recurs in a similar tectonic setting throughout geological time and in many parts of the world. A forbidding volume of literature has arisen around these rocks; and the authors have done good service in this timely conspectus.

As was to be expected of two premier experts in the field, this account is definitive and authoritative. It begins with an introduction in which the subject is outlined, and evidences of origin adduced; the authors come down strongly in favour of a deep-water, turbidity current hypothesis. There follow chapters in which the main features of the rocks are described: the descriptions are succinct and are illustrated by a very large number of excellent photographs. Throughout this section genetic implications are discussed, and this is further extended by the chapter on experimental investigations. Finally, the authors give two examples of palaeogeographical reconstructions based on their interpretations and here point the way for further developments in this field. The authors' coverage of the very extensive literature is complete, as is shown by the comprehensive bibliography.

There are perhaps two sources of disappointment. The first is that the treatment of some controversial issues is brief. The authors may well reply that in the limitations of space they could not be discursive: but this has meant that some very fundamental criticisms of the points of view of the authors, for example, those of Cummins (pp. 28–29) and Hubert (p. 253), are incompletely answered. The second omission is that there is scarcely a reference to calcareous flysch, and very little on turbidite conglomerates; yet both of these are widespread and an up-to-date synthesis of the scattered literature would have been welcome. However, perhaps this is to expect too much; we are fortunate in having this clarification of the central aspects of the problem.

J. E. PRENTICE

LIPIDS AND ATHEROSCLEROSIS

Metabolism of Lipids as Related to Atherosclerosis

A Symposium. Compiled by Fred A. Kummerow. Pp. xxxiv+300. (Springfield, Illinois: Charles C. Thomas, Publisher, 1965.) 14.50 dollars.

THE series of papers published in *Metabolism of Lipids as Related to Atherosclerosis* constituted a symposium held on the occasion of the dedication of the new Burnsides Research Laboratories at the University of Illinois, Urbana, in June 1963. Twenty-six scientists and clinicians from the United States and two from Canada contributed, and together they construct a most varied and stimulating picture of modern research into lipid metabolism. The relationship of their researches to atherosclerosis is close in some cases, and not so immediately obvious in others, but there can be no doubting the high scientific standard of every paper. Many disciplines are represented; the challenges of clinical medicine and epidemiology are met by pathologists, histochemists, biochemists, physical chemists, experimental pathologists and others. Modern techniques have opened new avenues of exploration: chromatographic techniques such as thin-layer or gas–liquid chromatography, infra-red and ultra-violet spectroscopy, electron microscopy, radioactive tracer methods and many other recent tools all show their value.

Dr. Irvine Page, in an introductory chapter, warns against enslavement to sophisticated instruments, but the preliminary thought and planning evident in these published papers render the warning unnecessary, and the results show that the instrument is more often the productive slave. Several of the studies are of a speculative nature and necessarily incomplete or inconclusive, but they all point to the possibility of an exceptionally productive new era in lipid research.

Dr. Louis Katz deals with clinical aspects of atherosclerosis, with particular reference to factors which increase the risk, and Dr. G. V. Mann outlines the present position of dietary treatment. The natural history of atherosclerosis, from the fatty streaks of infancy onwards, is discussed by Hartroft of Toronto and by McGill and his colleagues from New Orleans. Kummerow's group throw fresh light on the composition of the extractable and bound (so-called 'ceroid') lipids of the human aorta, and also on lipoprotein denaturation. There are three chapters on the physiological and pharmacological control of cholesterol metabolism: van Itallie and Hashim concentrate on serum cholesterol, Steinberg on cholesterol synthesis and Kritchevsky on the oxidation of cholesterol by rat liver mitochondria. The subjects of other chapters include the relationship between low-density lipoproteins; cholesterol and triglycerides; the synthesis of fatty acids; studies on phospholipids; essential fatty acids; poly-unsaturated fatty acids; coenzyme Q (ubiquinone); and an antithrombin and heparin co-factor. Klein examines the behaviour of sterols at interfaces, in a search for clues to enzymatic reactions and processes involved in the assembly of lipid structures.

Only the lipid chemist will understand the import of every paper, but all who are trying to apply basic knowledge of lipids to biological and clinical situations will appreciate this fine book. It certainly points the way for much future research; since the symposium took place two and a half years ago, much of this 'future research' is presumably well advanced by now. The almost exclusively American references in the various chapters are a tribute to the pace of lipid research in the United States, but workers in other countries perhaps deserve rather more recognition.

The book is compact, very well produced, well indexed and easy to read—altogether an attractive volume.

T. B. BEGG

MAINLY FERREDOXINS

Non-Heme Iron Proteins

Role in Energy Conversion. Edited by Anthony San Pietro. (A Symposium sponsored by The Charles F. Kettering Research Laboratory.) Pp. xiv+475. (Yellow Springs, Ohio: The Antioch Press, 1965.) 12.50 dollars.

THE Charles F. Kettering Research Laboratory is well known to workers engaged in the investigation of photosynthesis. It is becoming known to an even wider circle of research workers through its published symposia, of which *Non-Heme Iron Proteins* is the second. This volume describes the proceedings of a meeting held in March 1965, which included contributions by many of the leading workers in the fields under discussion. It is unfortunate, therefore, that this excellent volume suffers in several respects from a lack of purpose. Ostensibly concerned with non-haem iron proteins, it is in fact mainly concerned with ferredoxins. Ostensibly concerned with the part played by these proteins in energy conversion, this aspect is scarcely touched on, as one of the chairmen was led to remark. Several papers seem out of place in their particular sections, and the order in which they are arranged could be improved on.

These are more than minor irritations, since in general the papers are well written and contain valuable summaries of work in progress. However, they are presented in such a way as to make it extremely difficult to locate specific information (there is, of course, no index). It is impossible to list all the contributions in detail, but I shall try to summarize the contents of the four sections into which the symposium was divided.

The first covers the physical and chemical properties of iron compounds in general, and includes contributions on electron paramagnetic resonance and Mossbauer spectro-

scopy, and on optical rotatory dispersion. This is a most valuable compilation of information on these relatively new and less well-known techniques.

Next follows a section on photosynthesis, concerned mainly with ferredoxin. The papers fall into two groups, dealing with electron transfer and synthetic reactions respectively. Reviews of soluble protein factors in chloroplast electron transport, and of a ferredoxin in photosynthesis, summarize the development of present knowledge, and are followed by several papers on synthetic pathways involving ferredoxin, one on a proposed model of ferredoxin, and one on the kinetics of ferredoxin reduction.

Section 3 deals with nitrogen fixation. Although one can see the connexion with non-haem iron proteins in general, and with ferredoxin in particular, one cannot help feeling that this section was largely off the main line of interest of the symposium. Equally this difficult field still seems to lack sufficient information of a kind to stimulate the attention of the non-specialist reader. The papers report various experiments on aspects of nitrogen fixation, with little interrelationship between them.

The final section deals with a number of dehydrogenases, mostly from cell particles. Again, these are related only by that and the general theme of the section.

There is no record of discussion or comment, and the papers are apparently reproduced essentially as they were presented at the symposium. The remarks of the section chairmen are introductory, and not a summing up of the material presented. One has to rely on reading the individual papers to get an evaluation of the present status of each problem, and one is denied access to any record of the argument and discussion which are often among the most valuable results of such meetings.

The book itself is well produced and seems remarkably free of printing errors. In general there is little that one would wish to comment on so far as the content is concerned. The papers are largely concerned with experimental work, of which this is essentially a progress report, and which should be read in that light. The presentation might have been better, but nevertheless the book provides a much-needed summary of present work on iron proteins, particularly the ferredoxins, and is recommended to all workers interested in the role of iron in biological systems.

M. H. SMITH

VIRUSES, MYCOPLASMAS AND LEUKAEMIA

Methodological Approaches to the Study of Leukemias

Edited by Vittorio Defendi. (A Symposium held at The Wistar Institute of Anatomy and Biology, April 5 and 6, 1965. Symposium Monograph, No. 4.) Pp. ix+225. (Philadelphia: The Wistar Institute Press, 1965.) 7.50 dollars.

SINCE the discovery by Gross in 1951 that leukaemia in a particular strain of mice could be induced by a virus, the search for viruses as the cause of malignant conditions has become a major trend in cancer research. The electron microscope has revealed, in numerous experimental animal tumours, virus-like particles, the oncogenic properties of which have been proved by the injection of cell-free tumour extracts into suitable recipients. With the introduction of new techniques, the number of transplantable animal tumours in which such viruses have been found is increasing rapidly. Furthermore, it has also been found that malignant transformation of cells grown *in vitro* can be initiated by the introduction of virus into the culture. It was a natural development therefore that the search for oncogenic viruses should be extended to human tumours, especially to leukaemia, utilizing the methods used with success in the study of experimental animal leukaemias. *Methodological Approaches to the Study of Leukemias* contains the proceedings of a symposium which aimed at discussing how the various techniques could be used in the search for viruses in human tumours and at spot-lighting the many difficulties, both methodological and interpretative, which beset an investigation of this kind.

Some of the participants dealt with cell kinetics, stem cell differentiation and chromosome anomalies in relation to leukaemia, but most of the contributors focused their interest on subcellular particles shown by electron microscopy to be present in tumour cells cultured *in vitro* or in cells obtained from primary neoplasms. Such particles were identified in cultures of Burkitt's lymphoma or observed in the plasma from leukaemic patients. The principal points of discussion were whether these are the agents which are responsible for the malignant behaviour of cells, whether they are latent viruses which manifest themselves because of the leukaemic condition, or whether they should be looked on only as secondary invaders.

Several contributions were devoted to the mycoplasmas, the smallest micro-organisms so far observed which contain all the enzyme systems and genetic mechanisms compatible with free-living existence on agar. Mycoplasmas are known to be the cause of at least one type of pneumonia in man. This class of organism was first isolated from human tumours in 1937, but gained much importance only recently when mycoplasmas were identified in tissues of leukaemic patients. At the symposium much information was given about the morphology and metabolism of these micro-organisms, which are encountered in the most diverse pathological states. It was admitted that the possible presence of mycoplasmas in tissues under examination makes it even more difficult to investigate the role of viruses in leukaemia. The participants agreed that only future research can determine whether mycoplasma or virus have in fact anything to do with the aetiology of human leukaemia. The proceedings of the symposium are nevertheless a valuable source of information concerning the application of electron microscopy to leukaemia research, and from the volume the reader will also learn about the many potential pitfalls present in such an approach.

P. C. KOLLER

THE ASPERGILLI

The Genus *Aspergillus*

By Prof. Kenneth B. Raper and Dorothy I. Fennell. With a chapter on Pathogenicity by Peter K. C. Austwick. Pp. ix+686. (Baltimore, Md.: The Williams and Wilkins Company, 1965. Distributed in the U.K. by E. and S. Livingstone, Ltd., Edinburgh.) 160*s*. net.

THE aspergilli are a ubiquitous, prominent and notorious component of common mould. They occur everywhere in soil and compost, and cause deterioration of many materials including fabrics, leather, paper and foodstuffs; their fermentation products include sauces and alcoholic drinks, antibiotics and citric acid, and they find a use as a biochemical tool for the detection of minor elements in soil. In addition, some are pathogenic for man, animals (particularly birds) and plants, and others produce toxins which poison livestock and possibly induce cancer in man, while their spores may act as airborne allergens. As aspergilli are of such economic importance and because they are easily recognized in their asexual (imperfect or conidial) state, grow well in culture, and are both macroscopically and microscopically attractive organisms, they have received much attention during the past two hundred years.

The Genus Aspergillus is a third generation monograph. In 1926, Thom and Church published *The Aspergilli*, a volume of 272 pages in which sixty-nine species were accepted; this was replaced in 1945 by Thom and Raper's *A Manual of the Aspergilli* (373 pages, 77 species)

which, in its turn, has been superseded by the present work (686 pages, 132 species). This pattern reflects the steady growth of mycology, and each monograph has in its turn raised the study of the genus *Aspergillus* to a new level.

The most recent version is basically a much enlarged and improved edition of its immediate predecessor. There are well-illustrated descriptions of the species, arranged in eighteen groups each with its own specific keys, while two keys, based primarily on morphology and colour, respectively, are provided for the preliminary sorting into groups. After an excellent and characteristic portrait of the late Charles Thom (1872–1956), to whom the book is dedicated, there are introductory chapters on general aspects of the genus, methods of cultivation, etc. Here, as a new feature, is the most useful chapter by Austwick on "Pathogenicity", but pathogenicity to man and animals only it should be noted, the plant pathogenic members of the genus having to be laboriously sought under the different species. In conclusion there are lists of the twenty-eight generic and more than one thousand specific names which have at one time or another been applied, correctly or incorrectly, to aspergilli, a list of species and varieties at present accepted, a 54-page general bibliography, and an index.

One point that must be regretfully noted is that, as in the *Manual*, insufficient attention is paid to the International Code of Botanical Nomenclature which prescribes the present conventions for ordering the scientific names of fungi. It is surprising that in this comprehensive account of the genus the correct author citation for the validation of the name *Aspergillus* under the Code—Micheli ex Fries, 1821—does not appear. This is presumably because, if it did, it would have embarrassed the authors who use the name of *Aspergillus* for both sexual and asexual states while the name was validated for the asexual state only. This is not an occasion to elaborate the point. The Code is not penal, authors may do as they please, but when they infringe the Code they may find themselves penalized by the names and usages they personally prefer not being given general acceptance.

This technical blemish will not affect the sales or the popularity of an outstanding monograph. Everyone must agree that the purpose of the volume "to facilitate the identification of the Aspergilli by providing descriptions of the recognized species together with appropriate keys" has been most successfully achieved.

G. C. AINSWORTH

BALSAM FIR

Balsam Fir

Abies balsamea (Linnaeus) Miller. By E. V. Bakuzis and H. L. Hansen. (A Monographic Review.) Pp. xix+445. (Minneapolis: The University of Minnesota Press; London: Oxford University Press, 1965.) 76*s*. net.

MUCH has been written about the balsam fir and first records go back 300 years. It is a major coniferous species of eastern North America and it reaches its greatest proportion of total growing stock in south-eastern Canada, especially in Newfoundland and the maritime provinces where it may constitute more than 30 per cent by volume of standing timber. In the United States the tree is most important in Maine and to a lesser extent in New Hampshire, Vermont and New York. Because of its technical properties, balsam fir does not rank as a superior timber, but high-quality pulp and paper products can be manufactured from high-quality pulpwood. No longer is it an important lumber in the United States, but its use for fibre continues to increase. Indeed, some pulp and paper mills formerly geared to spruce as the main raw material for quality products have reorientated their processing technology to use more balsam fir. The position this species holds in the timber industry is indicated by what is described as a conservative estimate that the total merchantable volume of balsam fir in both Canada and the United States is about 36 billion cubic feet. Production figures on a national scale, embracing as they do a variety of sites and intensities of management, are not always very reliable, but even the range of 15–80 cubic ft. per acre represents a vast amount of timber increment. From the blisters on the tree an oleoresin is collected and this Canada balsam has long been known in the scientific world for optical work and for mounting media.

It is usually interesting to learn what caused the initial impetus to compile such a useful work as *Balsam Fir*. In this case it was the uncertainty of the successional role of balsam fir that was the basis for the recommendation to the University of Minnesota School of Forestry, by the Quetico-Superior Wilderness Research Centre Advisory Committee in 1953, that a complete literature survey be made of all research work conducted on this species. The various bodies which sponsored the work and the team responsible for collecting the scattered information and integrating it into one volume must be thanked and congratulated. The result is a coherent picture of balsam fir both in Nature and in forestry practice. This is no mere catalogue, but a most readable account of an interesting and important tree species.

The first three chapters are devoted to the botany, synecology and ecology of balsam fir. Although accepted as a single species, it is possible that more detailed taxonomic work will show that variations exist throughout its wide range of distribution, but the boundaries have not been well established in all the areas where it occurs. Balsam fir is essentially a species of the boreal region, and, even away from it, it retains its boreal character as expressed by its tendency to occupy moist and cool sites. Complex inter-relationships in its ecology have still to be worked out. The chapters on microbiology and entomology indicate that more knowledge is required on the fungi and insects associated with balsam fir. Due to the spruce budworm attacks having reached epidemic status at times, a great deal of attention has been concentrated on this insect. The silviculture of balsam fir is described in two chapters, and many of its characteristics are influenced by its great seeding ability and its shade tolerance. Chapters on growth and yield and on utilization conclude the study. Lists of associated fungi and insects are given and the 1,381 references are appropriately grouped by chapters. Not only has this most useful publication succeeded in its aim but it also directs attention to where further research is needed. Forest biologists will be glad to have such a complete reference work.

C. J. TAYLOR

NATURE'S HANDICAP: THE ANATOMY OF PLANTS BEGUN

The Anatomy of Plants

With an Idea of a Philosophical History of Plants and several other Lectures read before the Royal Society. By Nehemiah Grew. Reprinted from the 1682 edition, with a new Introduction by Conway Zirkle. (The Sources of Science, No. 11.) Pp. xviii+24+304+83 tables. (New York and London: Johnson Reprint Corporation, 1965.) 35 dollars.

SOME of us who were introduced to botanical science by the scholarly exponents of an earlier generation may have nostalgic memories of being shown treasured first editions of Hooke, Grew and Malpighi—the founders of plant anatomy, who did their work in the middle to later decades of the seventeenth century. A few of us, perhaps, still recollect how good, all things considered, some of the illustrations seemed to be. But, typically, we probably took passing note of the musty smell of the

old tomes and then put them aside with the thought that it was nice to know that we had such works in the university library. For me, at least, it has been an agreeable and refreshing experience to look into the excellent reprint of the 1682 edition of Nehemiah Grew's *Anatomy of Plants*, originally read before the Royal Society of 1672 and now reappearing as No. 11 in "The Sources of Science" series.

In a short but excellent introduction, Prof. Conway Zirkle, of the University of Pennsylvania, has reminded us of things that we ought not to have forgotten, and has directed our attention to some new and critical facets of these early studies of plant anatomy. He reminds us, for example, of the odd and remarkable fact that the microscopic study of plants and animals might well have been begun at a much earlier date, for the optical means were already available. A specially valuable part of the introduction is his critical assessment of the contributions made by the three primary exponents. Hooke, with his *Micrographia* published in 1665, was first in the field. He showed what could be achieved by microscopy over a wide range of materials, but his contributions to plant anatomy, although excellently illustrated, were considerably less fundamental than those of Grew and Malpighi. Between these two it was a close thing: their respective studies were submitted for publication almost simultaneously, and Prof. Zirkle has been careful and cautious in handling the relevant questions of priority and alleged plagiarism. The circumstances of the simultaneous publication of two major works make fascinating reading. So also do Grew's accounts of, and reflexions on, the structural features which he observed in his anatomical studies. Among others, for example, he gave us the term "parenchyma"; and some of his morphological observations were very much to the point.

As to the contents of Grew's book, it is with renewed surprise that one realizes how systematically thorough he was in his work and how direct and lucid in his writing. There is still an agreeable freshness, indeed modernity, in his 'discourses'. Thus, in 'the epistle dedicatory' to Charles II, he referred to the precision of the "mathematic lines of a flower"; and he stated explicitly that all we perceive in a plant, the miracle of "Nature's Handicraft" to be seen in the tissues of the meanest walking-stick, the ascent of sap, the distribution of air and of substances in plants and, indeed, many other aspects of vegetation, "are all contrived and brought about in a mechanical way". So we enter into a new world "whereof we see no end". The numerous original illustrations, here reproduced with fidelity, are still impressive because of their observational content, clarity and, not least, their sheer artistic quality. Of course, at 35 dollars, this volume is something of a collector's piece; but many would, undoubtedly, like to possess it. It might be salutary, and it would certainly be no bad thing, if it were made available for at least occasional student reference. C. W. WARDLAW

BIOLOGICAL CONTROL OF ROOT DISEASES

Ecology of Soil-Borne Plant Pathogens

Prelude to Biological Control. Edited by Prof. Kenneth F. Baker and Prof. William C. Snyder. (An International Symposium on Factors determining the Behavior of Plant Pathogens in Soil, held at the University of California, Berkeley, April 7–13, 1963.) Pp. 571. (London: John Murray, 1965.) 105*s*. net.

DISEASED roots of crop plants are less amenable to chemical control than diseased leaves, and they are also more difficult to examine, if only because soil is opaque and complex. Applying fungicides and sterilants on a field scale is usually prohibitively expensive; consequently the possibility of biological control by manipulating the microflora becomes correspondingly attractive, and, although successful in only a few cases with present knowledge, much is promised for the future.

As the editors point out in the foreword to *Ecology of Soil-Borne Plant Pathogens*, exploration of this difficult subject "awaited the overcoming of . . . compartmentalization of the scattered, diffuse, isolated and uncorrelated knowledge" in the disciplines of plant pathology, microbiology, soil science, plant physiology, plant anatomy, biochemistry, bacteriology, nematology, mycology, virology and zoology. For this reason, the Agricultural Board of the National Academy of Sciences–National Research Council, Washington, sponsored an international symposium on factors determining the behaviour of plant pathogens in the soil, with the object of assembling a group of specialists to compile and discuss existing information in preparation for further advances towards biological control. The conference was held at Berkeley, California, in April 1963. Generous financial aid brought together more than forty experts to present formal papers before an invited audience of more than three hundred participants from twenty-four countries.

The papers and recorded discussions are now published in a handsome (and weighty) volume, edited by two of the leading spirits in the group which initiated the conference. The resulting volume provides an invaluable course on the principles of soil microbiology in relation to root diseases. Individual papers are usually introduced by a critical survey of relevant literature, leading on to an exposition of the special topics studied by the author with an account of his own researches and conclusions, and ending often with a more speculative section that could stimulate further developments. There are copious bibliographies and, as inevitable in a symposium of this kind, there is some repetition because certain key papers are cited again and again, as the work of some authors is discussed from different angles.

Readers of the half-million or so words of this book will agree with the opening speaker, Victor R. Boswell, that it represents a landmark in biology. The first main paper, by S. D. Garrett, deals with fundamental concepts and prospects for the future of biological control of root diseases. Thereafter groups of papers deal with topics of increasing complexity. Soil microbes and their behaviour are surveyed by A. Burges, D. K. McE. Kevan, J. H. Warcup, J. M. Hirst, D. Park, A. S. Sussman and J. D. Menzies. Then the soil is considered as an environment for microbes by W. A. Raney and H. D. Chapman. Next, attention is focused on the host plant, particularly its roots and rhizosphere, by Flora M. Scott, H. G. Burström, A. D. Rovira, H. Katznelson, D. J. D. Nicholas, J. L. Harley, P. S. Nutman and A. Kerr. Host and pathogen are then brought together in a series of papers by N. T. Flentje, I. W. Buddenhagen, W. B. Mountain, C. H. Cadman, J. C. Walker, J. E. DeVay and I. A. M. Cruickshank. Mechanisms of microbial antagonism are considered by F. E. Clark, R. A. Fox, R. M. Jackson, M. G. Boosalis and R. Mankau. Theoretical aspects of soil inoculum are developed by R. Baker, A. E. Dimond and J. G. Horsfall. The final section is the most complex and deals with interactions between soil organisms and crop plant in a series of papers by Mary D. Glynne, G. C. Papavizas, Z. A. Patrick, T. A. Toussoun, T. S. Sadasivan, R. A. Ludwig, G. W. F. Sewell, W. A. Kreutzer, S. Wilhelm and A. W. Dimock.

The editors have maintained an exacting standard throughout their formidable task of dealing with papers, discussions, bibliographies, and an index of thirty-six pages. For its wealth of material this splendidly produced volume is a necessity in every centre where plant pathology is taught or practised. As one consequence, the Berkeley symposium has stimulated plans for the First International Congress of Plant Pathology in London in 1968. Another consequence will be eager searching of its records for clues to help fill hungry bellies.

P. H. GREGORY

Science and the Manager

By Prof. R. W. Revans. Pp. xi+160. (London: Macdonald and Co. (Publishers), Ltd., 1965.) 25*s*. net.

IN *Science and the Manager*, Prof. Revans has collected eight essays, written during the past 20 years and addressed to various types of readers. They have been pruned of material which is no longer topical or relevant, but there are neither references nor index and the book is best regarded as essentially new. Prof. Revans himself suggests that the essays illustrate three common themes: the need to apply the methods and attitudes of experimental science to industrial practice; the subsequent emergence of exceedingly difficult problems which require more than known scientific method to solve them; and the comparatively elementary character of the study of management and the development of theory from such study. Even more strikingly, the importance of clarity of thought and expression is emphasized throughout the book and exemplified in Prof. Revans's own prose, pointed and sometimes pregnant with prophetic authority. Beginning with a study of the sampling of attitudes on the shop floor, which strongly emphasizes this point about effective communication, the essays deal successively with decisions, communications and morale; science and the manager; technical knowledge; the pathology of automation; the scope of management control; industrial relations and industrial training; and the nature of operational research.

Prof. Revans's sense of the possibilities of using science in management is matched by his sense of the limitations of the scientific method as well as a deep respect for human personality, and he has a rare capacity for going to the root of things. This study of technical knowledge and the essay on industrial relations and industrial training are perhaps the best in the book and highly pertinent to Britain's present difficulties, outlining what needs to be done immediately. With so much good sense, constructive criticism and insight in this short volume, one wonders what Prof. Revans might have given us had he set out to discuss the technological society on the scale that Jacques Ellul has done. Perhaps he may yet give us a worthy successor to Bavink or Mumford. R. BRIGHTMAN

The Tissues of the Body

By Prof. W. E. Le Gros Clark. Fifth edition. Pp. ix+423. (Oxford: Clarendon Press; London: Oxford University Press, 1965.) 55*s*. net.

THE appearance of another edition of *The Tissues of the Body*, the fifth since its original publication in 1939, is itself some indication that this is no ordinary text-book. Sir Wilfrid Le Gros Clark is, of course, well known for his many and varied contributions to human and comparative anatomy, which gave impetus to the happy revitalization of academic anatomy that is now so much in evidence. Earlier editions of this, probably his best-known book, have exerted an intellectually stimulating effect on many medical students for whom the subject of anatomy might otherwise have seemed as inert as the dissecting-room specimens. In a direct and readable way the book succeeds in conveying the notion of anatomy as an exciting subject, with obvious relevance to bodily functions in health and disease. The author's wide experience of research is evident in the enthusiastic presentation of ideas and theories amenable to experimental investigation, rather than depending on mere preoccupation with morphological minutiae.

The present edition consists, as before, of thirteen self-contained chapters showing anatomy as basically the examination of biological organization at all levels: the cell, the tissue, the organ, the functional system and the integrated organism. The reader is offered not just factual information but reasoned interpretations based on the available evidence, with frequent indications of the actual limits of existing knowledge. There are well-chosen references in the text, which may encourage the student to develop at an early stage the habit of looking up original work. The opportunity has been taken, with little increase in length, to revise many sections in the light of recent findings; arising especially from the application of newer techniques in the field of cell biology. A few electron micrographs, of adequate but not inspiring quality, are now included in the illustrations. One cannot help feeling that perhaps more should have been done to emphasize the phenomenal scope of recent developments at the level of anatomical organization that is represented by molecular and cell biology. Nevertheless, this admirable book remains virtually in a class of its own, and can be recommended unhesitatingly to students of medicine and biology. J. A. ARMSTRONG

Neurospora Bibliography and Index

By Prof. Barbara J. Bachmann and Prof. W. N. Strickland. Pp. vii+225. (New Haven and London: Yale University Press, 1965.) 4.00 dollars; 30*s*.

THE fungus *Neurospora crassa* is of outstanding significance in the development of biochemical genetics and it is attracting increasing attention as a research tool. It is therefore of very great value that a bibliography and index has been prepared as a guide to its literature. The first section of the volume is comprised of the bibliography itself, listing 2,310 papers and taking the record to January 1964. The references are listed alphabetically and each one is assigned a code number which is used in the index to refer to the paper. The second section is an author cross-index. The third section indexes the subject matter of all papers in as much detail as has seemed useful. It is divided into three parts, a general index of subject matter, a mutant index and an index of *Neurospora* species other than *N. crassa*. Tests of the index have shown how effective it is. It appears from the preface that the indexes were the work of Dr. Bachmann, while the compilation of the references was done mainly by Dr. Strickland. Those who use this book (I hope a growing number) will realize what a great debt is owed to the authors. They have provided an easy guide by which all information on a great variety of subjects can be quickly traced in a complex literature.

D. G. CATCHESIDE

Bananas

By N. W. Simmonds. Second edition. (Tropical Agriculture Series.) Pp. xvi+512+106 photographs. (London: Longmans, Green and Co., Ltd., 1966.) 63*s*. net.

WHEN I reviewed the first edition of N. W. Simmonds's book *Bananas* (*Nature*, 186, 48; 1960), one of the "Tropical Agriculture Series", issued under the editorship of Mr. D. Rhind, I stated, with knowledge and conviction, that no book of equal status on this subject had hitherto been published. With the appearance of the second edition, I see no reason to change this view. However, a great deal that is new and interesting has happened in the banana industry since that time, and much of this has been successfully incorporated in the new edition. Accordingly, to those who are closely concerned with banana growing and all that is now involved in the harvesting, packaging, transport and ripening of this sometimes fickle and always delicate crop, the new edition will commend itself as affording ready access to the agricultural and scientific innovations in a highly competitive industry. In fact, it is quite surprising how many new and unexpected developments there have been. The preparation of the present volume has therefore involved extensive revision of the original text, the skilful splicing-in of critical new material at various points, and the incorporation of other quite new information of various kinds in a supplementary chapter—an overall enlargement of some forty-six pages. Like the first edition, this volume will prove instructive to a wide range of readers.

C. W. WARDLAW

QUASARS — A MINORITY REPORT

By JAMES H. HUNTER, jun., and SABATINO SOFIA

Yale University Observatory, New Haven, Connecticut

AND

EMERY FLETCHER

Van Vleck Observatory, Wesleyan University, Middletown, Connecticut

IT is generally accepted that the large red shifts observed in the spectra of quasi-stellar radio sources (hereafter called quasars) are due to the radial recession of these objects. According to the most widely accepted present view, these red shifts are of cosmological origin, and the resulting distances and luminosities of quasars are so enormous that the primary mechanisms responsible for their energy release are not yet understood within the framework of known physical processes. Proponents of a less popular view argue that quasars could be 'local' phenomena. According to one version of this local picture, the observed Doppler shifts of quasars are the result of recessional velocities imparted to these objects by a gigantic explosion that occurred in the nucleus of our Galaxy in the relatively recent past. This interpretation was first proposed by Terrell[1], and its major advantage lies in the fact that it implies energy requirements for quasars that can be very much less than the energy requirements on the cosmological picture.

It is fair to say that, as yet, no clear-cut case has been made in favour of either interpretation. Recent observational developments, however, justify a reconsideration of the fundamental problem of the distances of quasars. In this article we hope to make some progress towards resolving this question by using accepted procedures of classical astronomy.

Our first task is to attempt to put a reasonable upper bound on the distance of 3*C*273 *B*. Recent radio observations[2] indicate that 3*C*273 *B* undergoes variations in its radio flux having periods of the order of a few months. The simplest conclusion to be drawn from this result is that the diameter of 3*C*273 *B* is considerably less than one light-year. If this were not the case, the differences in light travel times between light emitted from different portions of the object would tend to smooth out radio variations resulting from pulsation of the object as a whole. We are fully aware that it is possible to construct more complicated models of quasars that exhibit variability[3]. However, in attempting to explain a new phenomenon it is desirable first to rule out the possibility of using a conservative, simple model, before considering more bizarre models. Therefore, we assume, provisionally, that the variations in radio flux are caused by oscillations of the radio source as a whole, and we adopt 0·5 light-years as a reasonable upper limit for the diameter of 3*C*273 *B*.

Recent, long-baseline interferometry at Jodrell Bank has established that the radio source 3*C*273 *B* is probably double, and that each component has a diameter of $\sim 0{\cdot}1$ sec of arc[3,4]. Apparently, the components may not have been completely resolved, but for want of a better figure, we will assume that the pulsating radio object subtends 0·1 sec of arc. This implies that the distance to 3*C*273 *B* is about 320 kiloparsec (kpc). At this distance, the proper motion of 3*C*273 would be $\sim 0{\cdot}0015$ sec/yr, which is less than the mean errors of $\pm 0{\cdot}0025$ sec/yr assigned by Jefferys[5]. Thus, our crude estimate of the upper bound for the distance to 3*C*273 using variability arguments is very nearly equal to the lower distance limit set by proper motion studies (if 3*C*273 were ~ 192 kpc from the Sun, the proper motion would be about 0·0025 sec/yr). While this upper bound to the distance of 3*C*273 can be questioned legitimately on several grounds, it will be shown, in due course, that energy considerations do not permit our variability upper limit to be exceeded by more than a factor of 10 if the local hypothesis is to be retained. Consequently, we regard it as encouraging that our tentative upper bound to the distance of 3*C*273 lies between the absolute lower limit set by Jefferys's proper motion studies and the upper limit imposed by energy requirements. A summary of observational data for nineteen quasars with known red shifts is given in Table 1.

Burbidge, Burbidge and Sandage[6] have set forth arguments which suggest that a violent event may have occurred in the nucleus of our Galaxy in the relatively recent past. Therefore, Terrell's hypothesis[1] is a logical one to account for the local distribution of quasars—that is, quasars were ejected from the nucleus of our Galaxy $\gtrsim 4 \times 10^6$ yr ago. In Table 2, we have assembled the distances and visual luminosities of the quasars listed in Table 1 assuming the foregoing time scale of 4×10^6 yr. These luminosities and distances should be regarded as lower limits, since the time scale of 4×10^6 yr places 3*C*273 at the lower distance limit (~ 190 kpc) set by proper motion considerations.

On the cosmological picture, the total energy requirement for each quasar is rather large: at least 10^{60} ergs for 3*C*273 (ref. 7). On the other hand, the local hypothesis, as outlined in Table 2, leads to an absolute visual magnitude for 3*C*273 of $-8^{m}{\cdot}6$, which implies a total energy output in visible light of the order of 10^{54} ergs, if we assume it has radiated at its present rate for 4×10^6 years. At proton–proton burning efficiency, this energy corresponds roughly to the conversion of 100 $M_\odot$ of hydrogen to helium. However, since the visible light represents only a fraction of the total energy associated with quasars, an estimate of a total mass of 1,000 $M_\odot$ /quasar is perhaps more realistic. Using the velocities of Table 1, the average relativistic kinetic energy per quasar of this mass would be $\sim 4{\cdot}3 \times 10^{56}$ ergs. If we postulate that our Galaxy has ejected 100 quasars, then $\sim 4{\cdot}3 \times 10^{58}$ ergs would be contained in the kinetic energy of these objects. This figure may be compared with energies quoted for material in the exploding galaxies *M* 82 ($\sim 10^{55}$ ergs[14]) and *NGC* 1275 ($\sim 10^{61}$ ergs[6]).

If quasars are indeed local, then their distances cannot greatly exceed the distances quoted in Table 2, because the local interpretation requires that the energy output per quasar increases as the cube of the distance from the centre of our Galaxy (energy requirement = luminosity × time, luminosity $\propto r^2$, and time $\propto r$). Their masses must also be increased if a substantial increase in energy is required, and thus the kinetic energy will represent a

Column number: (1) Identification; (2) present distance from centre of Galaxy; (3) present distance from Sun; (4) observed difference in apparent magnitude, $m_{object} - m_{3C273}$; (5) computed difference in apparent magnitude, $m_{object} - m_{3C273}$, on the assumption that all quasars are of the same absolute magnitude; (6) difference in magnitude differences, $\Delta m_{obs} - \Delta m_c$; (7) ratio of luminosity of quasar to that of 3C273, on the assumption that $\delta(\Delta m)$ is due to a difference in absolute magnitudes between the object and 3C273; (8) ratio of luminosity of quasar to the average luminosity of all quasars, on the same assumption.

large fraction of the total energy of our Galaxy over a cosmological time scale. For example, if we increase the distance of 3C273 to 30 Mpc, the upper bound to the distance recently proposed by Terrell[8], the total energy requirement of 3C273 is more than 3×10^{59} ergs, its mass at least $3 \times 10^7 M_\odot$, and the kinetic energy of all quasars more than 10^{63} ergs. On energy arguments alone, therefore, a reasonable upper limit for the distance of 3C273 is ~ 1 Mpc, meaning that the violent event in the nucleus of our Galaxy must have occurred between a few $\times 10^6$ and a few $\times 10^7$ years ago, converting between 10^{58} and 10^{60} ergs into kinetic energy of quasars.

An additional consequence of the local picture is that no absorption immediately shortward of Ly_α due to intergalactic hydrogen is to be expected, since quasars would be in rapid motion in a hydrogen medium approximately at rest with respect to our Galaxy. Thus, the fact that spectra of some of the highest velocity quasars (3C9, for example) exhibit a lack of total absorption (and, quite possibly, a total lack of absorption[9]) to the blue of Ly_α supports the local interpretation. Whether or not absorption appears to be present in a given spectrum depends on how the continuum is extrapolated from the red to the blue side of Ly_α—a most uncertain procedure, since the intrinsic shape of a quasar's continuum is unknown. (We thank Prof. M. Schmidt for directing our attention to this fact[9].) If some absorption is present, and if the density of the intergalactic medium (assumed to be hydrogen) has the cosmological value of $\sim 10^{-5}$ atoms/cm^3, Rees and Sciama[10] have shown that the temperature of the intergalactic material must be a few $\times 10^5$ °K.

We are justified in ignoring evolutionary effects in evolving cosmological models because of the following happy circumstances: (*a*) if the universe expands adiabatically, then the temperature, T, and number density, N, of the intergalactic hydrogen are related by the expression $T \propto N^{2/3}$; (*b*) the cross-section/hydrogen atom for absorption of Ly_α quanta, σ, is approximately proportional to $T^{-1/2}$; (*c*) in the high-temperature range that we are interested in, N_1, the number density of neutral hydrogen atoms in the ground state, $\propto N/T^{10,11}$. Hence, the Ly_α adsorption/unit length, $N_1\sigma$, goes as $N/T^{3/2} =$ constant, and we arrive at the important conclusion that the Ly_α adsorption should be independent of the evolutionary stage of an adiabatically expanding universe. Thus, Rees and Sciama's temperature bounds for the intergalactic hydrogen in a steady-state universe should apply, approximately, to evolving models as well.

However, since the Ly_α adsorption estimates are uncertain, we are led to one of the following conclusions: (1) quasars are local; (2) if the density of the intergalactic hydrogen at the present epoch is 10^{-5} atoms/cm^3, its temperature must lie between a few $\times 10^5$ °K and 3–4 $\times 10^6$ °K, the upper limit set from X-ray observations[12]; (3) the present density of hydrogen in the intergalactic medium is substantially less than 10^{-5} atoms/cm^3, in which case the temperature bounds are less severe than those already quoted.

Thus far, the local explanation of quasars has been self-consistent, However, Koehler[13] has reported a remarkable observation which, if substantiated, will probably establish the cosmological origin of quasars. In the spectrum of 3C273, he has reported what may be a slight absorption in the 21-cm line of neutral hydrogen by a cloud moving at $\sim 10^3$ km/sec, having co-ordinates which very nearly coincide with the Virgo cluster of galaxies. Since the cosmological red shift of the Virgo cluster is $\sim 10^3$ km/sec, the natural interpretation would be to assume that the cloud is associated with the cluster. Hence, 3C273 would have to be >10 Mpc from our Galaxy, and energy considerations alone would compel us to accept the cosmological interpretation. Consistency with local origin can be obtained only in the unlikely cases that: (1) a hydrogen cloud has been expelled from our Galaxy at 1,000 km/sec in the direction of 3C273, or (2) a cloud of neutral hydrogen

has been somehow focused in the wake of 3C273 as it ploughs through the intergalactic medium.

In summary, the local picture of quasars is consistent with all the observational data excepting for Koehler's result. On the other hand, it is difficult to account for the lack of total absorption to the blue of Ly_α in such quasars as 3C9 on the cosmological picture. Since only a projection observation such as Koehler's can unambiguously confirm the cosmological nature of quasars, it is imperative that such observations be pursued for all quasars for which they are geometrically possible, using any techniques which might extend the accuracy to the limit necessary for this crucial confirmation. Also, in order to eliminate the possibility that the 21-cm absorption reported by Koehler is caused by neutral hydrogen in the wake of 3C273, a search should be made for 21 cm absorption in the spectra of selected quasars that do not appear in projection on a cluster of galaxies. If Koehler's observation is not confirmed, then Terrell's local hypothesis must be taken much more seriously than it appears to be being taken at present.

A possible observational test of the local hypothesis would be to search for faint objects having large ultra-violet excesses surrounding relatively nearby galaxies.

Note added in proof. Using arguments different from ours, Hoyle, Burbidge, and Sargent (*Nature*, **209**, 751; 1966) have concluded that "either the quasi-stellar objects are at distances of ~ 10 Mpc or less, or the physical model associated with these objects must be substantially different from the theories at present in vogue". Our findings tend to substantiate the first alternative.

DISTRIBUTION OF QUASI-STELLAR RADIO SOURCES IN STEADY STATE COSMOLOGY

By DR. D. W. SCIAMA and W. C. SASLAW

Department of Applied Mathematics and Theoretical Physics, University of Cambridge

ONE of the most intriguing problems in astronomy to-day is to understand the origin and structure of quasi-stellar radio sources. The starting-point for any discussion of this problem must be a knowledge of the distances of quasi-stellar radio sources. However, it has not yet been possible to measure these distances directly, and three general hypotheses have been proposed concerning the location of quasi-stellar radio sources: (i) they are objects in our own Galaxy; (ii) they are extragalactic but relatively nearby (1–10 megaparsecs (Mpc)); (iii) they are at cosmological distances (> ~ 300 Mpc). We shall call these the galactic, local and cosmological hypotheses, respectively.

When the first quasi-stellar radio sources were discovered it was assumed[1] that they were galactic, both because of their star-like appearance and because of the observed variations[2] in their optical brightness. This situation changed with the discovery[3] that the quasi-stellar radio source 3C 273 has a red shift z of 0·158. Of the fifty or so quasi-stellar radio sources now known, twenty-three have had their red shifts measured[4], and all these red shifts are larger than that of 3C 273—in many cases substantially larger. The possibility that these red shifts are gravitational in origin has almost certainly been ruled out[5], and we are left with the hypothesis that the red shifts are Doppler shifts, signifying that these quasi-stellar radio sources are receding from us with velocities comparable with the velocity of light.

If we are to retain the galactic or local models for these quasi-stellar radio sources, we must suppose that they are debris of a violent explosion which has occurred in our Galaxy or in a nearby galaxy. This possibility has been examined by Schmidt[6], Terrell[7], and Hoyle and Burbidge[8]. It now seems to be implausible in view of Koehler's[9] recent discovery that 3C 273 has a 21-cm absorption line in its spectrum, which is due to absorption by a neutral hydrogen cloud with a red shift $z \sim 3 \times 10^{-3}$, presumably associated with the Virgo cluster of galaxies. It follows that 3C 273 lies behind the Virgo cluster and so has a distance of at least 12 Mpc. Presumably, the other quasi-stellar radio sources, which have much larger red shifts, would be correspondingly more distant. It is therefore natural to adopt the cosmological hypothesis and to attribute the large red shifts of the quasi-stellar radio sources to their partaking of the expansion of the universe. The distance of 3C 273 would then be 470 Mpc (for a Hubble constant of 10^{10} years) while the quasi-stellar radio sources with larger red shifts would be at correspondingly greater distances.

Most workers in the field have, in fact, adopted the cosmological hypothesis from the time when the red shifts of the quasi-stellar radio sources were discovered. It must be recognized that this hypothesis does make it difficult to construct a model of a quasi-stellar radio source which accounts for its size, energy content, optical variations and so on. Nevertheless, along with most other workers, we believe that these difficulties can be overcome. In particular, although it has been stated[10,11] that the radio variations of 3C 273 (refs. 10, 12, 13) are not consistent with the cosmological hypothesis, it is, in fact, possible[14–16] to construct a composite model of this source which is consistent with its being 470 Mpc away. Although such a model still awaits independent observational confirmation, it is inherently a plausible one, and the cosmological hypothesis seems by far the most likely to be correct.

Despite this apparently satisfactory situation, we wish to suggest that many quasi-stellar radio sources may turn out, after all, to be inside our own Galaxy. We have in mind those quasi-stellar radio sources which have not yet had their red shifts measured. We suggest that some of them may have an essentially zero red shift, corresponding to the relatively very small velocities possessed by galactic objects. On this view the population of quasi-stellar radio sources is not homogeneous, but consists of two entirely different and unrelated components. Our reason

for introducing this possibility has to do with the relation between counts of quasi-stellar radio sources and the steady-state model of the universe. This relation is our main concern in this article, but it seems worth pointing out at this stage that the assumption of a composite population for the quasi-stellar radio sources is by no means an arbitrary and implausible complication of an essentially simple situation. We may recall the history of what Sandage[17] has called quasi-stellar galaxies. Their discovery sprang from Sandage's attempt to pick out quasi-stellar radio sources in a rapid manner by using their ultra-violet excess as a means of identification. He soon found, however, that there were many star-like objects of similar colour which were not radio sources, and which he at first called 'interlopers'. These interlopers he took to be stars which have quasi-stellar radio source-like colours. Such stars are indeed known (white dwarfs[18] and *SS* Cygni and other variable stars[19], for example). However, a study of the Haro–Luyten catalogue[20] of blue stars convinced him that most of the stars with apparent magnitude V > 16, which he found to have quasi-stellar radio source-like colours, were actually extragalactic objects—radio-quiet quasi-stellar radio sources which he called quasi-stellar galaxies. This conclusion seemed to be confirmed by Sandage's important discovery that, of the five objects the spectra of which were obtained, two were featureless and three showed large red shifts. However, this conclusion has recently been challenged by Kinman[21], who in a special investigation has found that, of a group of Haro–Luyten objects half of which should be extragalactic according to Sandage's estimates, all are in fact stars (seven white dwarfs, four horizontal branch stars and one hot sub-dwarf). Kinman estimates that only a few per cent of the faint blue stars are, in fact, galactic. A similar conclusion has been reached by Lynds and Villere[26]. If this is correct, it shows that a population of radio-quiet starlike objects with quasi-stellar radio source colours, which was once thought to be homogeneous, is in fact composite, one component being galactic and the other extragalactic. It does not seem unreasonable to make the same assumption about star-like objects with quasi-stellar radio source colours which have significant radio emission. As we have said, our reason for making this assumption has to do with the cosmological interpretation of the radio source counts, and this is the problem to which we now turn.

Radio Source Counts

If all radio sources were extragalactic, uniformly distributed, and at rest in Euclidean space, the number N of sources the flux-density of which at some given frequency exceeds S would be proportional to $S^{-3/2}$. A plot of log N versus log S would then be a straight line with slope $-3/2$. In view of the large red shifts of many radio sources, cosmological corrections are required, and both evolutionary and the steady-state models lead to a progressive flattening of the slope as S decreases. On the other hand, the observed counts[22–25,27] have a steeper slope down to about 0·5 flux units (1 flux unit = 10^{-26} W m^{-2} (c/s)$^{-1}$) (see Fig. 1).

This result has led to much discussion (for surveys, see refs. 28–30). The interpretations are of two types: (i) the steep slope is attributed to an excess of faint sources, which is given a cosmological explanation; (ii) it is assumed that there is a deficit of bright sources, arising from a local irregularity in their distribution.

Ryle and Clarke[31] have argued in favour of (i). Their cosmological explanation is based on supposing that the intrinsic properties of the sources change with the epoch in an evolving universe (distant sources being seen at an earlier epoch than nearby ones). Possible modes of evolution have been constructed by Davidson and Davies[32–33] and by Longair[34]. Now such an explanation is not available to the steady-state model, and so Ryle and Clarke concluded that this model is incompatible with the counts.

This conclusion was challenged by Hanbury-Brown[35], Hoyle and Narlikar[36,37] and Sciama[38–40], all of whom adopted (ii). One of the crucial features of such an interpretation is the required size D of the local irregularity. If all the radio sources form a single population, then their distances (as derived from the red shifts of their optical components) imply[41] that $D \sim 300$ Mpc. This would rule out the Hanbury-Brown model, which was based on the observed irregularity of the galaxies out to ~ 30 Mpc. The Hoyle–Narlikar model invoked irregularities on a scale of ~ 300 Mpc, but on the basis of a very hot intergalactic gas ($T \sim 10^9$ °K) which is now known[42,43] to be inconsistent with the cosmic X-ray background[44] arriving at Earth.

It was pointed out by Sciama[38] that the radio sources need not form a single population. At that time (early in 1963) optical identifications were complete only down to a relatively large flux density (~ 25 flux units) where the slope of the log N–log S curve does not differ sensibly from $-3/2$. He therefore postulated the existence of a second population, intrinsically much fainter than the identified population, and assumed that the irregularity occurred in this population. Only below ~ 17 flux units (where the slope definitely begins to be steeper than $-3/2$) should this second population begin to show up in the identifications. The point of this postulate, of course, is that the required scale of the irregularity would then be much smaller. Now detailed calculations show[40] that if this second population is also extragalactic the counts of Ryle and Neville[23] at low flux densities cannot be accounted for. In fact, Sciama[38] proposed that the second population lies in the Galaxy, and that the scale of irregularity ~ 20 pcs.

The relevance of this discussion to the location of the quasi-stellar radio sources is the following. There are now enough quasi-stellar radio sources identified to make it possible to begin constructing a separate log N–log S curve for radio galaxies and for quasi-stellar radio sources This has been done independently by Véron[45] and Longair[34], and both have found that the slope for radio galaxies $\sim -1{\cdot}5$ and for quasi-stellar radio sources ~ -2 (see Fig. 2). Thus the quasi-stellar radio sources are entirely responsible for the steep slope. In the flux range where this separation has so far been possible most of the radio galaxies do not have very large red shifts, and it

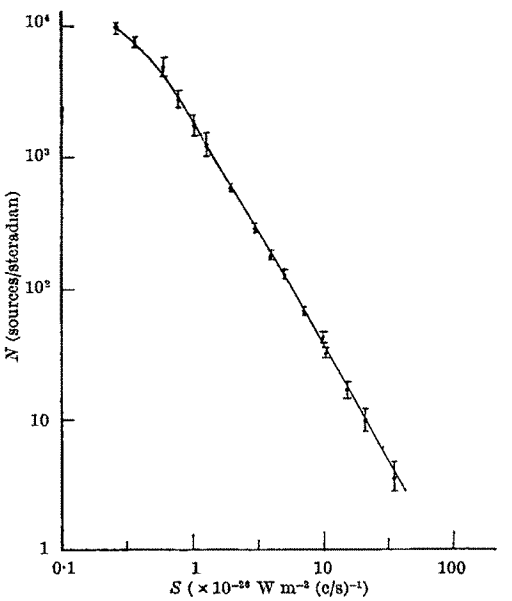

Fig. 1. The number-flux density relationship derived from Cambridge radio source surveys (refs. 22, 23, 27)

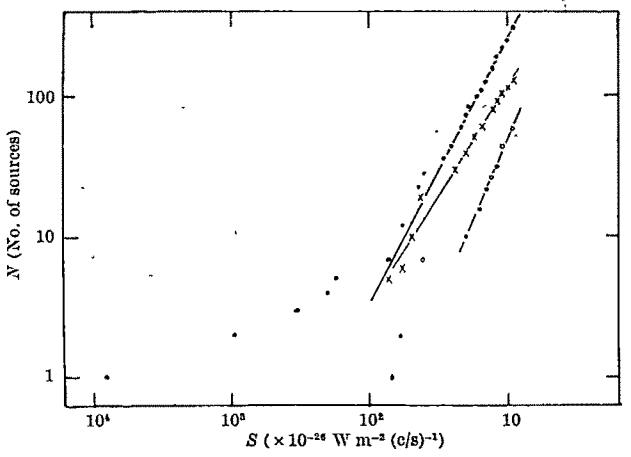

Fig. 2. The number-flux density relationships for quasi-stellar radio sources, ○; radio galaxies, ×, and all the extragalactic sources in the 3C revised catalogue. This diagram is due to Véron (ref. 45) and is based on the identifications listed by Wyndham (ref. 48). The lines have slopes of −2·20, −1·55, and −1·85 respectively

is understandable that they should conform to the three-halves power law. On the other hand, the quasi-stellar radio sources do have large red shifts and according to the evolutionary interpretation of the steep slope it is natural that they should exhibit significant evolutionary effects. Indeed, Longair[34] found that only the intrinsically brightest radio sources (among which the quasi-stellar radio sources are the dominant component) could evolve, if the log N–log S curve is to be explained in this way.

However, we can still maintain the galactic interpretation, and with it the steady-state model of the universe, if we assume that the quasi-stellar radio sources consist of two populations, one extragalactic and one galactic. We thereby make contact with the discussion in the first section of this article. It is worth noting that we could not have maintained the galactic interpretation if the class of objects having a steep slope were obviously extragalactic in optical appearance (for example, if they were radio galaxies). We therefore regard it as encouraging for this point of view that the objects which have a steep slope do have an optical appearance which is consistent with their being galactic. It thus seems worth while to pursue the possibility that many of the quasi-stellar radio sources fainter than ~ 17 flux units are in the Galaxy.

Required Properties of the Galactic Quasi-stellar Radio Sources

It was shown in refs. 38–40 that the radio data serve to fix many of the properties of the required galactic population of radio sources. We now know that these properties must refer to the galactic quasi-stellar radio sources. It seems appropriate to re-discuss this question since some relevant data have recently become available. These new data are as follows: (*a*) the 4C survey for a particular region of the sky[27]; (*b*) an improved luminosity function[46] for the extragalactic sources, made possible by an increase in the number of optical identifications, red shifts and so distances; (*c*) further data on the spectra of sources[47] and of the galactic background[49].

Our procedure is as follows: at high flux-levels ($S > 20$ flux units) nearly all the sources in the 3C catalogue have been identified with radio galaxies or with quasi-stellar radio sources of known red shift. Thus, we are here observing the extragalactic population, undiluted by the galactic sources (which are missing because of the local irregularity in their distribution). We can then calculate the expected number N_e' of extragalactic sources at lower flux-levels by using the red shift correction appropriate to the steady-state model. This red shift correction was computed on the basis of the new luminosity function derived by Longair and Scott[46].

The number N_g of galactic sources was then determined by assuming that at 2 flux units we are looking well beyond the local deficit, and that the total number of missing sources is comparable with the statistical error in the observed counts at this flux-level. It is then sufficiently accurate to take for N_g the difference $N–N_e'$ between the observed counts and the computed extragalactic contribution. We thus find $N_g = 0{\cdot}95\ (\pm\ 0{\cdot}05)\ N_g$, where N_g is the number of extragalactic sources uncorrected for red shift. A similar relation was, in fact, found previously[40], and the new log N–log S relation and the new luminosity functions do not change the analysis appreciably.

The details of the local deficit can now be determined from a comparison between the observed and computed counts, and we find that the galactic population begins to be noticeable at ~ 17 flux units and that beyond ~ 10 flux units there are no more missing sources, the total deficit being ~ 25 sources/steradian (Fig. 3). The model is thus completely determined by the counts down to 10 flux units, together with one count at a lower flux-level, which we have taken as 2 flux units. All the remaining counts between 10 and 0·25 flux units (the lower level of the Ryle–Neville survey) then serve as a test of the model. It will be seen from Fig. 3 that the model survives this test. In particular, the count at 0·25 flux units is correctly reproduced within the uncertainties. Furthermore, calculations with the new luminosity function show that the model is consistent with the identifications down to this flux-level which have been made by Shakeshaft and Longair[50]. This is of interest because Longair had some difficulty in fitting this point with an evolutionary model, despite the large number of adjustable parameters available in that case. Indeed, he had to introduce a very sharp cut-off in the number of sources with red shift $z > \sim 4$. As he suggested, such a cut-off may be associated with the original formation of radio sources, but the position of this cut-off

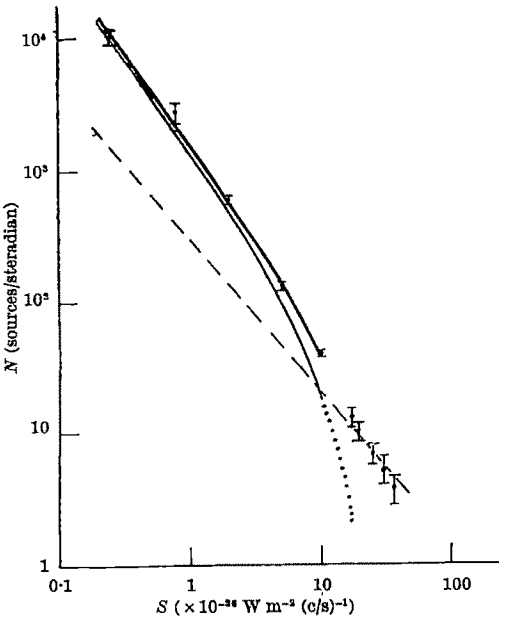

Fig 3 Comparison between predicted and observed radio source counts. – – – – –, Computed counts of extragalactic sources expected on the steady-state model. The curve is normalized to agree with the observed counts above 17 flux units. ●●●●●●, Counts of galactic sources in local irregularity derived from observed counts. ————, Expected counts of galactic sources beyond local irregularity (normalized to agree with observed counts at 2 flux units). ————, Predicted total counts of galactic and extragalactic sources. I, Observed counts of sources

cannot be predicted *a priori*. The present model thus faces a more severe test. In this connexion it is interesting to calculate the expected number counts at a lower flux-level of, say, 0·1 flux units, since the observations should soon penetrate into this region. We find that, according to our composite model, there should be ~ 44,000 sources per steradian brighter than 0·1 flux units (unless the edge of the distribution has been reached, in which case anisotropy should be observed (see below)). By contrast, if we did adopt the model considered earlier, in which the second population is also extragalactic, we should expect only ~ 19,000 sources per steradian brighter than 0·1 flux units. Evolutionary models would also predict far fewer than 44,000 sources.

Since the composite model with galactic sources reproduces the observed counts, it seems worth exploring further the properties of the galactic quasi-stellar radio sources. If P_0 is their median intrinsic radio luminosity and $\rho(P_0)$ the corresponding concentration, then our determination of N_g tells us $\rho(P_0)\ P_0^{3/2}$ up to a factor of order unity depending on the luminosity distribution. We would now like to obtain $\rho(P_0)$ and P_0 separately. This was done in the original discussion of the model in the following way. As was emphasized by Ryle[51] and Ryle and Clarke[21], the parameters of the galactic model are subject to two constraints: (1) the integrated emission of the galactic sources must not exceed the minimum observed galactic background; (2) the galactic sources must not show anisotropy down to about ~ 0·1 flux units, since the radio observations indicate no such anisotropy (statistical arguments are used[52] for flux-levels where individual sources cannot be resolved).

These two constraints act in opposite directions, and Ryle, and Ryle and Clarke, believed that they were inconsistent with one another, so that the galactic model could be ruled out. To see that they act oppositely we proceed as follows. Let r be the effective scale-length of the distribution of galactic sources in the direction of the minimum sky brightness B. Then, if we neglect for the moment the spread in intrinsic radio luminosity, we have:

$$\rho P_0 r \leq B$$

But we also know $\rho P_0^{3/2}$, which is X, say. Therefore:

$$\frac{P_0}{r^2} \geq \frac{X^2}{B^2}$$

Thus we cannot make P_0 as small as we would like to eliminate the anisotropy problem (by arguing that we are observing only the immediate vicinity of the Sun). In fact, at a flux-level less than X^2/B^2 we would be beginning to observe sources beyond the effective distance r, and so this is the critical level at which appreciable anisotropy should set in. The situation is worse if we allow for a spread in intrinsic radio luminosity. If an appreciable fraction of the sources have an intrinsic luminosity ten times the median, which seems plausible, then the critical flux-level will be $10\ X^2/B^2$. We shall adopt this value, while recognizing that it is somewhat arbitrary. Then, in view of (2), we must have:

$$\frac{10\ X^2}{B^2} \leq \sim 0{\cdot}1 \text{ flux units.}$$

Is this inequality satisfied? The value of X has already been determined from the counts. What can we say about the background brightness B? According to Turtle and Baldwin[53] the minimum background temperature at 178 Mc/s (the frequency of the Cambridge radio source counts) is 80° K. Of this, about 23° K has been attributed[54] to the extragalactic background. If we attribute the remaining 57° K to B we find that:

$$\frac{10\ X^2}{B^2} \sim 0{\cdot}1 \text{ flux units.}$$

Thus a solution is just possible if: (*a*) the source counts are anisotropic below ~0·1 flux units; (*b*) most of the galactic background in the direction of the minimum is due to the integrated effect of the sources rather than synchrotron radiation emitted by relativistic electrons moving in an interstellar magnetic field.

Conclusion (*a*) will be tested by future source counts, but (*b*) deserves a little discussion. It was argued by Scott[55] that the background has a different spectrum from the sources, so that (*b*) cannot be correct. However, estimates of the background spectrum have changed since Scott wrote his paper, and while there is not yet complete agreement about the correct spectrum, some workers[49] claim that it is straight from about 18 Mc/s to beyond 404 Mc/s, with a slope ~ 0·65 ± 0·15. On the other hand, most of the sources also have[47] a straight spectrum with a median spectral index ~ 0·7. In any event, exact agreement need not necessarily be expected since intrinsically faint sources contribute more to the integrated emission (through $\Sigma\rho P$) than they do to the sample used for determining spectra (which is selected on the basis of flux density and therefore of $\Sigma\rho P^{3/2}$). Thus, if the faint sources have atypical spectra, this will be reflected in the spectrum of the background.

Another unsettled question is the relative intensities of the halo and disk components of the galactic background. Some observers[56,57] now maintain that the halo is relatively unimportant, while others[58,59] deny this. We have chosen to accept provisionally Baldwin's result[58] that the halo is unimportant and that the disk component has a thickness at the Sun of about 400 pcs on each side of the galactic plane. Because of (*b*) this means that we should take ~ 400 pcs for r. This determines the scale of the distribution of galactic quasi-stellar radio souces and enables us to determine ρ and P_0 separately. We find[38-40]:

$$\rho \sim 10^{-2}\ pc^{-3}$$

$$P_0 \sim 3 \times 10^{10}\ \text{W (c/s)}^{-1}\ \text{ster}^{-1},$$

values closely similar to those adopted[60] in the original radio source hypothesis for the galactic background. Thus, according to this analysis, and allowing for the local deficit, the nearest galactic quasi-stellar radio sources are within 20 pcs of the Sun. Accordingly, their absolute optical magnitude must be very faint, and a possible astrophysical mechanism consistent with this has been proposed[39]. More to the point, they are close enough to have appreciable proper motions. We therefore predict that some of the known quasi-stellar radio sources the red shifts of which have not yet been determined should have detectable proper motions.

An alternative test of the model would be to find some essentially zero red shifts among these quasi-stellar radio sources, but the possibility exists that the spectra of the galactic quasi-stellar radio sources may show no lines. Spectra of this type are indeed found among the quasi-stellar radio sources[5,6] and the interlopers[17]. (In this connexion it is worth noting that some white dwarfs (which have quasi-stellar radio source colours) also have no lines in their spectra (type *DC*)[61].) Unless we are altogether wrong about the value of r (and the distance of the nearest galactic quasi-stellar radio source is proportional to r), it appears that the composite model stands or falls by the presence or absence of detectable proper motions among the known quasi-stellar radio source. Moreover, if the model falls, it looks as though the steady-state theory of the universe falls with it.

We thank Dr. P. A. G. Scheuer for helpful discussions. We also thank Mr. M. S. Longair, whose analysis of the new radio data stimulated us to re-examine the composite model and whose advice greatly simplified our task.

STRUCTURAL ABNORMALITIES OF THE *Y* CHROMOSOME IN MAN

By PATRICIA A. JACOBS and ALAN ROSS

Medical Research Council, Clinical Effects of Radiation Research Unit,
Western General Hospital, Crewe Road, Edinburgh, 4

DURING the past 5 years we and our colleagues have examined the chromosomes of several thousand individuals. Four have been found with an abnormality which we consider to be a structural abnormality of the *Y* chromosome and in whom there is no evidence of mosaicism. While the findings in two of these have been briefly reported elsewhere, the purpose of this article is to describe the findings in all four individuals and to discuss the implications of these in relation to the male determining role of the *Y* chromosome in man.

Case 1 is a 34-year-old phenotypic female, 155 cm tall, who has never menstruated. Her secondary sexual characteristics have not developed beyond the infantile stage. Abdominal surgery showed her uterus to be underdeveloped and that instead of ovaries there were 'streaks' of gonadal tissue in the infundibulo-pelvic ligaments comparable with those described in females with an *XO* sex chromosome complement. Microscopic investigation of these showed the absence of ovarian elements. The only other noteworthy clinical feature was the presence of a short neck with some slight suggestion of webbing.

Buccal cells were chromatin negative and both cultured lymphocytes and fibroblasts showed the chromosome number to be forty-six. There were only fifteen medium-sized sub-metacentric chromosomes and no normal *Y* chromosome. However, there was a structurally abnormal chromosome which appeared exactly metacentric with the distal parts of both arms showing a characteristically *Y*-like appearance (Fig. 1). Investigations of cells collected from a lymphocytic culture 4 h after the addition of tritium-labelled thymidine showed no evidence of any chromosome synthesizing DNA as late in the *S*-period as is characteristic of a second *X* chromosome. However, it is known that the *Y* chromosome is one of the last of the small chromosomes to complete DNA synthesis, and the labelling pattern of the abnormal chromosome was consistent with its being composed of *Y* chromosome material[1]. Furthermore, in several cells in which the abnormal

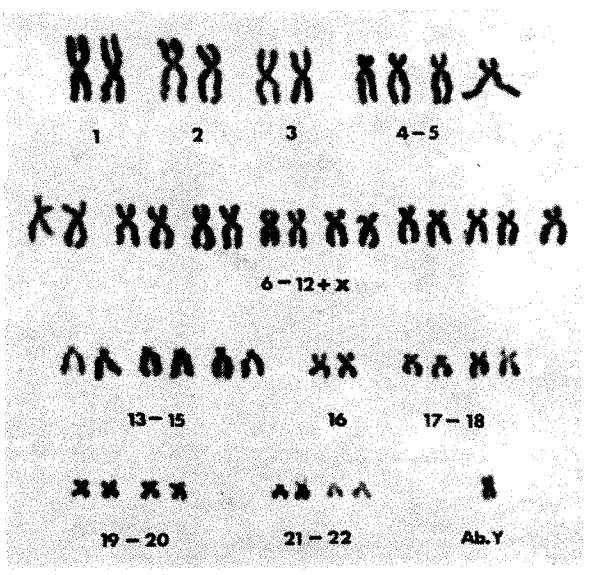

Fig. 1. Karyotype of cultured lymphocyte from Case 1

chromosome was labelled the labelling pattern appeared to be the same on both arms.

Studies of the chromosomes of the two surviving brothers of the patient showed each to have a normal *Y* chromosome.

After considering the clinical findings together with all the cytogenetic evidence, it was concluded that the abnormal chromosome was most reasonably interpreted as an isochromosome for the long arm of the *Y*.

Full details of this case have been published elsewhere[2].

Case 2 is a 62-year-old phenotypic female, 163 cm tall, who has never menstruated. Her secondary sexual characteristics have not developed beyond the infantile stage, and the condition of her gonads and internal genitalia is unknown. Apart from a rather deep voice the patient shows no evidence of masculinization and the only other noteworthy clinical feature is bilateral choroidoretinitis.

Buccal cells were chromatin negative and both cultured lymphocytes and fibroblasts showed the same karyotype as in Case 1. The pattern of DNA synthesis, as shown by the use of tritium-labelled thymidine, again showed no chromosome synthesizing very late in the *S*-period. However, the pattern of replication of the abnormal chromosome was again consistent with its being an abnormal *Y* chromosome, and the labelling pattern appeared to be the same on both arms (Fig. 2).

Studies of the chromosomes of the male relatives of Case 2 have not yet been possible.

After considering all the evidence it was concluded that the abnormal chromosome was most reasonably interpreted as an isochromosome for the long arm of the *Y*.

Case 3 was an 83-year-old man, 152 cm tall. He had a left-sided hare lip which had been repaired, but otherwise he was clinically unremarkable. His external genitalia and testes were normal for his age. He had been married, but his wife died after 9 years of marriage and they had no children. The patient died in his eighty-third year from generalized arteriosclerosis.

Buccal cells were chromatin negative and both cultured lymphocytes and fibroblasts showed a chromosome number of forty-six with no evidence of mosaicism. None of the cells showed a normal *Y* chromosome, but there was an additional chromosome closely resembling the autosomes of pairs 19–20 (Fig. 3). In a few cells it could be differentiated from autosomes 19–20 by the rather *Y*-like appearance of the chromatin material. Autoradiography was not carried out on the cells from this patient and it has not been possible to study the chromosomes of any of his male relatives.

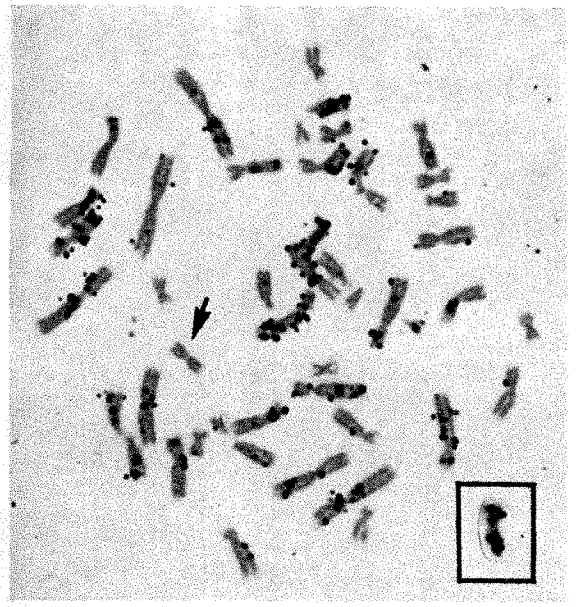

Fig. 2. Metaphase plate of cell from Case 2 after continuous labelling with tritium-labelled thymidine for 4 h before collecting, showing absence of labelling on the abnormal *Y* chromosome. Inset shows the abnormal chromosome from a cell labelled further back in the *S*-period showing symmetrical labelling

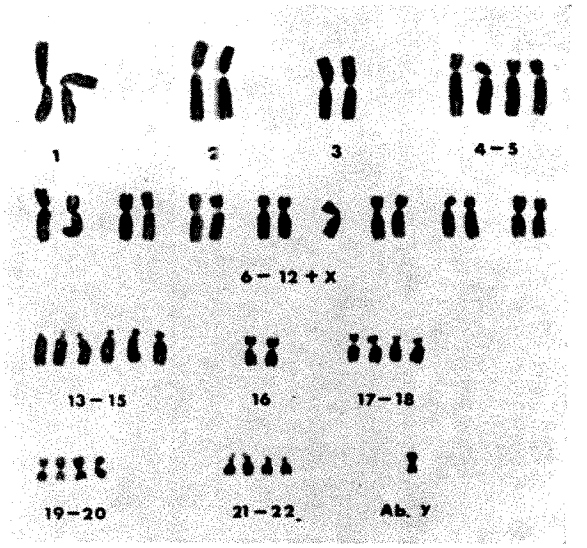

Fig. 3. Karyotype of cultured lymphocyte from Case 3

After considering the clinical and cytological evidence it was concluded that the abnormal chromosome was most reasonably interpreted as a *Y* chromosome in which there had been a pericentric inversion.

Full details of this case have been published elsewhere[3].

Case 4 is a 41-year-old man, 180 cm tall, with atrophic testes and some of the other features of Klinefelter's syndrome.

Buccal cells were chromatin positive and 'drumsticks' were present on his polymorphonuclear leucocytes. Both cultured lymphocytes and fibroblasts showed a chromosome number of 47. There was a normal female complement of chromosomes present but no normal *Y* chromosome. However, there was an additional chromosome resembling the autosomes of pairs 19–20, the chromatin of which often appeared characteristic of that of the *Y* chromosome. Investigations of cells collected 4 h after the addition of tritium-labelled thymidine showed that in 60 per cent of the labelled cells there was a very late synthesizing medium-sized submetacentric chromosome, presumed to be an *X* (Fig. 4). However, the abnormal small metacentric chromosome did not synthesize DNA very late in the *S*-period, but its labelling pattern was consistent with its being an abnormal *Y* chromosome.

The patient is illegitimate and has no known male relatives.

After consideration of the clinical and cytological findings it was concluded that the patient, in addition to having two *X* chromosomes, also has an abnormal *Y* chromosome, and that the additional small metacentric chromosome is a *Y* chromosome in which a pericentric inversion has occurred.

The *Y* chromosome of man is known to be strongly male determining. Thus individuals with an *XO* sex chromosome constitution are phenotypic females. The masculinizing effect of the *Y* chromosome can even overcome the female determining genes on as many as four *X*-chromosomes, as evidenced by the fact that individuals with an *XXXXY* sex chromosome constitution, while having a number of congenital abnormalities, are still undoubted phenotypic males. Furthermore, it is well known that the size of the *Y* chromosome in man can vary considerably in length from one person to another without any apparent phenotypic effect and that this

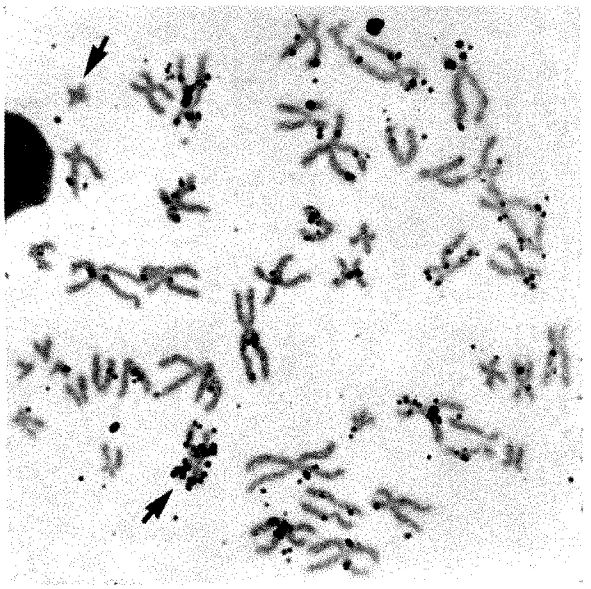

Fig. 4. Metaphase plate of cell from Case 4 after continuous labelling with tritium-labelled thymidine for 4 h before collecting, showing the late labelling *X* chromosome and the absence of labelling on the abnormal chromosome

polymorphism of the *Y* chromosome is an inherited characteristic. The *Y* chromosome usually approximates in size to the autosomes of pairs 21–22, but it may be as small as only half the size of these or it may be as large as the autosomes of group 13–15. These variations in size are due to differences in length of the long arm, the distal part of which often appears rather diffuse and stains faintly, thus suggesting that it is largely heterochromatic. The apparent differences in length of the *Y* chromosome may in some cases be due to genetically controlled variations in coiling of the distal part of the long arm and in others to actual variations in the amount of chromatic material.

With the exception of the variation in length of the *Y* chromosome in normal males, and the presence of a minute chromosome or a small-ring chromosome, which might be formed from the centromeric region of either the *X* or the *Y* chromosome, in one cell line of a number of individuals who have the clinical features of Turner's syndrome, there have been very few non-mosaic individuals described with a structurally abnormal *Y* chromosome. The four individuals described in this report, together with the father of an abnormal son described by Solomon and her colleagues[4], are the only instances known to us. The cytogenetic observations and the phenotypic appearance of these cases have to be considered in the light of the strongly male-determining effect of the normal *Y* chromosome in man and the fact that apparent variations in the length of its long arm are without obvious phenotypic effects.

In order to explain our observations and those of Solomon *et al.*, we would suggest: first, that the male-determining gene or genes in man are situated on the short arm of the *Y* chromosome; secondly, that the genes present on the long arm of the *Y* chromosome are not primarily concerned with the determination of sexual characteristics; and, thirdly, that an individual with a pericentric inversion of the *Y* chromosome is a normal fertile male, but that he may be liable, as a consequence of his abnormal *Y* chromosome, to produce a proportion of chromosomally abnormal sperm which would be expected to result in *XO* daughters and *XXY* sons.

If the abnormal chromosome described in Cases 1 and 2 is an isochromosome for the long arm of the *Y*, these individuals, while they have a double dose of all the genes on the long arm of the *Y*, are lacking the male-determining genes on the short arm. Presumably the latter act by causing the primordial gonads to develop into testes. In the absence of either male- or female-determining factors neither the cortex nor the medulla of the primordial gonad develops and the resulting individual is a phenotypic female who, having no functioning gonadal tissue, fails to develop secondary sex characteristics.

It is of considerable interest to compare females with an isochromosome for the long arm of the *Y* with individuals with an *XO* chromosome constitution, who are also 'genetically neuter'. It would seem reasonable to suggest that any differences between the two groups are due to genes on the long arm of the *Y* chromosome. Individuals with an *XO* sex chromosome constitution are invariably short in stature and often have a number of additional abnormalities such as co-arctation of the aorta, neck-webbing, pigmented naevi and a low hair line. Cases 1 and 2 are both of normal stature and, while Case 1 had a rather short neck with a slight suggestion of neck-webbing, there were no other stigmata associated with an *XO* sex chromosome constitution present in either of them. It would appear, therefore, that the presence of the material of the long arm of the *Y* chromosome prevented the development of dwarfing and many of the other stigmata associated with an *XO* constitution. Furthermore, with the exception of the deep voice of patient 2 there was no evidence of masculinization in either patient.

While Cases 3 and 4 also had a structurally abnormal metacentric *Y* chromosome, this was interpreted as being due to a pericentric inversion. Thus the short-arm material of the *Y* chromosome is still present and the chromosome is functioning as a normal *Y* chromosome. It is unfortunate that in neither case was it possible to examine the chromosomes of a male relative. However, Solomon *et al.* have described a similar abnormal *Y* chromosome in one cell line of a male with Klinefelter's syndrome, the other cell line having no *Y* chromosome. They found the same abnormal *Y* chromosome in his father, a normal fertile male, and while these authors state that "the exact nature of this abnormal *Y* chromosome is not clear" its appearance is very similar to that seen in Cases 3 and 4, and it is reasonable to postulate that it has also arisen by a pericentric inversion.

This interpretation also offers an explanation for the fact that two of the four individuals described with a pericentric inversion of the *Y* chromosome also have an extra *X* chromosome and show the clinical features of Klinefelter's syndrome. The *X* and *Y* chromosome have an end-to-end association in meiosis which appears to be between the short arm of the *X* and the short arm of the *Y* (McIlree—personal communication). A pericentric inversion would presumably interfere with this association and lead to a failure of pairing of the sex chromosomes in the first meiotic division, which would result in a proportion of the sperm having no sex chromosomes and a proportion having both an *X* chromosome and the abnormal *Y*. If these sperm fertilize a normal ova the result will be *XO* females and *XXY* males. This being the case, it is not surprising that two of the males with a pericentric inversion of the *Y* chromosome also have an additional *X* chromosome.

We thank Mrs. J. Bond, Dr. M. J. W. Faed and Dr. D. G. Harnden for the results of chromosome studies on the fibroblasts. We are also grateful to the following colleagues, Dr. T. N. McGregor, Mr. W. Selby Tulloch, Dr. I. S. Stokoe and Dr. J. A. Strong, who referred the patients to us, and to Mrs. Janet Barclay, Miss Muriel Brunton, Miss Gillian Woodcock and Mr. Duncan Davidson for their technical help.

OBITUARIES

John Anthony Newth

JOHN ANTHONY NEWTH was born on January 17, 1924, and died on November 18, 1965. He was educated at King Edward's School, Birmingham, and Trinity College, Cambridge. After graduation in 1943, he joined the staff of the Department of Physics, University College, Exeter, as an assistant in charge of the training of Signal Corps cadets, later becoming an assistant lecturer. In 1947, he was appointed assistant lecturer in the Department of Physics at Manchester and started research work on the newly discovered V-particles under the direction of J. G. Wilson and P. M. S. Blackett. During the following three years he and his students designed and built a large expansion cloud-chamber and magnet for operation at the Jungfraujoch station in Switzerland.

For the next eight years Newth led an active and successful team, working with this apparatus at the mountain station. During this period were produced a number of important papers on the properties of the strange particles. The large cloud-chamber turned out to be particularly suitable for measuring the lifetimes of particles and the group made a notable contribution in this field. It is common experience that a small group working in the isolated conditions of a mountain laboratory at this altitude is subject to considerable stress of both a physical and an emotional kind. The very high efficiency achieved and the cordial relations that existed between the members of this group throughout the period are a splendid tribute to Newth's leadership, understanding and sense of humour —qualities immediately apparent to anyone spending a few hours in his company. During the final three years of this period he was attached to CERN, where he made many friends and contributed notably to the atmosphere of that laboratory during its crucial formative years.

Newth was appointed senior lecturer at Imperial College in 1958 and reader in 1964. During his first few years at Imperial College, he was engaged in leading a research team using image intensifiers for various nuclear physics applications. His group became one of the world's leading teams in this field, and three major uses for image tubes in high-energy physics were developed. These were the photography of Cerenkov rings produced by single particles, the photography of tracks of particles in scintillating materials, and the use of image tubes to investigate the beam profiles of secondary particle beams at high energy accelerators.

By 1961 it was clear that a new and powerful experimental technique (the spark chamber) was rapidly changing the possibilities for counter experiments, and Newth and his team designed an experiment on the branching ratio of the decay modes $e^+ + e^-$ of the ω^0 meson. This experiment was carried out at the 7-GeV proton accelerator (*Nimrod*) at the Rutherford High Energy Laboratory during the winter of 1964. Anthony Newth's bold leadership and inspiration contributed greatly to the success of this difficult experiment, which exploited spark chamber and counter techniques to the full. At the time of his death he was very actively involved in planning a related experiment to measure the $\varphi^0 \rightarrow e^+ + e^-$ branching ratio.

P. ASTBURY

NEWS AND VIEWS

Nuclear Physics in the University of Lancaster : Prof. A. B. Clegg

DR. A. B. CLEGG, who will shortly take up his position as professor of nuclear physics at the University of Lancaster, was born in 1929 and was educated in Birkenhead (1939–47). He read physics at King's College, Cambridge (1949–55), and after gaining first-class honours in Part II of the Natural Sciences Tripos began research in the Cavendish Laboratory on nuclear structure problems. His interests were in the structure of the light nuclei and he participated in a number of early experiments to test the validity of the isotopic spin quantum number which had recently come into prominence. He left the Cavendish Laboratory in 1955 and went to the new synchrotron laboratory of the California Institute of Technology. There he worked originally on the radio frequency system of the synchrotron and later on elementary particle experiments. He came back to Britain in 1958 as a senior research officer in the Clarendon Laboratory, Oxford, and later in the new Nuclear Physics Laboratory there. His intentions from the beginning were ultimately to work on elementary particle problems on the Rutherford Laboratory's 7-GeV proton synchrotron *Nimrod*, then under construction. He chose as entry to this field, however, a reversion to his earlier study of nuclear structure using the 170-MeV synchrocyclotron at the Atomic Energy Research Establishment, Harwell. With this machine he pioneered much of the study of nuclear structure using intermediate energies and rapidly gained an international position in this new field. Despite his very considerable success with the intermediate energy work, he stuck to his original intention and transferred his efforts, in February 1964, to high-energy work when *Nimrod* became operational. His work on *Nimrod* has used spark chambers and has been concerned with the interactions and decay of pions and kaons. In going up to Lancaster, his research activity will transfer to the 4-GeV electron synchrotron *Nina* at the Daresbury Laboratory of the Science Research Council and his interest in elementary particle physics will continue.

Genetics in University College, Swansea : Prof. J. A. Beardmore

PROF. JOHN A. BEARDMORE has been appointed to the newly established chair of genetics in University College, Swansea. Prof. Beardmore was a student of the University of Sheffield, where he took his B.Sc. with special honours in botany and where he received his Ph.D. degree in genetics under Prof. J. M. Thoday in 1953. Beardmore's scientific work has been mainly in the field of population genetics, and he has published a number of experimental studies on *Drosophila*. Some of his later work was done at the laboratory of Prof. Dobzhansky, whose teachings in population genetics and evolution have greatly influenced a whole generation of geneticists. He spent two years at Columbia University, with an interruption of five months for an assignment as visiting professor at Cornell University. He was then appointed lecturer at the Universities of Sheffield and Leicester, and afterwards moved briefly to the University of Rochester, New York, as a visiting research associate. In 1961, he was appointed to the chair of genetics at the University of Groningen, where he succeeded Prof. Sirks. The task he took on himself was far from easy. He had to introduce new fields of research

in an old Institute not too well equipped for the purpose, and he was confronted with a foreign tongue. Without a trace of hesitation, he solved all problems speedily and elegantly, while at the same time he was, from the beginning, actively concerned with various aspects of genetics in The Netherlands, including the editing of the journal *Genetica*. He and his family were on the way to becoming true Dutchmen, except perhaps for the inborn necessity of a sabbatical retreat. The irresistible call to Swansea clearly came at the right time, although it is not a propitious one to genetics in The Netherlands, and the move is a disappointment to Dutch colleagues.

More German Research Funds

GOVERNMENT expenditure on scientific research is to be increased in 1966 by about 30 per cent compared with 1965. The budget of the Ministry for Scientific Research, now published, shows that the expenditure planned for 1966 is the equivalent of £116 million. This sum is, of course, separate from that spent on scientific research and development by other agencies of the West German Government. In 1965 it is estimated that a total of about 2 per cent of the West German gross national product was spent on scientific research and development, which implies an expenditure equivalent to £800 million a year.

On the funds available at the Ministry for Scientific Research during 1966, £32 million will be spent on the expansion of universities and other establishments of higher education, £44 million for the support of nuclear energy for peaceful purposes, and a total of more than £22 million on space research, including the development and construction of a German Earth satellite.

Grants for Industrial Scientists

THE Science Research Council in the United Kingdom has announced two schemes clearly intended to make it easier for industrial scientists to obtain further training and postgraduate qualifications. Thus the Council has announced a new scheme of industrial studentships for which young scientists working in industry are eligible. These awards will be available either for 6- or 12-month courses for advanced training, or for longer periods of up to 3 years for training in research normally leading to a higher degree. The scheme will start in October 1966 and it is thought that at least a hundred awards will be made. To obtain an award an industrial scientist must have been employed professionally for at least a year, and must also be academically suitable in the eyes of the Science Research Council and the intending university or college of advanced technology. The most welcome innovation in the new scheme may be that the Science Research Council has decided that industrial employers (if they wish) can supplement the amount of an industrial studentship so as to increase the student's income to that which he would have received at his job.

The second scheme devised by the Science Research Council is intended to encourage young graduates in science and technology to gain industrial experience before embarking on postgraduate training. The intention is that suitable young graduates should be given a guarantee of support from the Science Research Council for a course of postgraduate study to begin at any time from 1 to 5 years after graduation. The Council hopes this arrangement will enable young graduates to start an industrial career and to undertake further academic training at what they and their employers consider the most suitable time. Here, again, the Science Research Council hopes that employers will give their moral and financial blessing to further education.

Obviously the success of both ventures will be determined partly by the willingness of industrial companies to respond and partly by the willingness of young graduates, together with universities and colleges of advanced technology, to acknowledge that a ready exchange of people between academic life and industry can be advantageous. Thus even if the schemes should not—as the Science Research Council hopes—enhance the academic background of industrial scientists, they will provide a searching test of the honesty of recent protestations of goodwill towards industry by academic institutions.

Institute of Geological Sciences

A NEW organization called the Institute of Geological Sciences has been formed in Britain by the National Environment Research Council. The Institute is really an amalgam of the Geological Survey in Great Britain, the Museum of Practical Geology and the Overseas Geological Surveys. These organizations have worked closely together ever since the formation of the National Environment Council which followed the recommendation of the Brundrett Committee in uniting the home and overseas geological surveys in June 1965. The National Environment Research Council hopes that the title of the geological institute will emphasize the breadth and the range of scientific disciplines used in modern geological survey and research. It is intended to extend the field of activity of the existing organizations under the guidance of the Geology and Geophysics Committee of the Council, and steps are also being taken to see how best the headquarters of the new organization (but not the Museum) can be moved out of London.

Strontium-90 Levels in Australia, 1961–63

THE Atomic Weapons Tests Safety Committee in Australia has published the results of a survey of the amount of strontium-90 in the Australian environment during 1961–63 (*Austral. J. Sci.*, 28, No. 2; 1965). Strontium-90 fall-out over Australia during the period under review arose from nuclear weapons tests carried out in the Northern Hemisphere before 1959, and from the U.S.S.R. and United States test series of 1961–62, the total and fission yields of which were greater than those from all previous tests. Until the middle of 1962, there was no significant fall-out over Australia from tests later than 1958. During the remainder of the period under review, increasing levels of fall-out were recorded; they have been attributed mainly to the United States programme in the North Pacific Ocean during 1962, but towards the end of 1963 strontium-90 from tests by the U.S.S.R. may have been making a significant contribution. It is expected that all fall-out over Australia from nuclear weapons tests held during 1961–62 will eventually be comparable with that from all previous testing. The mean annual deposition of strontium-90 in precipitation at the chosen monitoring sites in Australia remained in the region of 1 mc./km² from 1958 to 1962 but rose to about 1·5 mc./km² in 1963. Regular differences in the annual strontium-90 fall-out between the sites are now well established: during the period of constant fall-out (1958–62), Townsville was lowest at 0·4 mc./km² per annum and Sydney highest at 1·3 mc./km² per annum, with the other stations in between in the ascending order, Darwin, Perth, Hobart, Adelaide, Melbourne and Brisbane. These levels are comparable with those for the period before 1960, as assessed by the National Radiation Advisory Committee. Levels of strontium-90 in Australian human bone are lower than those in the populations of the United Kingdom and the United States. However, it is of interest that the ratio of strontium-90 to calcium in bone tissue or in total diet, relative to the level of strontium-90 in precipitation, is higher in Australia than in the United Kingdom or the United States. Although fall-out levels continue to be much lower in Australia than in the United Kingdom and the United States, examination of substantial bodies of data indicates that the transfer of strontium-90 from fall-out through the food-chain to diet may be approximately twice as efficient in the Australian environment as in the United

Kingdom and the United States. This anomaly may occur in all foodstuffs, but it has been noted mainly in milk, where it has been attributed to marked differences in dairying practices.

No Mutations in Kerala

A SEARCH for possible genetic consequences of the comparatively intense background radioactivity in Kerala, South India, has yielded a negative result. The study and its results are described in a report now published in Britain by the Medical Research Council (*A Search for Genetic Effects of High Natural Radio-activity in South India*. H.M.S.O. 11*s*.). Within the limits of its statistical significance, the study bears on the suggestion, first given prominence in the late 'fifties, that the genetic consequences of small but chronic doses of radiation should be most apparent in populations of living things in exceptionally radioactive environments. A report of the committee on radiation appointed by the World Health Organization, and which reported in 1959, was one of several to urge that such exceptional populations should be studied with great care. Kerala commends itself as a site for such an investigation because of its monazite sand, rich in thorium.

The study has been carried out by a team under Prof. H. Gruneberg, honorary director of the Experimental Genetics Research Unit of the Medical Research Council at University College, London. The report explains that the study was concerned with wild populations of the black rat *Rattus rattus* L., because this animal is the only mammal other than man to occur in large numbers in the region. Wild rats were trapped at eight villages on the narrow coastal strip of monazite sand, and at eight nearby villages away from the strip. A total of 438 rats were trapped at the monazite villages, and 458 at those used as controls. The numbers of males and females were insignificantly different. Measurements were made of anatomical quantities such as the sizes of the crowns of molar teeth, which are substantially independent of age, and of other skeletal dimensions for which it was necessary to make a correction for age. Skeletons were also scrutinized for certain more or less well-defined variations of shape, while attempts were made to estimate fertility and pre-natal mortality from the incidence of pregnancy in female rats, and from characteristics of the unborn litters.

The intensity of the gamma-radiation on the coastal strip, equivalent to 1·6 r. a year, was seven and a half times that in the control areas inland. Measurements revealed that both populations of rats are heterogeneous, but that there are no systematic differences between the two groups that would suggest either systematic genetic differences or a larger genetic variance in the more heavily irradiated group. The authors of the report point to four hypotheses consistent with their results—the existence of a 'threshold' of radiation doses below which genetic damage does not occur; the possibility that genetic mutations due to radiation might be almost exactly balanced by natural selection; the possibility that an increase of genetic variance due to radiation might be almost exactly counterbalanced by a reduction in environmental variance; and the possibility that accidents of sampling may obscure a real effect. An extremely tentative calculation suggests that a difference of 0·3 per cent in the means of measurement from the two groups might be concealed by sampling errors. The authors echo a statement in an introductory note by the Medical Research Council to the effect that there is nothing in this apparently negative study conclusively to suggest that low doses of radiation have no genetic effects. Because of the way in which genetic effects may be masked by effects due to the environments or natural selection, however, the authors offer little hope that further studies of this kind will yield decisive results.

Aflatoxin in Malaysia

RESEARCH in progress at several institutions in Kuala Lumpur has shown that aflatoxin is present in various groundnut products on sale in Malaysia. In view of the social implications and the need for an interdisciplinary approach to them, the Malaysian Scientific Association has set up a committee with the following terms of reference: "To encourage investigation of aflatoxins in Malaysia and to collect and disseminate information on this problem. To formulate recommendations for the reduction of hazards arising from aflatoxins in this country".

Problems of Food Aid

A STUDY of some of the problems encountered in the organization of food aid to developing countries has been made by D. A. FitzGerald of the Brookings Institution, Washington, D.C. The study is published in a report, *Operational and Administrative Problems of Food Aid*, the fourth in a series of World Food Program Studies by the Food and Agriculture Organization of the United Nations (Pp. viii+63. Rome: Food and Agriculture Organization of the United Nations; London: H.M.S.O., 1965. 5*s*.; 1 dollar). The study covered the background to food aid from its beginning with the passing of an amendment to the United States Mutual Security Act in 1953, to the establishment of the World Food Programme in 1961 by the United Nations General Assembly. The purpose of the study was to analyse the experience gained in the organization of food aid and to draw conclusions for the guidance of member governments in deciding whether the World Food Program should be continued beyond its original three-year period. Assistance to developing countries has been supplied either as bulk-supply, project-oriented or emergency food aid, the first of these categories being by far the major part of all food aid in the first 6 years. The problems encountered in organizing each of these three types of aid are considered under separate headings.

Electronics Star Catalogue

THE Smithsonian Astrophysical Observatory has now published in the United States a comprehensive star catalogue giving the positions and proper motions of more than a quarter of a million stars. The *Smithsonian Astrophysical Observatory Star Catalog* is available either in printed form, occupying four volumes, or as two reels of magnetic tape compatible with IBM 729 units. The books, available at the United States Government Printing Office, Washington, D.C., cost 20 dollars; the tapes cost 50 dollars, and are to be had from the Smithsonian Astrophysical Observatory.

The availability of the catalogue on magnetic tape is in accord with the extent to which the Institution has relied on computers in the compilation of the new catalogue. Work began more than 8 years ago and a computer programme was used to correlate information about the positions and proper motions of stars given in various catalogues and to refer these to the Epoch and Equinox 1950·0. In effect, the new catalogue is a combination of several earlier catalogues, including these catalogues: the *FK* 4, *FK* 3, *GC*, *AGK* 2, *AGK* 1, Greenwich *AC*, Yale, Cape, Cape Zone, *Me* 3, and *Me* 4. Transferring this mass of information into print was accomplished by means of a Stromberg Carlson computer which was programmed so as to present an image of one page of print at a time on the face of a cathode ray tube. This was then photographed to produce lithographic plates for printing. At the Smithsonian Astrophysical Observatory the information is now being transferred to sky maps which are expected to be complete by this summer. The density of stars is such as to provide an average of six stars per square degree. The average standard deviation of the position of the stars at the time of their first observation

is one-fifth of a second of arc. The average standard deviation of positions for the present epoch obtained by using the proper motions given in the catalogue amounts to half a second of arc.

Mössbauer Spectroscopy

THE U.S. National Bureau of Standards is now issuing a reference standard intended as a standard absorber in Mössbauer spectroscopy. The standard consists of a single crystal of sodium nitroprusside. This material has been selected on account of its chemical stability, very low temperature coefficient, the narrowness of the X-ray lines, and because of its doublet line structure. The standard is intended to be used in comparison with measurements with other materials, and may be purchased for 150 dollars.

University and College News:

Battersea College of Technology

DR. K. HOSELITZ has been appointed to the first visiting professorship of the College, while remaining deputy director of Mullard Research Laboratories. Dr. Hoselitz will be associated with the work of the Solid State Physics Group which recently received a grant of £25,000 from the Science Research Council for work on the structure and chemical properties of crystalline polymers. This appointment is one of the very few so far in Britain to have been designed to bring industrial scientists more fully into academic work. Dr. M. B. Waldron, group leader in physical metallurgy at the Atomic Energy Research Establishment, Harwell, has been appointed to the chair in and headship of the Department of Metallurgy and Materials Technology as from September 1.

Cambridge

PROF. W. R. HAWTHORNE, Hopkinson and I.C.I. professor of applied thermodynamics at the University of Cambridge, has been appointed chairman of the Advisory Council on Scientific Research and Technical Development of the British Army, as from April 1. He succeeds Sir Charles Dodds, president of the Royal College of Physicians, who has been chairman for the past five years.

Lancaster

THE University has announced the appointment of Dr. K. D. Tocher as its first industry-based part-time professor. Dr. Tocher, head of the Department of Operational Research, The United Steel Companies, Ltd., Sheffield, will work in the Department of Mathematics. The University regards this appointment as the beginning of the establishment of a liaison between the University and industrial scientists.

London

THE following appointments have been made: Dr. C. C. Booth, senior lecturer in medicine at the Postgraduate Medical School of London, to the chair of medicine, tenable at that School; Prof. D. T. Donovan, professor of geology in the University of Hull, to the Yates-Goldsmid chair of geology, tenable at University College.

Appointments

MR. R. G. VOYSEY has been appointed director of the United Kingdom Scientific Mission in Washington, D.C., and counsellor (scientific) at the British Embassy in Washington. He replaces Dr. J. A. Saxton, who is returning to the United Kingdom after holding this post since January 1964.

DR. J. A. SIMMONS has been appointed head of the Metal Physics Section at the National Bureau of Standards.

DR. D. W. MATHIESON, reader in pharmaceutical chemistry in the University of London, has been appointed professor of pharmaceutical chemistry as from September 1.

Announcements

A CONFERENCE on "Calculation of the Properties of Vacancies and Interstitials" will be held in Washington during May 1–5. Further information can be obtained from A. D. Franklin, National Bureau of Standards, Washington, D.C.

THE eighteenth international symposium on "Crop Protection" will be held in Ghent on May 3. Further information can be obtained from Prof. J. Van den Brande, Rijksfaculteit der Landbouwwetenschappen, Coupure Links 235, Ghent.

A MEETING of the Society for Analytical Chemistry, devoted to short papers on "Research Topics in Analytical Chemistry", will be held in the University of Bristol on May 4. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

AN international seminar on "Research and Education in Chemical Engineering and Physical Chemistry" will be held in the Technical University of Karlsruhe during May 2–July 15. Further information can be obtained from the United Nations Educational, Scientific and Cultural Organization, Place de Fontenoy, Paris 7.

A SYMPOSIUM on "Graphite", organized by the Electrothermics and Metallurgy Division and the Industrial Electrolytic Division of the Electrochemical Society, Inc., will be held in Cleveland as part of the Spring meeting of the Society during May 1–5. Further information can be obtained from S. W. Bradstreet, Air Force Materials Laboratory, Wright Patterson Air Force Base, Ohio.

THE annual general meeting of the Polarographic Society will be held at the Imperial College of Science and Technology, London, on April 27. The programme will include a lecture on "Polarographic Characteristics of Organic Compounds in Organic Solvents", by Dr. M. E. Peover. Further information can be obtained from Mrs. B. Lamb, 42 Blenheim Gardens, Wembley, Middlesex.

DR. W. J. ECKERT, director of the Watson Laboratory of the International Business Machines Corporation at Columbia University and professor of celestial mechanics in the University, has been awarded the James Craig Watson Medal of the National Academy of Sciences for his contribution to the scientific application of electronic computers and to the theory of the motion of the Moon.

ERRATUM. In the article entitled "Finding Metarchons for Pest Control" by R. H. Wright, which appeared on p. 103 of the July 3, 1965, issue of *Nature*, lines 16 and 17 of the fourth paragraph should read, "likewise completely ineffective in preventing the fruit-flies from congregating".

CORRIGENDUM. In the article entitled "Typography of Bacteria", which appeared on p. 332 of the October 23, 1965, issue of *Nature*, in section 13 (*c*), the word '*kauffmanii*' should read '*kauffmannii*', and in section 13 (*d*), the example should read '*Salmonella kauffmanni* [serotype] London'.

CORRIGENDUM. In the article entitled "Is the Early Evolution of Life Related to the Development of the Earth's Core?" by Prof. C. Sagan, which appeared on p. 448 of the May 1, 1965, issue of *Nature*, in lines 13 and 14 of paragraph 4, '125 km' should be '260 km' and '30 km' should be '200 km'. In line 8 of paragraph 7, '2×18^8' should be '2×10^8'.

THE CARNEGIE INSTITUTION OF WASHINGTON

YEAR Book 64 of the Carnegie Institution of Washington, covering the activities of the Institution in the year ended June 30, 1965, includes, besides the President's review, reports from the several Departments of Terrestrial Magnetism, Plant Biology and Embryology, the Mount Wilson and Palomar Observatories, the Geophysical and Cytogenetics Laboratories, the Committee on Image Tubes for Telescopes and the Genetics Research Unit*. There is also a bibliography of publications during the year, the report of the Executive Committee and a list of officers and staff.

The president comments that the work of the Institution again illustrates the important part played to-day in many scientific fields by programmes of relatively low cost built around the work of the gifted individual investigator, and refers first to the Institution's activities in the planetary sciences, astrophysics and astronomy (see also *Nature*, 209, 743; 1966). Spectacular red-shifts were observed for some of the quasi-stellar radio sources first catalogued by radio astronomers, and much progress was made towards the optical identification of radio sources. An analysis of the new data suggests that we may be on the verge of conclusive evidence about the validity of important hypotheses concerning the dynamic structure of the Universe. A theoretical investigation of background cosmic light from galaxies completed during the year indicated that the combined light of the zodiac and the galaxy would be more than 100 times stronger than the cosmic signal.

The staff of the Observatories were actively concerned with investigations for the site of a possible new major observatory in the Southern Hemisphere. Two prospective sites in Chili offer superlatively good observing conditions, and the Institution is prepared to co-operate in establishing such an observatory. A 200-in. mirror-size instrument would be the most effective, subject to appropriate sponsorship. The Committee on Image Tubes for Telescopes has now met the rather stringent requirements by a 'cascaded' image tube developed for the Committee by the Electron Tube Division of the Radio Corporation of America. Twenty of the tubes were delivered during the year, and the Committee has now designed five different optical systems for efficiently presenting the optical image from a telescope to the tube and for projecting its output on to a photographic plate for recording; these tubes have been made available to five observatories. The Mount Wilson and Palomar Observatories continued their investigations of the spectra of Mars, Venus, Jupiter and Galilean satellites, the asteroid Vesta and the Moon.

The Geophysical Laboratory continued its investigations into the magnetic properties of the Earth meteorite minerals and the organic components of ancient rocks. Much attention was given to present and potential petrographic applications of discriminant function analysis, with particular emphasis on the interesting properties of linear and higher-order discriminants in the closed array. The influence of water on the melting behaviour of simple silicate systems was studied as a contribution to the understanding of volcanic eruptions. A detailed investigation was begun, at the recently developed Strathcona Mine at Sudbury, Ontario, into the formation of copper–iron–nickel sulphide ore. Investigations of the melting relations of the members of volcanic basalt–trachyte associations have confirmed a direct relation between liquid iron enrichment and liquidus temperatures for the rocks of the oceanic alkali provinces of Hawaii and Tristan da Cunha.

The Department of Terrestrial Magnetism continued its Andes seismic programme, and efforts were made to extend the scope of indigenous analysis procedures for the local groups by establishing a 'Carnegie Analysis Centre' in Antofagasta. The nuclear physics programme continued to be directed towards the interactions of polarized nuclear particles. It was observed that the size–frequency-of-occurrence pattern of the foreshocks of the large Chilean earthquake of 1960 differed remarkably from the pattern of aftershocks for the same region. Apparently each seismically active region has a characteristic 'normal' ratio of small shocks to those of moderate intensity. Investigations of heat flow and thermal properties at the bottom of Lake Superior and of Seneca Lake have suggested a possible new method of measuring the outward flow of heat from the inside of the Earth's crust that avoids the costly drilling of large numbers of very deep holes. The Biophysics Group of the Department has further examined the processes of replication and preservation of the genetic information which is transmitted from cell to cell in the coded form of base sequences in the deoxyribonucleic acid of the cell. Animal deoxyribonucleic acid was found to possess numerous copies of, or very nearly identical, gene sequences when fragmented in suitable suspension and eluted from single-stranded deoxyribonucleic acid immobilized in agar. The degree of homology indicated by the varying firmness of binding is tied to the degree of sameness or identity of the gene fragments, both for the same species or for related animals. Selective repression of lysogenic cells among susceptible bacteria can be effectively obtained by: (1) introduction of defects into deoxyribonucleic acid by radiation or radiomimetic drugs, such as mitomycin; (2) inhibition of repair mechanisms in the deoxyribonucleic acid by agents like hydroxyurea or phenethyl alcohol inhibiting the deoxyribonucleic acid synthesis; (3) inhibition of protein synthesis by drugs such as chloramphenicol, puromycin, or amino-acid analogues; (4) addition of chelators, such as ethylenediamine sodium tetraacetate to amplify the increasing effectiveness of the initial radiation or radiomimetic agents. It remains to be seen if this combination chemotherapy can be effective in inhibiting solid tumours of animals and man.

In the Department of Plant Biology the chemical composition and the function in photosynthesis of the pigment complexes in plants have been a major concern, and efforts were intensified to separate the two pigment systems without altering their characteristic absorption spectra or photochemical activity. Attempts were made to determine what step in the photosynthetic process is responsible for oxygen utilization, and changes in rates of oxygen uptake lasting some minutes were induced in *Chlorella* by illumination for only 1 sec, but not in cells treated with glucose or with antimycin. The location of the copper-containing protein plastocyanin in the electron transport chain of photosynthesis has been more specifically established, while in experimental taxonomy differences continued to be found in the photosynthetic ability of plants native to various climates. Races of *Mimulus lewisii* from high altitudes require considerably higher light intensities to saturate photosynthesis than races of *Mimulus cardinalis* from lower altitudes. Further investigation of the mechanics of light absorption and utilization in *Mimulus* showed that the capacity to absorb light varies between races, and the study of evolutionary relations in *Mimulus* has been extended to the genetics

* Carnegie Institution of Washington. *Year Book 64*. Pp. xii + 64 + 596 + 21 plates. (Washington, D.C.: Carnegie Institution of Washington, 1964–65) 1.50 dollars.

of other related species in the Erythranthe section of *Mimulus*.

The Department of Embryology continued to explore the relation of the egg deoxyribonucleic acids to the somatic deoxyribonucleic acids of the eggs of *Xenopus laevis* and *Rana pipiens* and also the mechanism and site of action of actinomycin *A* in inhibiting the developing heart and somites in chick embryo. A mitochondrial factor was isolated which affords protection against anmycin and also prevents the action of antimycin in monolayer cultures of embryonic skeletal muscle. Evidence was obtained that myoblasts can be infected by Rous sarcoma virus. Experiments are in progress to determine the amount and rate of viral synthesis in muscle at each major point in its development and to compare the infectivity of muscle clones with clones of cartilage cells and with clones of fibroblastic cells. Studies of the fate of small fragments of radioactively labelled chick embryos transplanted orthotopically in unlabelled hosts showed that cells of the epiblast may be found in autoradiographic preparations in sites approaching the primitive streak and leaving it and in the streak itself.

In the Genetics Research Unit, progress was made towards the completely accurate physical mapping of phage genes. Work on the structure and function of phage deoxyribonucleic acids showed that the deoxyribonucleic acid fragments in the defective bacteriophage *T*4 particles terminate at random points in the genome of the phage and that the deoxyribonucleic acid molecule and the genome are collinear. Experiments with phage lambda afforded a first physical description of the sequence in the activity of different parts of the phage genome, and other work in the Unit was concerned with the components of actin of the regulators *Spru* and *Ac* present in maize. The Cytogenetics Laboratory reports investigations of the fine structure of chromosomes, the mitotic cycle and deoxyribonucleic acid replication of *Haplopappus gracilis*, the deoxyribonucleic acid of mitotic chromosomes of *Drosophila* and the base composition of heterochromatic deoxyribonucleic acid in *Drosophila melanogaster*.

THE ROYAL SOCIETY OF NEW ZEALAND

THE Royal Society of New Zealand Act, 1965, which came into force on January 1, 1966, consolidates and amends the previous Act of 1933. The Society was established as the New Zealand Institute in 1867 and had three primary functions. First, it provided scientists in New Zealand with an independent forum for scientific discussion, and an open channel for publishing their research findings and, secondly, it offered an independent and authoritative voice to the community and to the Government on scientific matters. Its third function was to act as a body through which New Zealand scientists were linked to the world organization of science, and it is the New Zealand section of the International Council for Scientific Unions.

From its inception, the Society has been federal in structure, linking the activities of regional scientific institutes or societies in the main New Zealand Centres. The new Act and constitution place the policy and control of the Society in the hands of the Fellows while retaining the links established with the member bodies. The Fellowship of the Society, established in 1919, is a self-perpetuating body, at present limited to one hundred scientists, and their part in administering the Society has hitherto been restricted to the appointment of two out of about thirty councillors.

Under the new Act, control of the Society is vested in a council of fourteen, of whom four officers and eight councillors are elected by the Fellows from among their number. The two other councillors represent the member bodies and are appointed by a Member Bodies Committee acting as an electoral college.

The objects of the Society are defined as to promote science, to encourage and stimulate high standards of scientific endeavour and achievement and to give recognition to notable achievements in the advancement of science in New Zealand; to inform the Minister of fields in which, in the opinion of the Council, the scientific effort of New Zealand should be increased, and to suggest how this may be done; to initiate and maintain contacts between New Zealand scientists and scientists in other parts of the world, especially through the unions of the International Council of Scientific Unions and other scientific bodies overseas; to administer funds for scientific research or scientific projects; to initiate meetings or participate in meetings of scientists in New Zealand; to initiate and maintain contacts between scientists in New Zealand, and provide liaison between co-relating efforts of its member bodies and other scientific bodies in New Zealand; and to publish and disseminate scientific knowledge and make available sources of scientific information. The present Council remains in office until the appointment of officers and councillors under the new Act at the annual general meetings of Fellows in May 1966, and one of the last acts of the Council was to adopt new rules which have now been published in the *New Zealand Gazette* of December 22, 1965. Besides the branches of the Royal Society itself, the member bodies listed in the first Schedule to the Act include the Auckland Institute, the Geological Society of New Zealand, the New Zealand Institute of Chemistry, the New Zealand Economic Society and the New Zealand Society of Soil Science.

BRITISH REPRESENTATIONAL SERVICES OVERSEAS

THE debate on a Ministry of External Affairs in the House of Lords on December 21 was opened by Lord Gladwyn, who asked whether the Government had now concluded that the time had arrived for establishing a single Ministry of External Affairs. After referring to the recommendation to this effect in the Plowden Report on Representational Services Overseas, Lord Gladwyn urged that it was now even more important for overseas matters to be handled by a single Ministry of External Affairs.

Lord Caccia supported him, and urged that all that had happened in the past 2 years strengthened the argument. He thought that the present pattern of events was unlikely to change.

Lord Inchyra, while agreeing with Lord Gladwyn, pointed out that the Foreign and Diplomatic Services had already been amalgamated and that the process seemed to be proceeding more smoothly than was anticipated; the time had come, he said, for change. Lord Sherfield also did not see why a single office should not be so organized as to avoid any additional burden on the Secretary of State. He was also supported by Lord Hankey, who thought that if the change was made it might be necessary to have an extra minister in the Foreign Office, though not necessarily a Cabinet Minister.

Lord Walston said that he had an open mind about the actual process of co-ordination of the two Offices, but he

emphasized the importance of paying due consideration to the views of other countries in the Commonwealth. He thought, on the grounds of efficiency, however, that there was much to be said for one office.

With the creation of an integrated diplomatic service, the main recommendations of the Plowden Committee had already been put into effect. Since January 1, 1965, eighty-eight members of the former Foreign Service had been posted to posts in the Commonwealth Relations Office and forty-two members of the Commonwealth Relations Office had been posted to Foreign Office posts. The communications system and the cyphers had been unified, as had the information services of the two offices, and significant progress had been made in the making and implementation of policy, but he could not give Lord Gladwyn any assurance that the two offices would be merged within the next year. The Government was in fact working towards an organization in which, whether or not there were two Departments of State, and two Secretaries of State, the co-operation between the two was such as to eliminate very largely the inefficiencies and illogicalities.

REFORM OF SCOTTISH UNIVERSITIES

THE Universities (Scotland) Bill received the Royal Assent on March 9. The Bill has as its purpose to implement some specific proposals of the Robbins Report for the development of higher education in Scotland. As Lord Hughes explained in moving the second reading in the House of Lords, its aim is to modernize the constitutions of four old Scottish universities and to pave the way for establishing a new university at Dundee. After looking at the constitutions of the existing universities, the Robbins Committee recommended that the four older Scottish universities should be free from the cumbersome outmoded procedures, under the Universities (Scotland) Acts, 1858 and 1889, by which they still had to conduct academic and other business. This procedure involved consultations between the four universities, laying ordinances before Parliament, and approval of them by the Privy Council. This process could take anything from 6 months to a year, and extended into such business as the founding of new chairs and making regulations for new degrees.

There is no controversy about the basic aim of the Bill to modernize the constitutions of these four old universities, although there had been a sharp difference of view on the means by which this should be achieved. The present university authorities asked only for certain minimum reforms to the existing acts, but the Association of University Teachers urged that no really satisfactory reforms could be achieved unless the universities revised their constitutions by drawing up charters.

Lord Hughes said that the Bill was essentially an enabling one, adjusting the balance of power within the Universities to give all the members of a university a due share in its government, and leaving it to the university to decide the rate and nature of constitutional reform. Part I empowered each of the four universities to contract out of the present legislation by petitioning for a Royal Charter whenever it judged the time to be right, provided that the views of all members of the university were canvassed before any such move was made.

In Part II, the essential minimum reforms to the present constitutions were made. By Clauses 2 and 7 the composition of the main organs of university government, the court and the senate, were revised, and non-professorial staff—readers and lecturers—were given a larger share in the management of the university. Clauses 4 and 6 swept away the outmoded and time-wasting procedures at present obtaining and replaced them by new procedures which distinguish between matters of public importance and academic and other business lying properly within the discretion of the university.

Part III of the Bill took the legislative steps necessary to separate Queen's College, Dundee, from St. Andrew's University when the new University of Dundee came to be founded by Royal Charter. This part of the Bill is wholly non-controversial but somewhat complex and technical in character.

LATITUDE-PERIOD DEPENDENCY OF GEOMAGNETIC MICROPULSATIONS

By T. J. HERRON and DR. J. R. HEIRTZLER
Lamont Geological Observatory, Columbia University, Palisades, New York

IN the analysis of geomagnetic micropulsations in the period range of ten to several hundred seconds, various authors have commented on the dependence of period on latitude. The nature of such a dependence, if one exists, has not been fully resolved. The subject is of importance to theories of origin which attribute micropulsations to hydromagnetic oscillations in the magnetosphere. The study of period difference at latitudinally separated stations has involved the direct comparison from analogue records of simultaneous micropulsations, the comparison of power spectra of simultaneous micropulsation wavetrains, and the comparison, over an interval of several months and at various latitudes, of the predominant periods of micropulsations that are not necessarily simultaneous. The conclusions reached have been varied. Voelker[1] recorded micropulsations simultaneously with three similar instruments (48·9°–54·6° geomagnetic latitude) and reported a systematic increase of period with latitude for the H-component of Pc-type oscillations and for the H-component of a damped pulsation named 'pulsation single effect'. Obayashi and Jacobs[2] compiled a statistical scatter diagram of period versus latitude from data of eleven observatories (28°–67° geomag. lat.) which, despite considerable scatter, showed an increase of period with latitude. Duncan[3] compared the predominant periods at three Australian stations (29°–52° geomag. lat.) and found an increase of period with latitude. Other investigators, however, have not found such an effect. Ellis[4], studying the data from the three Australian stations used by Duncan[3], found no latitude-period dependence. Komack *et al.*[5] computed power spectra of magnetotelluric micropulsations at stations separated in latitude (22°–40° geomag. lat.) and reported little or no difference in the period.

To study the latitude-period dependency, the Geomagnetism Group of Lamont Geological Observatory recorded micropulsation activity simultaneously at pairs of stations ranging from 36° to 61° geomagnetic latitude. Because the results of Obayashi and Jacobs[2] indicated a much more rapid period increase near the auroral zones

Table 1. STATIONS OCCUPIED

Station	Geographic Lat. N.	Geographic Long. W.	Geomagnetic latitude	Recording interval, U.T., 1963
Miami, Florida	25° 45′	80° 30′	36°	2300 Aug. 7–2400 Aug. 8
Folkston, Ga.	30° 49′	82° 02′	42°	1400 Aug. 5–2100 Aug. 6
Smithfield, N.C.	35° 14′	78° 08′	46°	0100 Aug. 3–1500 Aug. 4
Lebanon, N.J.	39° 38′	74° 32′	50°	Simultaneous with other stations
Plattsburgh, N.Y.	44° 43′	73° 15′	55°	0200 July 28–0900 July 29
St. Leonard, Que.	46° 02′	72° 22′	57°	1600 July 20–1800 July 21

St. Felecien, Que.	48° 34′	72° 28′	60°	1900 July 24–0900 July 25
Chibougamau, Que.	49° 46′	74° 26′	61°	1700 July 22–1600 July 23

(nearly a doubling of period from 50° to 60°), the Lamont stations were established over a latitude range sufficiently wide to test the dependency found in these earlier studies. A rubidium vapour magnetometer was operated at a base station in the Lebanon State Forest on the New Jersey coastal plain. A second rubidium magnetometer was operated at other sites (Table 1) approximately on a north–south line through Lebanon. Recording was continued for at least 24 h at each station pair during a 2·5 week interval of generally high micropulsation activity. Only those station pairs that showed micropulsation activity throughout a major part of a diurnal interval were used in this analysis. Each instrument recorded on a strip chart recorder at a paper speed of 1 in./min and a sensitivity of 1·3 γ/in. The rubidium magnetometers measured the components of magnetic variation in the direction of the total field (mainly the vertical component at the higher latitudes where the magnetic lines of force approach the vertical).

Investigation of Individual Micropulsations. The records for each station pair were examined throughout the recording interval and the highest amplitude oscillations occurring at both stations were selected for study. The period of an amplitude group, usually 5–10 cycles in duration, was determined by numbering the peaks and troughs of the oscillation and plotting the occurrence times of the peaks and troughs versus the cycle number. The slope of the best-fit line through the plotted points was the average period. The ratio of the period at the high-latitude station to the period at the low-latitude station was plotted against time of day. Fig. 1 gives the results for three pairs of stations in which the field stations are at lower latitudes than Lebanon. Fig. 2 presents the

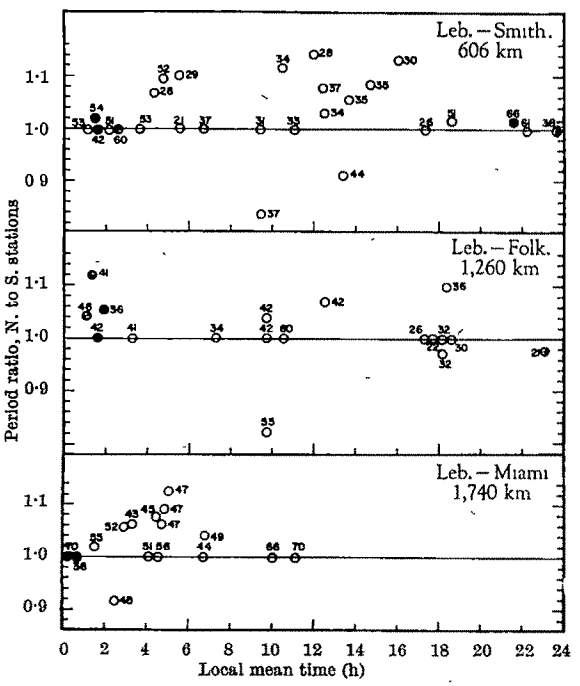

Fig. 1

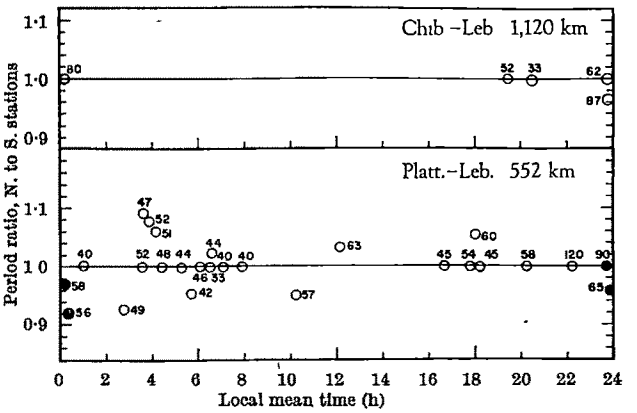

Fig. 2

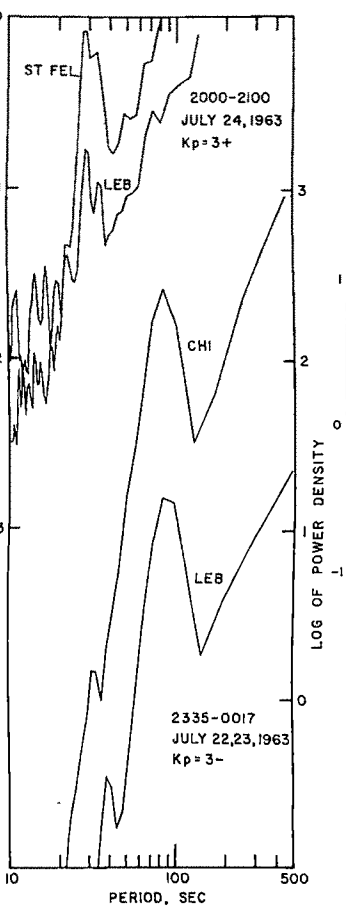

Fig. 3

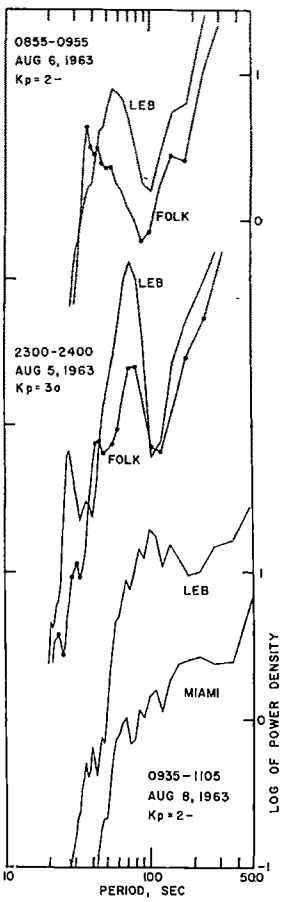

Fig. 4

period ratios for two of the four stations at higher latitudes than Lebanon. The open circles indicate *Pc*-type oscillations. The solid points indicate *Pt*-type oscillations. The number next to each point is the period at the lower-latitude station.

For most of the station pairs in Figs. 1 and 2, more points fall above the 1·0 axis than below; this could indicate a tendency for the period to be longer at the higher-latitude station. However, the average period resolution for the method used is no better than about 5 per cent allowing a somewhat greater error in the ratio determination. The scatter of ratio points is mostly within a 10 per cent variation and is no greater for the more widely separated stations, indicating that the scatter is probably caused by error in measuring the periods. Thus, within the accuracy of the method, there is no dependence of period on latitude for the simultaneous micropulsation groups.

Power Spectral Analysis. Power density spectra were computed of approximately 1-h intervals of strong micropulsation wave-trains occurring at both the base and field stations. Digital sampling intervals of 1–3 sec were used. The data were pre-whitened before the spectral analyses were performed by use of a filter that attenuated at 6 dB/octave toward the long periods. The maximum lag used was 10 per cent. Smoothing of the raw spectrum was done with a hamming window. The spectra were restored after analysis to compensate for the pre-whitening. Power density was computed in units of $\gamma^2/c/s$.

Fig. 3 presents two pairs of spectra for field stations at higher latitudes than Lebanon. The Lebanon–St. Felecien pair in the upper part of the figure shows strong spectral peaks at the 30-sec period. The Lebanon–Chibougamau pair in the lower part of the figure shows very strong spectral peaks at about the 86-sec period. For each pair, the spectral peaks at Lebanon (the lower latitude station) are at periods 2–3 sec longer.

Fig. 4 presents three pairs of spectra for two field stations at lower latitudes than Lebanon. The Lebanon–Miami pair at the bottom of the figure shows a group of spectral peaks between the 60- and 100-sec period. There is no measurable difference in period of the peaks between stations. The Lebanon–Folkston pair in the middle of the figure shows large spectral peaks at the 74-sec period at Lebanon and at the 76-sec period at Folkston. The Lebanon–Folkston pair at the top of the figure shows a concentration of energy at the 55-sec period at Lebanon and the 37-sec period at Folkston. Closer examination of this upper pair reveals that the broad spectral maxima between 30 and 70 sec are a superposition of spectral components of 37, 45 and 55 sec (and perhaps other) periods. The components are evident in both spectra, if only as minor humps. The 37-sec component has the greatest amplitude on the Folkston spectrum and the 55-sec component has the greatest amplitude on the Lebanon spectrum. The first impression of a period dependence on latitude, in this case, would appear to be rather a case of amplitude dependence on latitude of a number of distinct spectral components. The Lebanon–Miami pair clearly shows that a group of distinct spectral peaks can occur at both of two widely separated stations. Previous investigations summarized by Troitskaya[6] have shown that amplitudes of micropulsations usually increase with latitude. In agreement with this, the five pairs of spectra show that, except for several narrow-band peaks, the higher-latitude station had higher amplitudes over a broad period range.

In summary, ten pairs of power spectra at north–south stations were computed, of which the five pairs shown are typical. Cases where the higher latitude station had slightly longer periods were observed as were cases where the lower-latitude station had slightly longer periods. Both the investigation of power spectra and the investigation of individual micropulsation groups indicate no sizable or consistent difference in period between latitudinally separated stations. These results apply to geomagnetic latitudes between 36° and 61°, to the component of variation in the direction of the total field, and to the time of year indicated in Table 1. The results do not preclude a period-latitude dependence for any type of rarely occurring micropulsation or at some other season of the year or in a different component of the field. The conflicting results of this and previous investigations indicate the necessity of carrying out a more extensive study involving three orthogonal components of the field recorded over a wide latitude range at several seasons of the year.

We thank Mr. M. Davidson, Mr. J. Chute, and Mr. J. Foster for help in collecting and processing the data. The work was supported by a contract from the U.S. Office of Naval Research and by a grant from the National Science Foundation.

ICE SHELF THEORY OF PLEISTOCENE GLACIATIONS

By E. P. J. van den HEUVEL
Sterrewacht 'Sonnenborgh', Utrecht, The Netherlands, and Sterrekundig Instituut, Vrije Universiteit, Brussels, Belgium

A. T. WILSON[1] developed a theory for the origin of the ice ages. In his theory, Antarctica plays an important part. Although he is able to give an excellent explanation of highly important features of the ice ages, his theory is open to some criticism.

Wilson's theory. Briefly, the main points of Wilson's theory are:

(1) Antarctica is covered by an ice sheet several kilometres thick. The pressure on the rocks below the ice sheet is very high. Computations show that where there is little precipitation the ice at the base of the cover will reach its pressure melting-point; however, where there is considerable precipitation on the surface of the ice sheet, the pressure melting-point will not be reached at the bottom. Thus a decrease in surface precipitation may cause instability of the ice sheet.

(2) If instability occurs the ice sheet will flow radially outwards into the surrounding sea. A large ice shelf will be formed, covering both Antarctica and the ocean around it. As a consequence of the increased albedo of the earth, cooling will occur and also extensive glaciation will be induced in the northern hemisphere.

(3) When the expansion of the southern ice shelf stops, the ice cover of the ocean will slowly start to melt. After some time, only the ice cover of Antarctica will be left. Clearly it will be much thinner than before the outflow. Because of the slow decrease of the albedo, the Earth will slowly return to its interglacial temperature. In the subsequent warmer period the Antarctic ice cover will grow again by precipitation, until a sudden decrease of precipitation induces a new instability. In this way the cause of the ice ages would resemble a kind of relaxation mechanism, like the 'flip-flop' in electronics. The 'controlling pulse' would be the relatively sudden decrease of precipitation.

(4) The fact that no ice ages occurred more than 1 million years ago is explained as follows: Wilson's mechanism needs a large area of rocks and mountains close to the south pole. Because of continental drift (Wegener's hypothesis) Antarctica would have arrived close to the pole several million years ago. At that time Wilson's mechanism could start. First, small ice shelves would be produced, but as Antarctica gained a more symmetric position with respect to the pole, larger ice shelves would be produced which would result in ice ages.

(5) The coincidence of the ice ages in the northern hemisphere with the insolation-minima computed by Milankovitch[2] can be explained as follows: the decrease of

precipitation would be caused by a decrease of 'insolation'. Thus a decrease of insolation would be the real 'controlling pulse' of the 'flip-flop' mechanism.

My criticism is directed against this last-mentioned point. Milankovitch computed his insolation curves for the northern hemisphere. Because the astronomical causes of variations in insolation have different consequences for both hemispheres, the insolation curves for the southern hemisphere will in general be entirely different from the northern. This can be seen in Fig. 1.

In order to demonstrate why the insolation changes are different in the two hemispheres, I shall now review Milankovitch's theory.

Milankovitch's theory. The changes of the insolation are caused by two different mechanisms:

(1) The obliquity ε of the ecliptic oscillates between 21° 58·6′ and 24° 36′, with a period of 40,400 years. This is a consequence of secular perturbations caused by the major planets. If ε is maximal the high latitudes on both hemispheres will receive considerably more solar radiation during a year than when ε is minimal. Thus the situation with minimal ε is favourable for the occurrence of glaciations on both hemispheres. Changes in ε give rise to equal insolation changes for both hemispheres.

(2) Owing to the precession, the perihelion length Π of the Earth's orbit increases by 360° in about 21,000 years. If $\Pi = 0°$, then the lengths of summer and winter are equal for both hemispheres (see Fig. 2). In this case there will be no difference in insolation. However, 5,250 years later, when $\Pi = 90°$ (and if the eccentricity e of the orbit does not equal zero), the northern summer will last longer than the winter. In this event, the northern summer will be long and cool, and the winter will be short and mild. The southern summer will be shorter than the winter. The summer will be warm and the winter cold. The difference in duration between summer and winter is:

$$\Delta T = \frac{4e}{\pi} \sin \Pi \,.\, 365{\cdot}24 \text{ days} \qquad (1)$$

Milankovitch[2] claims that in times of cool summers the yearly amount of precipitation is large. During a hot summer and the subsequent cold winter the amount of precipitation is small. Since glaciers grow by precipitation, the situation with $\Pi = 90°$ will be favourable for the occurrence of extensive glaciation in the northern hemisphere, and unfavourable for it in the southern hemisphere.

If $\Pi = 180°$, there will again be no difference in insolation between the hemispheres. If $\Pi = 270°$, the situation

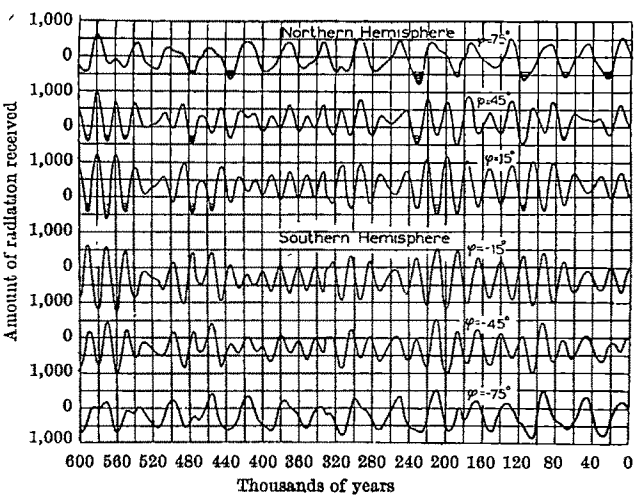

Fig. 1. Milankovitch's insolation curves for the past 600,000 years. The figure represents the curves for geographical latitudes $\varphi = \pm 15°$, $\varphi = \pm 45°$ and $\varphi = \pm 75°$. Note that the curves for $+15°$ and $-15°$ show opposite variations; the amounts of radiation are given in 'canonic' units[2]. The curves for $\varphi = +75°$ and $\varphi = -75°$ show maxima and minima at almost the same times. The curves for $\varphi = +45°$ and $\varphi = -45°$ are irregular and show no correlation. The same holds for the curves for latitudes between $\pm 45°$ and $\pm 75°$

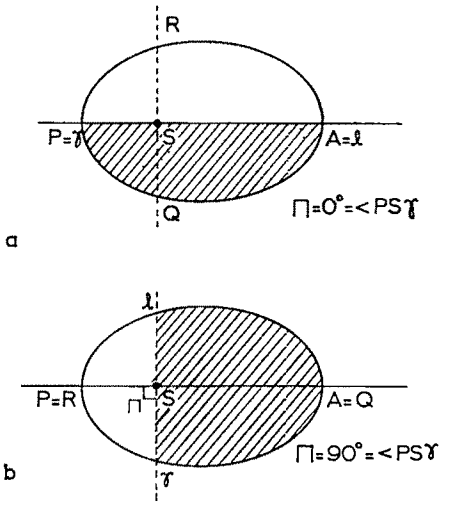

Fig. 2. *a*, If the perihelion length $\Pi = <PS\gamma = 0°$, the Sun is in the equatorial plane when the Earth is in the point P of its orbit. (γ is the equinox, S is the Sun.) The Sun reaches its maximal angular height above the equatorial plane when the Earth is in the point Q (mid-summer) and is again in the equatorial plane when the Earth is in the point A (aphelion). Mid-winter in the northern hemisphere occurs if the Earth is at the point R. Thus if $\Pi = 0°$, the length of the summer (area PQA) is just equal to the length of the winter (area ARP). The same occurs if $\Pi = 180°$. In that case $A = \gamma$ and $P = \mathcal{A}$, while R and Q are interchanged. *b*, If $\Pi = 90°$, mid-summer for the northern hemisphere occurs when the Earth is in the aphelion A and mid-winter when it is in the perihelion P. Thus the northern summer (area $\gamma A \mathcal{A}$) will be long and cool, the winter short and mild. For the southern hemisphere the winter is long and cold, the summer short and hot. The situation for $\Pi = 270°$ is just opposite to that for $\Pi = 90°$. As a consequence of the precession and the proper motion of the perihelion the angle Π increases by 360° in a time-interval of about 21,000 years

will be favourable for the occurrence of glaciations on the southern hemisphere and not the northern. According to the value of e (between 0·0000 and 0·0677) the contrasts between the northern and southern mean temperatures will be small or large (see equation 1). If $e = 0$, there will be no contrast at all. Thus the ε-variations act symmetrically on both hemispheres and the Π-variations act unsymmetrically.

The occurrence of ice ages. Since the periods of the ε-variations and the Π-variations are different, the insolation curves for the northern hemisphere will have an irregular character: sometimes the ε-variations will act in the same direction as the Π-variations, in which case the insolation will reach an absolute minimum or an absolute maximum. If the variations act in opposite directions, no extreme insolation situation will occur. The ice ages for the southern hemisphere are expected to occur if a minimum of ε coincides with times at which $\Pi = 270°$ and if simultaneously e is large.

On the northern hemisphere an ice age is expected if a minimum of ε coincides with a moment at which $\Pi = 90°$, and if simultaneously e is large.

Milankovitch's curves and Emiliani's minimum temperatures. By computing the diagrams for summer insolation, Milankovitch obtained curves as shown in Fig. 1. The minima of the curves for medium latitudes indicate the presumed times of the ice ages. From Fig. 1 it can be seen that for latitudes smaller than 70° the curves have an irregular character. The minima of the southern insolation curves do not coincide with those of the northern curves. Only for geographical latitudes larger than 70° are the curves for the northern and southern hemispheres more or less the same. This is due to the fact that in Arctic regions the insolation variations caused by changes of the obliquity ε of the ecliptic are much larger than the insolation variations caused by changes in Π. Thus for latitudes higher than 70°, one expects insolation minima at the same times for both hemispheres. Milankovitch[2] postulated that the insolation variations at latitudes of about 65° are the most important indications for the occurrence of the glaciations in the hemispheres, since the absolute insola-

tion variations are maximal at these latitudes. The 65°-curves are different for both hemispheres.

Emiliani[3] determined very carefully the changes in the temperature of the North Atlantic Ocean for the past 300,000 years. He obtained the temperatures by measuring the contents of oxygen-16 and oxygen-18 in ocean bottom sediments. His curve shows minima which coincide more or less with the insolation minima for 65° northern latitude. The minima in Emiliani's curve show a periodicity of about 40,000 years. They also coincide more or less with the minima of ε.

The contradiction in Wilson's theory is that the northern ice ages do not coincide with the southern insolation minima : if the northern ice ages were caused by an instability of the Antarctic ice cover it would be expected that they would coincide with the southern insolation minima and not with the northern insolation minima as is actually observed.

However, this criticism is not so serious as it seems, since it can be removed by considering the Antarctic instability mechanism in more detail or by changing somewhat Milankovitch's theory.

(*A*) Let us first consider the Antarctic instability mechanism in more detail. One can read Milankovitch's northern summer insolation curves as southern winter insolation curves since a northern summer coincides with a southern winter and inversely.

Milankovitch claims that in times of long and cool northern summers ($\Pi = 90°$) the yearly amount of precipitation in the northern hemisphere is enhanced. At the same time, the southern winters are long and cold, the summers short and hot, causing the yearly amount of precipitation on the southern hemisphere to be reduced. For this reason the minima of yearly precipitation for the southern hemisphere coincide with Milankovitch's northern insolation minima. Hence antarctic instability will just occur at times at which Milankovitch expected the northern ice ages to occur. It would therefore be quite logical that also according to Wilson the ice ages coincided with Milankovitch's northern summer insolation minima, which in fact indicate southern precipitation minima. This coincidence is only a question of mere chance due to the fact that northern summer insolation curves can be read as southern winter insolation curves. This removes my criticism. The issues of Milankovitch's and Wilson's theories, however, remain entirely different, and previously it would seem that these theories contradicted each other.

(*B*) The second possibility would be to use the fact that, according to Emiliani[3-5], the northern ice ages coincide more or less with the ε-minima. Milankovitch postulated that the insolation variations at 65° latitude are the most important. One could, however, abandon this postulate and assume that the variations in arctic regions are more important. Because the insolation curves for latitudes greater than 70° are almost the same for both hemispheres, the northern and southern insolation minima would coincide in that case. If now the instability of the antarctic ice cover would occur at times of minimal southern insolation, it would also occur at times of minimal northern insolation and again there would be a coincidence between the northern insolation minima and the ice ages.

Conclusions

Neither of the proposed adaptations of Milankovitch's theory to that of Wilson contradicts Emiliani's temperature determinations. Only a careful search for synchronism between variations in northern and southern temperatures will provide information that will make it possible to decide which of the two theories is correct. If the northern glaciations were to follow the 65° northern insolation curve and if the southern one were to follow the southern insolation curve, then obviously Milankovitch's theory would be right.

If, on the other hand, synchronism were found, then Wilson's theory would be right. Synchronism with a periodicity of 40,000 years would mean that variations in insolation in arctic regions were more important than those at 65° latitude. Only perfect synchronism between the 65° northern summer insolation curve and the ice ages in both hemispheres would be a decisive indication that Wilson's theory is right.

So far, however, it is only possible to say that there seems to be a correlation between the occurrence of the northern ice ages and the secular summer insolation variations in the 65° latitude region of the northern hemisphere.

THE GRANITIC ROCKS OF HAIG FRAS

By DR. C. S. EXLEY

Department of Geology, University of Keele

IN an account recently published, Smith, Stride and Whittard[1] describe an area of granitic rocks situated about 60 miles west-north-west of the Scilly Isles. The specimens from this area, which appears to be surrounded by Devonian or Carboniferous rocks, include: (*a*) Seven granites and thirteen gneisses collected by scientists from the National Institute of Oceanography embarked in R.R.S. *Discovery II* in 1962. (*b*) Two granites and one gneiss obtained by University of Bristol scientists in R.V. *Sarsia* in 1962 and 1963. All *Discovery's* specimens were obtained by dredge; one of *Sarsia's* specimens was obtained by dredge and two by corer. An account of the petrology of all the rocks is given in an appendix by Dr. P. A. Sabine[1].

I have been fortunate to have the opportunity to examine in some detail the rocks collected by *Discovery II* and to have been given enough material from some of them for chemical analysis. Unlike *Sarsia's* specimens, which were taken from three sites, respectively in the north-west, east and south of the area, those recovered by *Discovery II* came from a single station in the north central part. (Ref. 1, Fig. 4.)

The Granites. In view of their position and age (277 ± 10 m.y.), Smith, Stride and Whittard conclude that the Haig Fras granitic rocks comprise a westerly addition to the granites of South-west England. It is therefore appropriate that some comparisons should be made.

From both the mineralogical and the chemical standpoints, certain similarities are apparent; for example, both suites of rock contain tourmaline as a normal constituent and both have a characteristically low potassium : rubidium ratio[2]. However, the greater part of the granite of the mainland is coarse-grained and porphyritic, with megacrysts upwards of about 3 cm in length, whereas the Haig Fras specimens are fine-grained, the largest crystals being no longer than about 3 mm. *Sarsia's*, as well as *Discovery's*, samples are reported to be fine-grained and it may be that no large mass of coarse rock is exposed

in the area. Further, the coarse rock of the mainland is distinctly potassic, only rarely becoming sodi-potassic[3], while the Haig Fras rocks are generally sodic (Table 2, columns 1–3, 6). It would appear, therefore, that the Haig Fras rocks do not resemble the bulk of the south-west granites either texturally or compositionally and that similarities must be sought among less common varieties.

Comparing them first with the fine-grained granites that occur in all the main outcrops, it is found that there is a reasonably close textural correspondence, apart from the foliation of the Haig Fras rocks[1], which is unusual. In composition, however, the fine-grained varieties of the mainland are manifestly more mafic and more potassic than the submarine specimens (Table 2, columns 1–4).

Two other groups of rocks might be regarded as possible counterparts; these are the fine-grained early and late sodic facies of the main granites.

Worth[5] suggested that the felsites of southern Dartmoor constitute an early chilled facies of the main granites there, a view later endorsed by Brammall and Harwood[6] in the light of their chemical analyses which gave $K_2O : Na_2O$ ratios respectively of 0·47, 0·53 and 1·1 for the Legis Tor, Ludbrook and Broadall Lake felsites. These values are very like those of the Haig Fras rocks (Table 2, columns 1–3, 6). In all other respects, however, the felsites are entirely different.

Among the youngest rocks of the granitic suite of South-west England is a group of leucogranites which occurs in the form of sheets and veins, seldom more than 4 or 5 ft. thick and intrusive into both granite and country-rock. Such rocks have been seen in all the major intrusions including that of the Scilly Isles, which is the nearest to Haig Fras. From the analyses in Tables 1 and 2 (columns 5 and 7) it can be seen that although there are some notable differences in mineralogical composition, there is very good chemical agreement between these rocks and the Haig Fras granites (Table 2, columns 1–3). It is also evident that the Haig Fras 'aplogranite' (Table 2, column 6) is chemically close both to the mainland leucogranites and to the Haig Fras granites. The most striking mineralogical difference lies in the proportions of the two feldspars. While not wholly illusory, this difference is in fact less important than it first appears because of the perthitic nature of the potash feldspar, a phenomenon which is not taken into account in the mode and which also explains some of the seemingly anomalous alkali ratios. The anorthite content of the Haig Fras plagioclases (An_{10}) is identical with that of the Bodmin Moor leucogranite (Table 1, column 7) in which the potash feldspar is largely microcline, as it is in the Haig Fras rocks, although not commonly in the other south-west granites. Finally there is a tendency for the leucogranites to develop a planar structure somewhat similar to the foliation in the Haig Fras rocks, although not so marked.

Fine-grained varieties occur among granites of similar age in Brittany but these are generally much more mafic, have a rather different feldspar content and contain little or none of the characteristic tourmaline.

The Gneisses. Injection and permeation gneisses and schists are not associated with any of the granites on the mainland, such metamorphism as there is being mainly

thermal, with some metasomatism. This is true both of the envelopes of the granites and inclusions within them. In particular, metasediments of the Devonian and Carboniferous when metamorphosed bear no resemblance to the gneisses and schists of Haig Fras. A similar situation was observed on White Island in the Scillies by Osman[7], who described 'pneumatolysed' inclusions of schist and concluded that, far from being part of the Devonian or Carboniferous roof of the granite, they were part of the much older floor. Comparing the White Island inclusions with the schists of the Lizard, he claimed that the resemblance in both structure and mineralogy was 'striking'.

The fragments of Haig Fras metamorphic rock are too small to be very helpful, but a comparison between the fragments themselves, Dr. Sabine's description of them[1], and Osman's description of the White Island inclusions[7], indicates that the former have been much more extensively granitized than the latter. This is confirmed by the chemical analysis in Table 3; unfortunately there is no analysis of the White Island rock, but a cursory examination of an analysis of an Old Lizard Head Series pelitic schist (Table 3, column 2) shows how extensive an alteration would be required to produce a Haig Fras-type injection gneiss. On the other hand, the analysis of a Porthallow granite-gneiss (Table 3, column 3) is not dissimilar, especially in its alkali content. The possibility of sodium metasomatism is suggested by the low $K_2O : Na_2O$ ratio in both these cases and is supported by the nature of the plagioclase, which is albite or oligoclase in the Porthallow rock and oligoclase (An_{11}) in the Haig Fras gneiss. A difference in age between this gneiss (Table 3, column 1) and the associated granites (Table 2, columns 1–3) is hinted at by its relatively high zirconium and barium content.

The Position of Haig Fras. The igneous and metamorphic area lies more than 40 miles to the north of the projected south-westerly trend of the known granites of the south-west. This may be due to either of two causes. On the one hand the Haig Fras granites may belong to a mass which is quite separate from the elongated 'batholith' underlying Devon, Cornwall and the Scillies, while on the other there may be a dextral fault, or series of

faults, under the sea between Haig Fras and the Scillies. Such a structural feature would be in keeping with the pattern of wrench-faults postulated by Dearman[9] for the mainland.

As Smith, Stride, Whittard and Sabine[1] have said, the Haig Fras granitic rocks represent a suite of granites and related gneisses resulting from granitization of schists. However, the former show strong mineralogical and chemical affinities with one of the youngest suites of granitic rocks in Devon and Cornwall, and probably comprise small, late intrusions which have penetrated through an earlier granite phase of which there is so far no evidence. If this is the case, only the uppermost part of the granite body has been revealed by erosion. By analogy with what is seen on the mainland, the gneisses seem much more likely to represent part of the 'basement' than metamorphosed Devonian or Carboniferous metasediments; this may mean that the high ground of Haig Fras is flanked by faults which have brought the metasediments into juxtaposition with the older metamorphics or, more probably, that it is flanked by an unconformity between these two groups of rocks.

I thank Mr. A. H. Stride for directing my attention to the Haig Fras rocks, for discussing them with me and for his helpful comments on these notes; also the Director of the Geological Survey for permission to examine and analyse the specimens; Mr. A. J. C. Steventon for the major element analyses; and Mr. G. M. Power and Mrs. M. A. Humphreys for the trace element analyses.

CHEMICAL COUPLING OF ENZYMES TO CROSS-LINKED DEXTRAN ('SEPHADEX')

By DR. ROLF AXÉN and DR. JERKER PORATH
Institute of Biochemistry, University of Uppsala, Sweden

ENZYMES and other organic catalysts may be chemically attached to insoluble polymers with retention of all or part of their catalytic activities[1–6]. Such modified catalysts possess certain properties which make them attractive as tools for synthesis and degradation of biopolymers. They are often more stable than original enzymes. A great advantage of their use in polymerization and depolymerization reactions is the fact that the products can be freed rapidly and completely from the enzyme simply by filtration.

The coupling reaction to be used for binding the catalyst must proceed under mild conditions. Extremes of *p*H must be avoided and the coupling must be performed within a narrow range of temperature in aqueous solution.

The insoluble polymer must fulfil certain requirements. It must be stable, should not significantly inhibit the enzyme and should not cause disturbing unspecific adsorption. Since the enzymatic reactions take place in aqueous solutions, hydrophylic polymers are preferred as enzyme carriers[4,6]. A cross-linked dextran, 'Sephadex', would act as an almost ideal matrix except for possible screening effects caused by steric hindrance. To ascertain whether this is the case we have synthesized a number of products which we expected to show hydrolytic activities. These substances include polymer-fixed histidine peptides, chymotrypsin, trypsin and β-amylase.

We have described elsewhere the synthesis of isothiocyanate derivatives of dextran and 'Sephadex' (from *AB* Pharmacia, Uppsala, Sweden) and their conjugation with peptides and proteins[7]. With different selectively protected amino-acids it was shown that, with the coupling and washing procedures used, the main product is a substituted thiourea. Therefore, the coupling of a protein occurs mostly at its α-amino groups and at the ε-amino groups of lysine. The content of bound protein was determined after acid hydrolysis according to the method of Spackman, Moore and Stein. The high content of carbohydrate does not disturb the analysis.

Preparation of p-nitro-phenoxy-hydroxypropyl ethers of 'Sephadex G200'. A mixture of 10 g 'Sephadex *G*200' and 2 g *p*-nitro-phenylglycidyl ether[8] was suspended in 10 ml. toluene, and 40 ml. 1 M sodium hydroxide was added. The suspension was heated at 70° C for 18 h. When less substituted products were desired the reaction was run for only 6 h. The product was acidified with acetic acid, washed with water, shrunk by dropwise addition of ethanol to the stirred water suspension, filtered, washed with acetone and then dried. The content of nitro-groups was determined by titration with titanium chloride[9]. The values agreed with the results of nitrogen determinations performed according to Dumas. 'Sephadex *G*100' and '*G*25' were converted to the nitro-derivatives in the same fashion, except that only 20 ml. and 10 ml. 1 M sodium hydroxide were used, respectively.

Reduction. Reduction of the *p*-nitro-phenoxy-hydroxypropyl-ethers of 'Sephadex' was effected on a preparative scale using sodium dithionite. 10 g polymer was swelled in 50 ml. water and 20 ml. 5 M sodium hydroxide, and 1 g sodium dithionite was added. The reaction was carried out at 65° C for 1 h with stirring. After cooling, the reaction product was collected on a filter and washed with water, 0·1 M hydrochloric acid, and again with water. It was then suspended in water, allowed to sediment, and

the finer beads were decanted. The heavier particles, about 80 per cent of the total, were treated with ethanol and acetone and were then dried. The consumption of titanium chloride on titration of the amino polymer was about 10 per cent of that observed in titrating the original nitro-polymer.

Conversion to isothiocyanate derivatives. The amino groups were converted to isothiocyano groups by treatment of the amino-polymer swelled in 3·5 M potassium hydrogen phosphate buffer (*p*H 6·8) with a 10 per cent solution of thiophosgene in carbon tetrachloride. The suspension was agitated thoroughly at room temperature with a vibrator during the reaction. 1 g of the swelled amino-'Sephadex' was vibrated for 20 min with 1·5 ml. thiophosgene solution. A second 1·5 ml. portion of thiophosgene was then added and the agitation was continued for 20 min. The gel was washed on a filter with water, acetone, 0·5 M sodium hydrogen carbonate (5 min) and again with water. The product can be used directly for coupling reactions or it can be shrunk for storage by adding acetone to the water suspension and then dried at 100° C under vacuum. The isothiocyanate content was determined by the iodometric titration of the hydrogen sulphide evolved on acid hydrolysis of the dried product.

Fixation of peptides and proteins. The isothiocyano-'Sephadex' was tested by coupling with some model substances. The polymer was swelled in 0·3 M sodium hydrogen carbonate and a five-fold excess of glycyl-leucine was added. The reaction was allowed to proceed for 24 h at room temperature. After washing and drying the content of leucine was determined. In some other experiments, insulin in 1·5-fold excess was coupled to 'Sephadex *G*100' and '*G*200' derivatives. The results are listed in Table 1.

Table 1. DEGREE OF SUBSTITUTION OF 'SEPHADEX' DERIVATIVES IN THE SYNTHETIC SERIES NITRO- (AMINO-), ISOTHIOCYANO-PHENOXY-HYDROXYPROPYL-'SEPHADEX', AND YIELD ON COUPLING WITH MODEL SUBSTANCES

'Sephadex'-derivatives	Grade of 'Sephadex' *G*25	*G*100	*G*200
p-nitro-phenoxy-hydroxypropyl-'Sephadex' Nitro-group determination (μmole/g)	360	240	230 (190)
p-isothiocyano-phenoxy-hydroxypropyl-'Sephadex' Isothiocyanate determination (μmole/g)	290	180	190 (150)
Amount (μmole/g) of coupled Gly-Leu (5-fold excess of peptide in 0·3 M $NaHCO_3$)	232	155	173 (112)
Amount (μmole/g) of coupled insulin (1·5-fold excess of insulin in 0·3 M $NaHCO_3$)	—	29·5 170 mg/g	30 173 mg/g

The reaction time in the synthesis of the nitropolymer was 18 h or 6 h (values in parenthesis).

Chymotrypsin was coupled to *p*-isothiocyano-phenoxy-hydroxypropyl-'Sephadex *G*200' by the following procedure (preparation *CHY* : 1). 100 mg isothiocyano-'Sephadex' was swollen in 3 ml. 0·05 M borate buffer of *p*H 8·6, to which 50 mg crystallized, salt-free chymotrypsin was added over 30 min. The reaction mixture was stirred with a slow stream of nitrogen for 15 h at 5° C. The gel was poured into a column, where it was washed successively with the borate buffer (24 h), 10^{-3} M hydrochloric acid (24 h), 0·5 M sodium chloride (6 h) and 10^{-3} M hydrochloric acid (24 h). The washing solutions were delivered with a peristaltic pump at 10–15 ml./h. 50 per cent of the gel was then suspended in water and shrunk by slow addition of acetone. After filtration, the shrunken gel was kept in acetone for 30 min and then was dried at 40° C in vacuum (Product *CHY* : 1*a*). The content of coupled enzyme was determined (Table 2). The remainder of the swelled gel was transferred to a smaller column and was treated with 0·2 M phosphate buffer of *p*H 7·6 containing 0·02 per cent sodium azide. This material was used for several experiments at +5° C (hydrolysis of *p*-nitro-phenylacetate, methionine methyl ester and *N*-acetyl-tyrosine ethyl ester). After 4 weeks the gel was washed with water, shrunk and dried (Product *CHY* : 1*b*). A suspension of *CHY* : 1*a* in 0·2 M phosphate buffer of *p*H 7·6 was stirred for 6 h and the gel was centrifuged down. The supernatant showed no activity toward *N*-acetyl-tyrosine ethyl ester. The

Table 2. CHEMICAL FIXATION OF ENZYMES TO *p*-ISOTHIOCYANO-PHENOXY-HYDROXYPROPYL-'SEPHADEX'

Enzyme-'Sephadex'	Preparation No.	Content of isothiocyanate μmole/g	Polymer/enzyme ratio by the coupling	Content of fixed enzyme μmole/g	mg/g
Chymotrypsin-'Sephadex *G*200'	*CHY* : 1	190	100 mg/50 mg	8·9	220

trypsin-'Sephadex', β-amylase-'Sephadex', and the other chymotrypsin-'Sephadex' samples listed in Table 2 were prepared in the same way.

Determination of activities. Measurements of catalytic activities of the insoluble chymotrypsin toward *p*-nitro-phenylacetate were made and compared with some other histidine-containing derivatives of 'Sephadex' and with imidazole and free chymotrypsin. The rate of hydrolysis of a $5{\cdot}5 \times 10^{-5}$ M *p*-nitro-phenylacetate solution in 0·2 M phosphate buffer of *p*H 7·6, containing 5 per cent (by volume) dioxane at 22° C in the absence or presence of catalyst (10^{-4}–10^{-6} M in histidine), was measured and the rate constants for these reactions, k_0 and k_c, respectively, were calculated.

The β-amylase-'Sephadex' was assayed with 1 per cent soluble starch (Merck) in 0·02 M sodium acetate at *p*H 4·8, using 3,5-dinitro-salicylic acid as a colour reagent[10]. The β-amylase-'Sephadex *G*25' was inactive.

The esterase activity of chymotrypsin-'Sephadex' was determined under the following conditions with tyrosine ethyl ester as a substrate: 2×10^{-3} M tyrosine ethyl ester (0·02 M Ca^{++}) in 0·05 M *tris* buffer of *p*H 7·0 at 22° C. The activity of trypsin-'Sephadex' was determined toward *N*-benzoylarginine ethyl ester: 10^{-3} M ester (0·02 M Ca^{++}) in 0·05 M *tris* buffer of *p*H 8·0 at 22° C (ref. 11). The activities of the enzyme-derivatives were compared with the activities of the corresponding free enzymes. Proteolytic activity was determined by the casein digestion method[11].

Catalytic properties. The catalytic constants $(k_c - k_0)/c$, *c* being the concentration of histidine[12], were calculated for various products and are compiled in Table 3. The *p*-amino-phenoxy-hydroxypropyl-'Sephadex *G*200' shows no catalytic effect toward *p*-nitro-phenylacetate.

The catalytic activities of histidine-containing polymers are of the same order as reported for the corresponding polypeptide polymers prepared by Katchalski *et al.*[13]. Thus the nature of the polymer does not appear to influence very much the catalytic action displayed by the fixed groups. It is also interesting to note the similar catalytic constants of chymotrypsin 'Sephadex *G*25' and '*G*200'. This finding indicates that the chymotrypsin buried in the interior of the matrix ('Sephadex *G*200') exhibits the same or closely the same activity as the 'surface-fixed' enzyme ('Sephadex *G*25'). The activity ratios listed in Table 4 were determined within 5 days after the coupling product had been shrunk and dried once. The activities of the preparations *CHY* : 2 and *TRY* : 1 dropped by about 20 per cent after storage under 10^{-3} M hydrochloric acid for 1 month at +5° C.

Table 3. CATALYSIS OF THE HYDROLYSIS OF *p*-NITROPHENYLACETATE AT 22° C IN 0·2 M PHOSPHATE BUFFER OF *p*H 7·6 (5 PER CENT BY VOL. OF DIOXANE) OF SOME DERIVATIVES OF 'SEPHADEX' COMPARED WITH IMIDAZOLE AND CHYMOTRYPSIN

Catalyst	Preparation No.	Histidine-content of the polymer μmole/g	$\frac{k_c - k_0}{c}$ l./mole/min
Imidazole	—	—	28
Chymotrypsin	—	—	10^4

His-His-'Sephadex *G*25'	—	350	4·8
Chymotrypsin-'Sephadex *G*200'	*CHY* : 1*a*	17·8	2,000
Chymotrypsin-'Sephadex *G*200' (after 4 weeks)	*CHY* : 1*b*	17·8	1,600
Chymotrypsin-'Sephadex *G*25'	*CHY* : 4	7·2	2,100

Table 4. COMPARISON OF RATES OF HYDROLYSIS OF SOME SUBSTRATES BY FREE ENZYMES AND CORRESPONDING 'SEPHADEX' DERIVATIVES

Enzyme-'Sephadex' (Preparation No.)	Substrate	Activity ratio bound to free enzyme (%)
Chymotrypsin-'Sephadex G200' (*CHY* . 1*a*)	Tyrosine ethyl ester	14–25
Chymotrypsin-'Sephadex G200' (*CHY* · 1*a*)	Casein	3–5
Chymotrypsin-'Sephadex G200' (*CHY* : 2)	Tyrosine ethyl ester	19–34
Chymotrypsin-'Sephadex G25' (*CHY* : 4)	Tyrosine ethyl ester	20–33
Chymotrypsin-'Sephadex G25' (*CHY* : 4)	Casein	2·5–4
Trypsin-'Sephadex G200' (*TRY* : 1)	*N*-benzoyl-arginine ethyl ester	17–24
Trypsin-'Sephadex G200' (*TRY* . 1)	Casein	2 5–4
β-Amylase-'Sephadex G200'	Soluble starch	0

The activity was not affected by five cycles of swelling with water and shrinking with acetone performed at room temperature over a period of 2 days.

The activity of the dried polymer *CHY* : 1*a* was unaltered after storage for 5 weeks at −10° C, but a sample *CHY* : 1*a* lost 80 per cent of its activity after storage at room temperature for the same time.

The coupling of chymotrypsin and trypsin to 'Sephadex' by way of isothiocyanate derivatives can be performed with retention of enzymatic activity. The method should be applicable to other enzymes. The synthesis of the corresponding soluble dextran derivatives is under investigation.

The results in Table 4 confirm the expected effect of steric hindrance. Soluble starch apparently is excluded from the enzymatically active regions of β-amylase. The low molecular weight substrates are hydrolysed more efficiently than the substrate polymers. This discriminating effect on the activity towards substrates of different molecular size should make applications possible utilizing this behaviour to advantage. Occasions might arise, for example, where preferential digestion or other selective action is desirable.

Another fascinating potential of solid phase fixed enzymes might be mentioned, although it must have occurred to students in the field and has probably been stated elsewhere. If the space distribution of the enzyme could be controlled, it should be possible to build up protein sequences in a properly ordered manner so as to make possible syntheses similar to those occurring in Nature. For many reaction pathways this may perhaps be effected simply by mixing separately prepared fixed enzymes in granular form or by using stratified beds. Reaction routes including very short-lived intermediates may require more sophisticated methods for production of satisfactory functioning multiple enzyme systems.

This investigation was supported by grants from the Swedish Technical Science Research Council and the U.S. Agricultural Research Service.

We thank Dr. David Eaker for help and advice with the amino-acid analysis and Mr. Sverker Ernback, Mr. Sune Karlsson and Mr. Ragnar Thorzelius for valuable technical assistance.

ALTERED PROPERTIES OF DEOXYRIBONUCLEIC ACID NUCLEOTIDYLTRANSFERASE AFTER INFECTION OF MAMMALIAN CELLS WITH HERPES SIMPLEX VIRUS

By DR. H. M. KEIR, J. HAY and J. M. MORRISON
Institute of Biochemistry, University of Glasgow
AND
DR. H. SUBAK-SHARPE
Medical Research Council Experimental Virus Research Unit, Institute of Virology, University of Glasgow

THE activity of DNA nucleotidyltransferase (*EC* 2.7.7.7) increases markedly in mammalian cells after infection with vaccinia virus[1,2], with pseudorabies virus[3] and with herpes simplex virus[4]. In the last-mentioned case, the increase has been related in time to an increase in the activity of deoxyribonuclease (*EC* 3.1.4.5), and to the appearance in the infected cells of complement-fixing antigens, herpes DNA, morphological particles and infective virus[5]. Measurements of nucleotidyltransferase activity in soluble preparations derived from sub-cellular fractions of the herpes-infected cells have shown that the activity increases by 600 per cent in the nuclei, by 200 per cent in the mitochondria-microsome fraction and by only 50 per cent in the cell sap fraction[4].

We now have evidence which indicates that the DNA nucleotidyltransferase activity in herpes-infected cells is attributable at least in part to an enzyme different from that in the uninfected control cells.

*BHK*21 (*C*13) cells[6] were grown as previously described[5], and the monolayers were infected *in situ* with herpes simplex virus strain α at a multiplicity of exposure of 10. Four hours later, the cell sheets were washed with phosphate-buffered saline, removed from the glass with versene (0·5 mM in phosphate-buffered saline), washed twice with phosphate-buffered saline by centrifugation at 0° C, and stored at −70° C. The incubation period of 4 h (after addition of the virus) was chosen because previous results had indicated that by this time the DNA nucleotidyltransferase activity has increased substantially while the post-infection increase of deoxyribonuclease activity is as yet minimal[4]. Because the high levels of deoxyribonuclease activity which develop in the infected cells by 8 h after infection could interfere seriously with the nucleotidyltransferase assay by damaging the DNA-primer and the DNA-product, the gathering of the cells 4 h after addition of virus represents a safeguard which allows valid comparison of control and infected nucleotidyltransferase preparations.

The frozen control and infected cell batches were thawed at 0°–2° C and were quickly homogenized in 10 volumes of 0·02 M *tris*-hydrochloric acid *p*H 7·5, 0·001 M versene, 0·005 M 2-mercaptoethanol. Magnesium sulphate and potassium chloride were immediately added to final concentrations of 0·004 M and 0·15 M, respectively, and

the preparations were centrifuged for 1 h at 105,000*g*. Each supernatant fraction (*S*) representing the initially soluble material was collected, and the sediments were homogenized vigorously for 30 sec in 0·02 M *tris*-hydrochloric acid buffer *p*H 7·5, 0·001 M versene, 0·005 M 2-mercaptoethanol, sonicated for 30–60 sec (ref. 7), and centrifuged for 1 h at 105,000*g*. The supernatant fraction (*P*), representing the material solubilized in the course of the re-extraction procedure, was collected and made 0·004 M in magnesium sulphate and 0·15 M in potassium chloride. An important feature of the re-extraction is that potassium chloride and magnesium sulphate are excluded during homogenizing, ultrasonication and centrifugation (see ref. 8).

DNA nucleotidyltransferase was assayed by a standard procedure[9,10] involving measurement of incorporation of [^{32}P] thymidine 5′-monophosphate from [α-^{32}P] thymidine 5′-triphosphate in the presence of the 5′-triphosphates of deoxyadenosine, deoxycytidine and deoxyguanosine, and denatured DNA-primer.

The heat-inactivation data for DNA nucleotidyltransferase plotted in Fig. 1 were obtained as follows: The enzyme preparations at *p*H 7·5 were heated at 45° C or at 50° C for various times in the presence of DNA, and cooled to 0° C. The four triphosphates and other standard assay components were then added and the mixtures were incubated at 37° C for 1 h for assay of nucleotidyltransferase.

The data suggest that: (i) the infected preparations are much more heat-resistant than are the corresponding control preparations; (ii) the *P* preparations are more heat-resistant than the *S* preparations; (iii) the infected preparations, but not the controls, are activated after 30 min pre-incubation at 45° C; (iv) the activity of the control *S* fraction actually increases during the first 5 min at 45° C (the *P* fractions behave somewhat similarly at 10 min).

The effect of pre-incubation was investigated at 50° C. The results (Fig. 2) show: (i) more than 90 per cent of the control cell nucleotidyltransferase was inactivated by 15–20 min pre-incubation; (ii) the infected preparations were again much more heat-resistant than the controls, 20–25 per cent of the initial activity surviving heating for 80 min; (iii) the infected preparations, but not the controls, clearly exhibited increased activity after 20–30 min. Omission of DNA during pre-incubation resulted in quick and drastic loss of activity from all samples (more than 50 per cent after 2 min at 45° C, and more than 90 per cent after 9 min at 45° C).

Two features stand out from the heat-inactivation data. First, at 45° C there is apparently a brief heat-activation phase after about 5–10 min; we attribute this tentatively

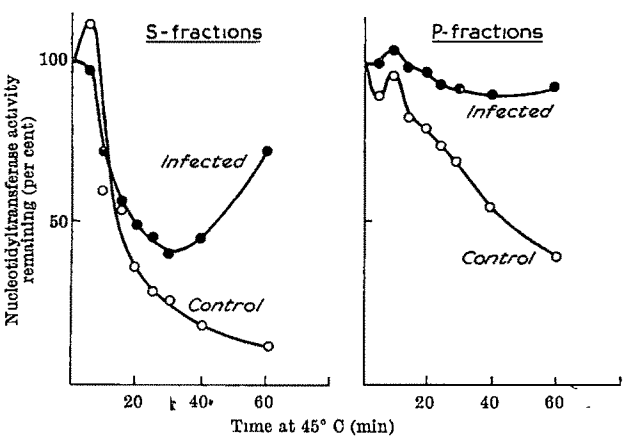

Fig. 1. Heat-inactivation of DNA nucleotidyltransferase. The enzyme preparations were heated at 45° C in the presence of 80 μg of denatured DNA, and cooled rapidly to 0° C. The triphosphates were then added together with 52 μg of denatured DNA, and incubation then followed at 37° C for 60 min for measurement of enzyme activity by the standard procedure (refs. 9, 10)

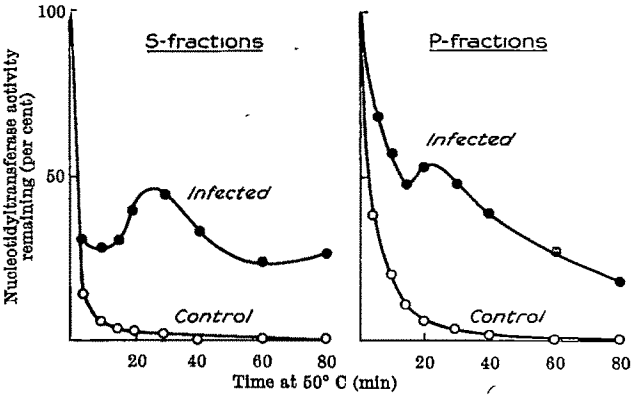

Fig. 2. Heat-inactivation of DNA nucleotidyltransferase at 50° C. The experiment was conducted according to the plan described in Fig. 1 except that the prior heating was at 50° C

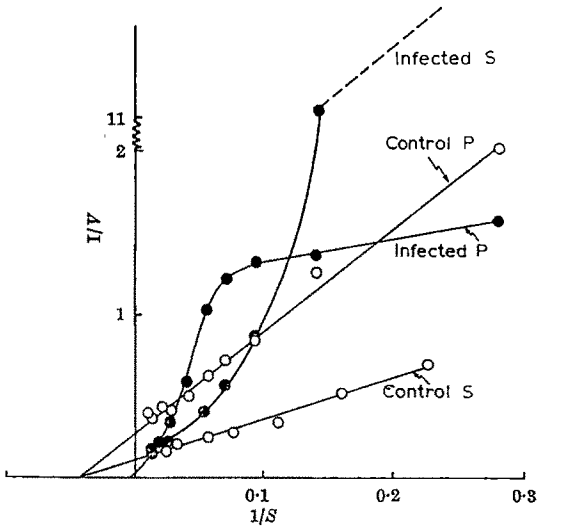

Fig. 3. Nucleotidyltransferase activity at various concentrations of DNA-primer

to activation of the heat-labile, host cell nucleotidyltransferase that is present in control and infected cells. Secondly, further activation occurs at 45° C in the infected samples only, beginning at about 40 min. At 50° C, the early brief activation observed at 45° C is no longer detectable and activation is confined to the infected samples only, now beginning at 15–20 min. This later activation effect induced by both the 45° C and the 50° C pre-incubations we attribute either to a herpes virus-coded nucleotidyltransferase or to the host enzyme modified by virus action.

When *HEp* 2 cells (human epithelioid carcinoma) were used as host cells, enzyme prepared from control and infected cells yielded results similar in all main aspects to those illustrated in Fig. 2 for *BHK* 21 host cells (hamster fibroblasts). Since the genetic origins of the *HEp* 2 and *BHK* 21 cells are quite different, while the same stock virus was used, this evidence strongly supports our hypothesis that the heat-stable nucleotidyltransferase in infected cells is virus-coded.

The rates of DNA nucleotidyltransferase activity at various concentrations of DNA-primer were measured for the control and infected samples, and the results are expressed as double reciprocal plots[11] ($1/v$ versus $1/S$) in Fig. 3. The plots are linear for the controls, but bimodal for the infected preparations.

Other evidence of different behaviour between DNA nucleotidyltransferase preparations from control (*BHK* 21) and infected cells stems from preliminary investigations of the magnesium ion requirements of the reaction. These showed that the infected *S* and *P* preparations have essentially one Mg^{2+} optimum (20–24 mM) while the

control *P* preparations have two (8–10 mM and 20–24 mM). The control *S* preparations show only the lower Mg^{2+} optimum. Pre-incubation of the infected preparations (or of the control *P* fraction) at 50° C results in a shift of the Mg^{2+} optimum from 20–24 mM to 8–10 mM.

In concurrent experiments using nucleotidyltransferase preparations from control and infected *HEp* 2 cells, we have tested the priming capacities of native herpes virus DNA, and of native and heat-denatured Landschutz ascites-tumour cell DNA. We have consistently observed that native DNA, though a very poor primer for the control enzyme preparations, is a highly effective one for the enzyme prepared from infected cells. Moreover, preliminary results indicate that native herpes DNA is a better primer than native mammalian DNA for the infected cell enzyme. In contrast, heat-denatured DNA serves as a good primer for both enzyme preparations. Similar results with respect to priming by native and denatured DNA from the ascites-tumour cells have been obtained for enzyme prepared from control and infected *BHK* 21 cells.

Consideration of the data presented in Figs. 1–3, of the Mg^{2+} requirement data, of the investigations of DNA priming, and of the similar behaviour of nucleotidyltransferase prepared from infected hamster cells and infected human cells, prompts us to suggest the following hypothesis. Nucleotidyltransferase as obtained from infected cells at the time when they are most actively synthesizing herpes DNA (see ref. 5) exists principally in a native conformation characterized by possession of two polymerizing sites which operate interdependently in the native enzyme. One catalyses nucleophilic attack by the 3′-hydroxyl group of the substrate triphosphate on the α-phosphate group of a 5′-triphosphate terminus on one of the growing daughter DNA strands (see refs. 12 and 13), the other concurrently catalyses nucleophilic attack by the 3′-hydroxyterminal group of the other growing daughter strand at the α-phosphate of another incoming substrate triphosphate. The concerted and interdependent action of the two catalytic sites on the enzyme thus allows unidirectional and semi-conservative replication along the parent DNA double-helix producing two daughter double-helices each identical with the parent. This implies that the two catalytic sites are not identical. An extension of the hypothesis is that the native enzyme can undergo a transition such that the two active sites are no longer fully interdependent (for example, a dimer to monomer transition). The transition may occur naturally, *in vivo*, or it may be induced *in vitro*, for example, by pre-incubation at elevated temperatures. We postulate that the uninfected cell nucleotidyltransferase is of a similar nature but comparatively much less stable, thus in our experiments is already mainly in monomer form.

In conditions in which the two sites are no longer interdependent, that is, after the postulated dimer to monomer transition, polymerization along denatured single-stranded template (as in the standard nucleotidyltransferase assay) should proceed at an increased rate. This increase is in fact observed (Figs. 1 and 2) with heat-denatured DNA as primer, and it suggests that the postulated dimer to monomer transition proceeds much more readily with the host enzyme (after 5 min at 45° C) than with the herpes-induced enzyme (after 20–30 min at 50° C).

Interdependence operates only when both sites are actively engaged in replication of one primer molecule of double-stranded DNA, or of two primer molecules of single-stranded DNA held in close apposition by the binding sites on the enzyme.

The infected cell enzyme was always isolated at a time when it could be expected to be fully engaged in production of herpes virus DNA (4 h after infection). Thus we would expect it to possess the ability to use native and denatured DNA with equal efficiency, because it is expected to have been obtained almost entirely in the active or dimeric form. On the other hand, only a relatively small proportion of the control cells would have been actively engaged in DNA synthesis at the time of preparation of the enzyme, since these cells were not synchronized with respect to the growth cycle and therefore most of the control nucleotidyltransferase would be expected to be found degraded to the monomeric conformation. This accords with our observation that the control preparation has only a very limited ability to accept native DNA as primer.

Similar reasoning may be applied in interpretation of our results obtained with Mg^{2+} concentration requirements. Thus, the higher Mg^{2+} optimum is ascribed to the requirement of the intact, dimeric nucleotidyltransferase; the higher optimum is displayed by the herpes virus-induced enzyme and also by some of the control *P* fraction. The latter would be expected to contain enzyme from the cell nuclei and the nuclei would reasonably be expected to contain all of that amount of enzyme of the control cells that was collected while in the phase of DNA synthesis. These ideas are supported by the observations: (i) that pre-incubation of the infected preparation at 50° C or of the control *P* fraction at 45° C results in a fall of the Mg^{2+} optimum from 20–24 mM to the lower level of 8–10 mM, and (ii) that the control *S* fraction exhibits only the lower optimum.

The data shown in Fig. 3 are difficult to interpret with real confidence, but it may be noted that the lower limbs of the infected plots show a curvature that is concave upwards while the control preparations are virtually linear. If the points on the curved plots of the infected samples are replotted as $1/v$ versus $1/S^2$ they plot for both the *P* and *S* fractions as a straight line; thus these data fit the hypothesis that the action of infected-cell nucleotidyltransferase is bimolecular with respect to single strands of DNA. The upper limb of the infected-*P* plot in Fig. 3 is clearly linear on the $1/v$ versus $1/S$ plot, and therefore, at these low DNA concentrations, the linearity might be regarded as due to nucleotidyltransferase molecules with only one of the two binding sites occupied by a strand of DNA.

In conclusion, we believe that the results presented here are informative in two ways: First, they suggest that the increase of DNA nucleotidyltransferase activity observed after infection with herpes simplex virus can be attributed either to elaboration of a virus-coded enzyme or, less likely, to induction of modifications in the host enzyme by the infective process. We favour the former view not only for genetical reasons but also because modification probably could not account for the increased level of activity which rises to 5–7 times above the control level at 5–6 h after infection[4]. Secondly, the behaviour of the two nucleotidyltransferase systems under the experimental conditions used here has suggested a hypothesis for the mechanism and control of DNA synthesis *in vivo*.

We thank Prof. J. N. Davidson and Prof. M. G. P. Stoker for their interest and support. The investigation was aided by a grant from the British Empire Cancer Campaign for Research. J. Hay and J. M. Morrison held Medical Research Council scholarships during the course of this work. We also thank Miss H. Moss and Mr. P. Ferry for technical assistance.

LIPIDS OF PHOTOSYNTHETIC SYSTEMS

By A. T. JAMES and B. W. NICHOLS
Unilever Research Laboratory, Sharnbrook, Bedford

THE chloroplast has one of the highest contents of lipid (~ 50 per cent dry weight) of all cell organelles, but unlike the pigments, quinones and tocopherols, the function of acyl lipids has not yet been defined even though their structures are now well understood (see Benson[1] and Carter[2]). These lipids could function as either (or both) chemical or structural components of the photochemical system.

The ideal approach to this problem would be to isolate whatever unit of the chloroplast is capable of carrying out all the known photochemical reactions as well as the associated lipid syntheses, and to fully define all its protein, enzyme, and lipid-soluble components. Since this is difficult in any single laboratory we have adopted the indirect approach of investigating the fatty acid and acyl lipid composition of a variety of photosynthetic systems, that is, photosynthetic bacteria, yellow, blue-green and green fresh-water algae, marine algae, mosses, and leaves from widely different species of higher plants. In addition, we have studied the effect of light on etiolated leaves and algae so far as their fatty acid composition, rate of biosynthesis of unsaturated fatty acids and turnover of the acyl lipids are concerned. These data, together with those already published, enable some conclusions to be reached as to the function of these lipids in the photosynthetic particle.

Acyl lipids as chemical co-factors in photosynthesis. Chemical involvement of acyl lipids in the electron transport chain would require some easily oxidizable component, and for this role the unsaturated fatty acids are the most likely candidates. We might then expect photosynthetic systems of the same type to contain unsaturated fatty acids of similar structure and that there should be some form of light-stimulated production of these components paralleling that of some of the photosynthetic pigments.

* Blackpine, *Pinus thunbergii*

A summary of the unsaturated fatty acids occurring in photosynthetic systems is given in Table 1*A* and *B*. Of these, only monoenoic fatty acids occur in the photosynthetic bacteria and in one of the fresh-water blue-green algae (*Anacystis nidulans*), whereas all the other systems contain a variety of *cis*-polyunsaturated fatty acids of chain-lengths ranging from C_{16} to C_{22} having usually (but not invariably) a methylene-interrupted sequence of double bonds.

Two classes of photosynthetic organisms occur, one group comprising the photosynthetic bacteria, and the other the algae and plant leaves. Both are believed to have similar fundamental photochemical pathways but only the latter is able to evolve oxygen under the influence of light (the Hill reaction).

However, the blue-green alga *Anacystis nidulans* can carry out the Hill reaction but its only unsaturated acids are monoenoic. Thus there is no correlation between the distribution of any type of polyunsaturated fatty acid and the occurrence of the Hill reaction. This suggested correlation was put forward by Erwin and Bloch[3] on the basis of a study of the distribution of fatty acids in plants and algae, and on the effect of light on the biosynthesis of α-linolenic acid.

While it is true that exposure to light of an etiolated leaf (Table 2) or transference of green algae to an entirely photosynthetic mode of existence (Table 3) does cause a stimulation of α-linolenic acid synthesis, this acid is already present in dark-grown leaves and heterotrophically grown *Chlorella*. Also, α-linolenic acid is found in all plant tissues and is not specifically associated with chloroplast-containing structures[4]. The action of light on etiolated leaves causes a rapid synthesis of chlorophyll, β-carotene, lutein and zeoxanthin[5] and the production of a specific fatty acid, *trans*-Δ-3-hexadecenoic acid[6]. This fatty acid was first identified by Debuch[7] in lipid extracts

from both leaves and green algae. We[6,8,9] and others[10,11,16] have found it to occur only in the phosphatidyl glycerol of green leaves and algae (Tables 2 and 3), and to be completely absent from etiolated systems. There was thus more reason to associate this fatty acid, rather than α-linolenic acid, with some active role in photosynthesis, particularly as the fatty acids of phosphatidyl glycerol turn over more rapidly than those of any other lipid in photosynthetic systems[6,12]. However, *trans*-Δ-3-hexadecenoic acid does not occur in some blue-green algae[13], so that unless there is some discrete difference between the mechanisms of photosynthesis in green algae and leaves and in blue-green algae, even this acid cannot be involved.

As an alternative explanation for the wide distribution of polyunsaturated fatty acids, it should be pointed out that leaves, and to a lesser extent algae, must be able to function even at low ambient temperatures, since they cannot regulate their own temperature. A high content of unsaturated fatty acids would ensure that their lipoprotein structures were fully mobile over a wide temperature range.

Lipids as structural components. Lipids can be considered as having two possible functions as components of the protein–enzyme–pigment–lipid complex of the chloroplast: (*a*) As specific structural components maintaining the lipid soluble pigments in correct spatial alignment with one another and their associated enzymes. The existence of specific interaction forces would require a similar lipid or group of lipids to occur in all the photosynthetic systems of a given type. (*b*) As relatively non-specific micellar elements which exclude water and in which the pigment–protein–enzyme complexes could be partially or completely embedded. Such water-free areas could allow the operation of electron transport chains that would be inhibited by free water. The lipid would thus act as an organized medium of low dielectric constant.

The formation of complex micelles that provide water-free areas could be done by a variety of ampiphatic lipids. Thus the different types of photosynthetic tissue could contain a wide variety of lipids performing similar functions.

Distribution of acyl lipids in photosynthetic tissues. The distribution of compound lipids in the different photosynthetic systems is shown in Table 4. There is a clear differentiation between the two groups defined by the Hill reaction. Those capable of evolving oxygen always contain mono- and di-galactosyl diglycerides, sulpholipid (6-sulpho-α-D-quinovosopyranosyl-(1–11)-diglyceride[14]), and also phosphatidyl glycerol, whereas the systems incapable of the Hill reaction have only phosphatidyl glycerol in common. Phosphatidylcholine, -ethanolamine, -inositol and cardiolipin occur in green algae and leaf extracts but are absent from both blue-green algae and washed isolated leaf chloroplasts. Investigation of the fatty acid composition of the individual lipids from these sources has shown that polyunsaturated acids and particularly α-linolenic acid are concentrated in the galactosyl diglycerides. In the case of *Anacystis nidulans*, however, which contains only saturated and monoenoic acids, there is no such particular concentration of unsaturated fatty acids[13].

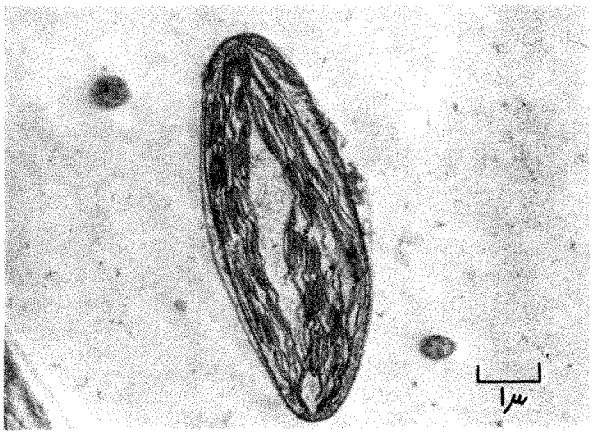

Fig. 1. Electron micrograph of chloroplast in *Ricinus communis* leaves

Leaves grown in the absence of light do not possess the normal layered structure of the chloroplasts seen in Fig. 1 but a lattice-like organization[15] having what appears to be a hexagonal structural unit (Fig. 2). This etiolated system possesses the four acyl lipids present in chloroplasts although their fatty acid composition is somewhat different, as already detailed (Table 3). During exposure to light trans-Δ-3-hexadecenoic acid, chlorophyll, pigment and α-linolenic acid particularly are synthesized. The electron micrograph shown in Fig. 3 demonstrates that after exposure to light the prolamellar structure breaks down to give a number of membranes which rearrange to give the normal lamellar structure of the mature chloroplast. The fact that very similar lipids (though in altered proportions) form part of such different structures suggests that they do not determine the detailed microstructure.

The photosynthetic bacteria operate the non-oxygen-evolving parts of the photosynthetic process with quite

different lipids (Table 4), suggesting that part of lipid function is to provide water-free structures into which the photochemically active components can fit. If this is the case, an exact stoichiometric relationship between the amounts of the different lipids, the pigments and protein (originally suggested by Lichtenthaler and Park[32]) is unlikely.

The data collated here do not support the concept that unsaturated fatty acids are chemically involved in any part of the photosynthetic processes. Four acyl lipids, namely, mono- and di-galactosyl diglycerides, sulpholipid and phosphatidyl glycerol are specifically associated with photosynthetic organelles capable of the Hill reaction and are the sole lipids of blue-green algae, but no general pattern of fatty acid composition in this group is discernible. Apart from the oxygen-evolving system, photosynthesis seems able to operate with a wide range of ampipathic lipids the general pattern of which is diglyceride linked to a polar group, suggesting that the real requirement is for non-aqueous complexes capable both of solubilizing the pigments, quinones and tocopherols and of non-specific interaction with water-soluble macromolecules such as proteins and polysaccharides.

We thank Mr. M. Stubbs for permission to reproduce his electron micrographs.

DYNAMIC ASPECTS OF GROWTH AND METABOLISM IN *Candida utilis*

By Dr. P. S. S. DAWSON

Prairie Regional Laboratory, National Research Council, Saskatoon, Saskatchewan, Canada

THE microbe, as an independent unit of life, possesses many unique advantages that make it a useful agent for investigating growth and metabolism in a cell, and for more than a century microbes have played an important part in the investigation of metabolism. Investigation of the metabolism of the single cell has been impracticable, however, and the microbial culture, comprising the cell population and its substrate, has been used instead. The traditional batch culture has served this purpose and provided the material for investigation.

In the closed system of the batch technique, cells grow in a limited amount of medium; as these cells multiply and form a population, which flourishes initially but subsequently diminishes, they produce a sequence of change in the culture that is often referred to as the 'growth cycle'. In this sequence two relatively constant phases of growth have been recognized that produce the 'proliferating cells' and the 'resting cells' of the biochemist, and much of the contemporary knowledge of microbial growth and metabolism has been obtained by their use. The batch technique, despite many limitations, has been a keystone in the development of microbiology and related disciplines.

New methods have recently been developed for cultivating micro-organisms in open systems of continuous culture[1]. In these methods, cells grow in a continuous

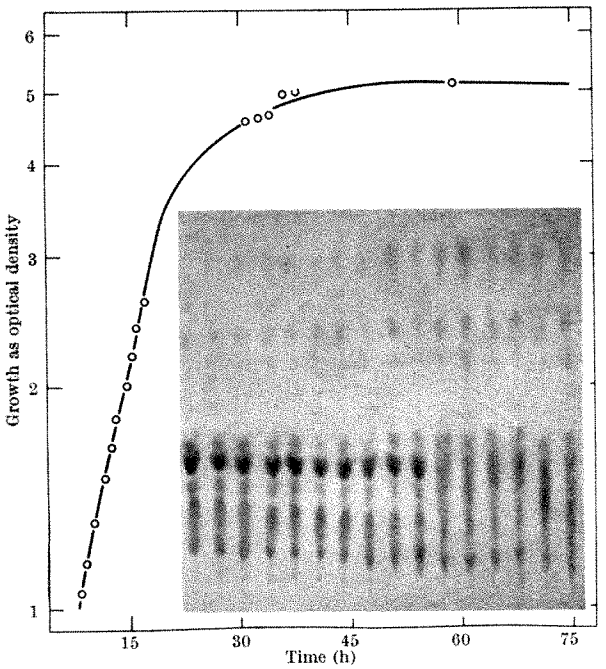

Fig. 1. Batch growth of *C. utilis* on glucose (N-limited) medium. Inset shows paper chromatogram of amino-acid pools corresponding to the points on the growth curve

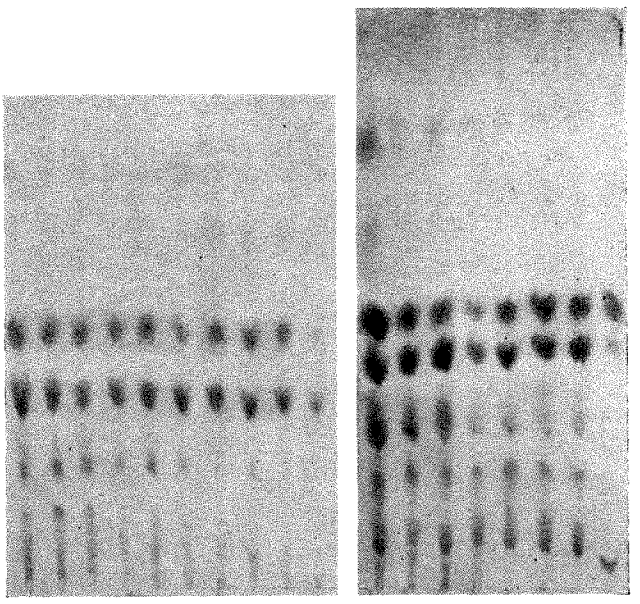
flow of medium in arrangements that use a constant volume of culture in a steady-state condition of growth. One technique, now generally referred to as chemostat culture, enables the microbial growth to be examined in any one of an infinite number of steady states that are definable, constant, and reproducible. The system confers advantages that are in sharp contrast to the transient changes of the batch growth and the often erratic reproducibility of that method.

Another important advance in methods for cultivating micro-organisms is the recent introduction of synchronization techniques to phase all, or most, of the cells in a culture, so that they divide together ('in step')[2]. In this way, the growth of a cell can be magnified by the size of the population in the culture, and the cell cycle thus becomes available for analysis by conventional methods.

The ultimate expression of cell metabolism is growth and multiplication, and in consequence these new techniques for growing microbial cells offer fresh approaches for studying the growth metabolism of the cells, especially for investigating the integrated metabolic systems of the cell *in vivo*. Because of this, the new techniques could be of fundamental importance for the future development of microbiology, biochemistry and cell physiology.

The important part that enzymes play in cell metabolism has long been recognized, but it is only recently that some indications of the nature of their formation and function in cell metabolism and cell regulation have been obtained[3]. Changes in growth and metabolism in a cell require changes in enzyme constitution, and these, reflected in the protein synthesis of the cell, must ultimately be linked to the supply of the precursors, that is, of amino-acids arising by *de novo* synthesis, turnover, or by incorporation from the medium. Variations in the synthesis of other macromolecules in the cell will likewise require a changing supply of precursors, so that changes in metabolite pools, besides those of the amino-acid pool, might be expected under different circumstances.

Various workers have reported changes in microbial amino-acid pools under different conditions of medium, and recently Holden[4], reviewing the accumulated information on the subject, concluded that the apparent lack of constancy in the composition of the pools was likely to be a consequence of the dependence of the pool on the external environment and of the ease with which this could be changed. In much of the work covered by his review, batch cultures were grown on media that contained amino-acids, and interpretations of the results were, in consequence, often complicated by inadequately defined growth and problems associated with transport and permeation phenomena. These difficulties would largely be eliminated if cells were grown in chemostat and closely controlled batch cultures using simple chemically defined media devoid of pre-formed metabolites, that is, amino-acids.



The possibility of using such techniques to examine the behaviour of various metabolic pools, as a method for examining *in vivo* metabolism in a microbe, was investigated using the yeast *Candida utilis*[5].

Cells of *Candida utilis* were grown in nitrogen-limited batch culture under defined conditions of aeration and temperature, on a simple medium that contained glucose and mineral salts. The cells obtained from samples of the culture collected during the exponential, retardation and stationary phases of growth were extracted, and the amino-acid pools obtained were chromatographed on paper. Details of the methods have been published elsewhere[6]. It can be seen (Fig. 1) that changes occurred in the spectrum of the amino-acids constituting the pool for different phases of growth, but the pool appeared to be of constant composition during the exponential phase.

When cells were grown in chemostat culture on the same medium under identical experimental conditions, but at different growth rates, the chromatograms of the extracted pools showed changes in the amino-acid spectrum with growth rate. In Fig. 2*a* the changes for nitrogen-limited growth are illustrated, and in Fig. 2*b* are shown the changes on the same medium, but under carbon-limited conditions.

Further characteristic patterns of change in the pool, with changes in growth rate, were obtained when glucose was replaced in the medium by other different carbon sources such as glycerol, ethanol, acetate and lactate, in chemostat cultures under similar nitrogen-limited conditions of growth.

Profiles, obtained by gas chromatography[6], of the amino-acid pools extracted from cells of the same doubling time (7·0 h) grown under identical conditions of culture

(*a*) (*b*)

in the chemostat on different media are illustrated in Fig. 3. The widely different spectra would suggest that metabolism is determined by the medium conditions and not by linkage to the growth rate.

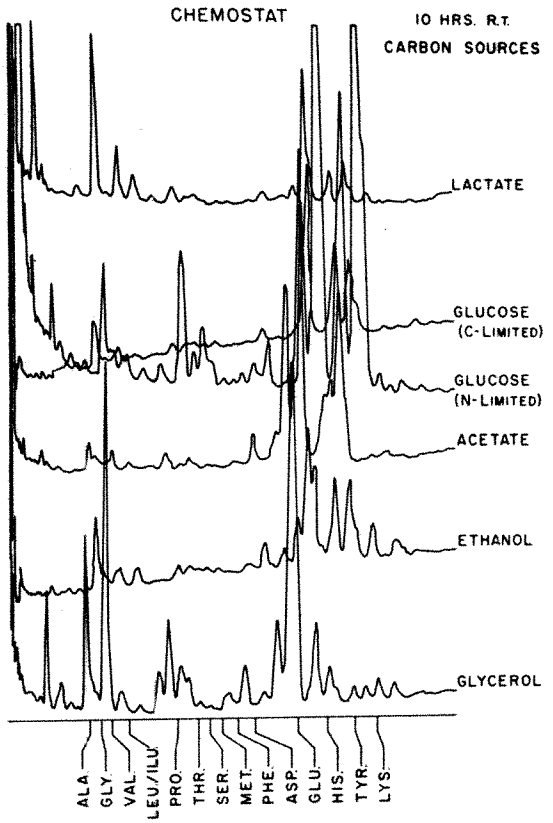

Fig. 3. Profiles of amino-acid pools, obtained by gas chromatography, for chemostat cultures of the same growth rate (residence time 10 h*) on different (N-limited) media

* Doubling time of 7 h.

A method of continuous phased culture has been devised, and is described in another paper[7], which enables the population of a chemostat culture to be maintained in a very high state of synchrony over periods of many months. Amino-acid pools extracted from sequential samples of cells grown over a cycle in this apparatus, when chromatographed, gave a pattern of change over the cycle. Variations in this pattern occurred with changes in the cycle time; that is, with the growth rate. Fig. 4 shows spectra obtained for doubling, or cycle, times between 2 h and 8 h 20 min on glucose nitrogen-limited medium, under conditions of culture identical with those used for the batch and chemostat experiments.

The pools extracted at intervals over a cycle of phased growth, when combined, produce an average pool, the spectrum of which corresponds with that obtained from cells grown in a chemostat at the same doubling time. This establishes a common basis for the two techniques[5].

The foregoing results show changes in the amino-acid pools of cells grown on the same medium, in the same culture vessel (a cyclone column fermenter)[8], and under identical cultural conditions, but in different growth systems; that is, as batch, chemostat, and phased cultures.

These results show that the amino-acid pool, in addition to being characteristic of the medium, of the environmental conditions, and of the growth rate, as already reported in a previous publication[6], also underwent a pattern of change during the cell cycle that was characteristic for the conditions operating during that cycle.

The intracellular amino-acid pool, first demonstrated in microbes by Gale[9] and extracted by his simple technique of boiling a suspension of washed cells in distilled water, was found to be adequate as a register of the overall metabolism of a culture and for detecting small changes in metabolism. However, since McQuillen *et al.*[10] had reported a rapid synthesis of cell protein in microbial cells, accelerated procedures of extraction and isolation of the pool appeared to be advisable, if the pool was to be representative of that in the cell. A rapid procedure based on the method of Gale, but modified to use membrane filtration techniques, was therefore devised

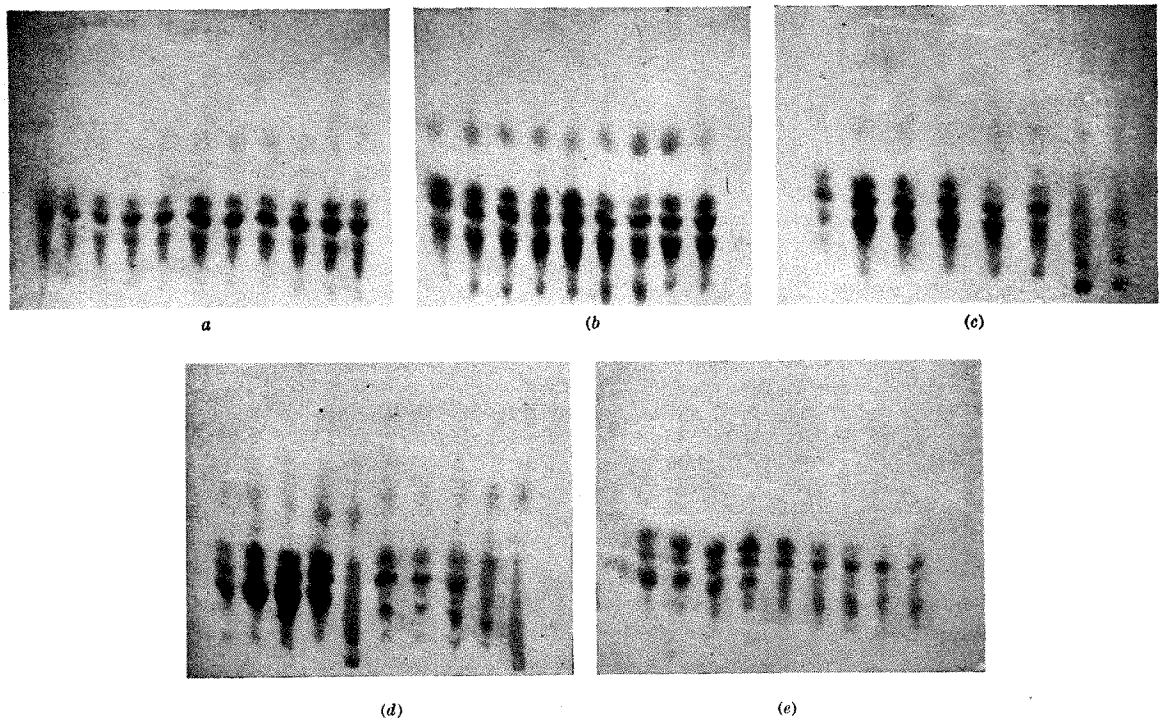

Fig. 4. Chromatograms of amino-acid pools extracted from cells of *C. utilis* growing on glucose (N-limited) medium. Sequences obtained by interval samples from phased growth for cycle times of (*a*) 2 h, (*b*) 2 h 40 min, (*c*) 3 h 15 min, (*d*) 6 h 30 min, and (*e*) 8 h 20 min

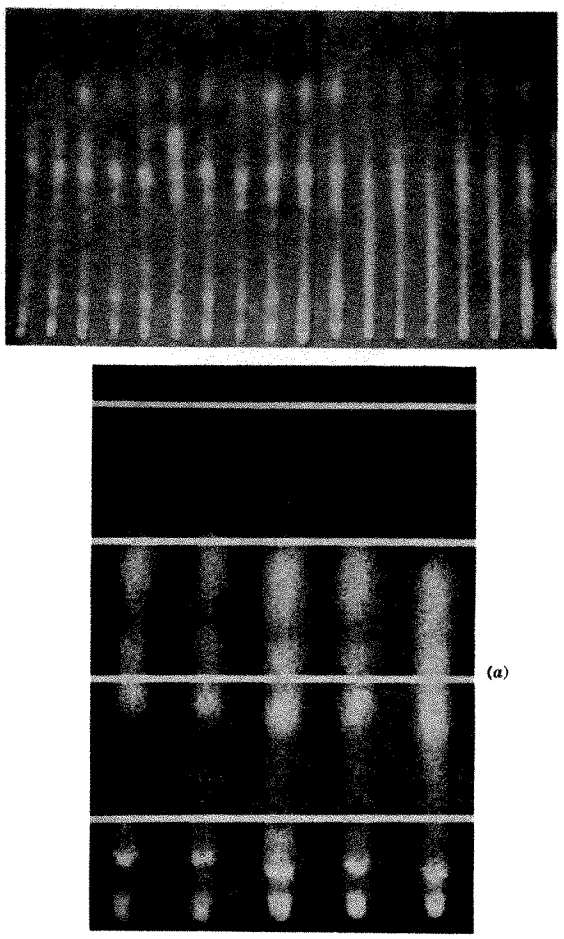
and used to extract the amino-acid pools in the foregoing experiments.

Membrane filters are resistant to a number of solvents, and the extraction method described earlier was adapted to give a serial fractionation of cells, so that empirical fractions as pools of amino-acids, nucleotides (as materials absorbing at 260 mμ) and lipids were obtained; however, freeze–thaw techniques were used instead of boiling water for the initial extraction[5].

When cells, grown by the different cultivation procedures of batch, chemostat, and phasing, were extracted in this serial manner, and systematically examined in a fashion analogous to those already employed and described for the amino-acid pools, it was found that the other constituents, nucleotides, lipids and other compounds, also changed and varied in amount, and in ways analogous to those of the amino-acid pool[5].

Fig. 5 illustrates the changes taking place in the pool of nucleotide materials during a batch culture in glucose (N-limited) media, and during a synchronous cycle of 4 h 15 min in phased culture on glycerol (N-limited) medium.



In Fig. 6 changes taking place in various other pools of the same growth are illustrated by a series of chromatogram sequences, and further aspects of this growth are summarized in Table 1.

Changes in the lipid components will be published in detail elsewhere.

It is evident that continuous variations were taking place in the cell metabolites throughout the whole of the cell cycle. These changes were repeated cycle after cycle, and the pattern was constant under unchanged conditions of cultivation, that is, of medium conditions, of growth rate and of environment. Controlled changes in the experimental parameters produced alterations in the cycle patterns under the different chosen conditions, and were analogous to the steady states obtainable in a chemostat. Continuous phased cultures operated indefinitely, like those of a chemostat, and a unit was working for over 18 months.

In the experiments reported here, the use of simple chemically defined media and closely controlled conditions of growth ensured that the metabolites extracted from the cells were products of the cell metabolism and directly reflected the active metabolism of the cells. The amino-acid and other metabolic pools, as registers of the cell metabolism, showed that the metabolism of the cell was in continual flux throughout the whole of its growth, whatever the rate of that growth. The results established that whereas the batch growth outlined the metabolic range of the organism and chemostat cultures enabled selected steady states to be closely examined, continuous phased cultures enabled this to be done on the basis of the cell cycle. The pattern of metabolism over the cell cycle, as portrayed by the pool changes, was characteristic of the environment of the cells and was constant, as a repeating pattern over the cycle, when the environment was constant.

The advantage of the continous methods for examining cell metabolism, by stabilizing growth conditions, was demonstrated by these experimental results: the techniques provide convenient methods for the systematic study of integrated metabolic systems *in vivo*, in cultures—

(b)

(a)

Fig. 5. Paper chromatograms showing materials absorbing at 260 mμ extracted from successive samples of cells of *C. utilis* (*a*) growing batch-wise on glucose (N-limited) medium, and (*b*) during phased growth on glycerol (N-limited) medium for a cycle time of 4 h 15 min

by the chemostat, or in the cell—by the phasing method. These techniques offer new dimensions for experimental explorations of the cell and open up new horizons for microbiology, biochemistry and cell physiology.

It will be apparent that the randomized conditions of the cells in conventional culture does not reflect a constant performance from the cells but only an average pattern of behaviour; that is, stabilized in chemostat and changing in batch growths. This difference will have important repercussions for many experiments using tracers where uniform or steady-state conditions in a cell have been assumed, and, as Mitchison[11] has already pointed out, much published work will need to be re-examined in the light of the dynamic changes now demonstrated as taking place in the cell over the cell cycle.

As discussed more fully elsewhere[5], the amino-acid pools do not reflect the pattern of amino-acids directly used in the current synthesis of protein taking place in the cell, but rather reflect the overall balance between the

supply and demand of these components in the cell metabolism, and more probably serve as an indication of a pattern of feed-back in the cell. Such a role would be in harmony with the suggestions of Stent and Brenner[12], and of Kurland and Maaløe[13], that the transfer-RNA molecules, or the activating enzymes themselves not saturated with their amino-acids, could serve as repressors of RNA synthesis. The changing spectra of other cell metabolites, operating in like fashion, could also have important significance in the overall regulation and control of metabolism in the cell.

The metabolic pathways leading to the precursors used for macromolecular synthesis in the cell are closely integrated at the lowest levels and largely comprise what Davis[14] has called the amphibolic area of cell metabolism. Our knowledge of the interplay and overall patterns of feed-back mechanisms is still rudimentary, but evidence is available of the possibility for integrated controls of different pathways, for example of nucleotides by amino-acids and vice versa[15–18]. The description by Magasanik[18] of the elegant control of the histidine and guanylic acid biosynthetic pathways by purine and amino-acid components, respectively, is an outstanding example of how feed-back mechanisms might be integrated.

The possibilities offered by an integrated network based on twenty channels of amino-acid feed-back and five or six channels of nucleotide feed-back lead to a system that would suffice to co-ordinate a wide range of metabolic activity, and serve to link the amphibolic metabolism with the biosynthesis of the vital macromolecules, proteins and nucleic acids. In such a system, feed-back mechanisms could operate back from a master template, to order and modulate the supplies of precursors required for the ultimate duplication of the template. The arrangement, linked to cell intermediates and connected to other areas of cell metabolism, could satisfactorily account for the phenotypic variations of the genotype observed in cellular metabolism and growth under different conditions.

In recent articles in *Nature*, Dean and Hinshelwood[20–22] have discussed the possible integrations and implications of cell reactions, cell organization and cell regulation. The work described in this article, in demonstrating a characteristic and organized behaviour of intracellular pools, lends support to their general thesis and emphasizes also the lack of information available from contemporary investigations of cell metabolism in relation to the neglected but important question of the overall supply of building units for the architecture of the cell.

The investigation of metabolic pools is an empirical exercise; their nature, origin, behaviour and complexity are unknown. It would appear that a closer investigation of metabolic pools, and of other aspects of metabolism *in vivo*, might now be attempted with advantage, possibly by using some of the methods described here, in a systematic manner.

I thank Drs. C. G. Youngs and B. M. Craig, of this laboratory, for the determinations of amino-acids and fatty acids by gas chromatography, and E. G. Darichuk for technical assistance.

POSSIBLE IMPLICATION OF MYRISTICIN AS A PSYCHOTROPIC SUBSTANCE

By DR. ALEXANDER T. SHULGIN
The Dow Chemical Co., Walnut Creek, California

WITHIN the past decade there has been a rapid expansion of knowledge of psychotropic medicine. The development of the ataraxics, and more recently of the 'psychic energizers', has depended on chemical syntheses in areas almost totally unknown in Nature.

A third field of investigation concerns those psychotropic materials known as the hallucinogenic drugs. Substances that could 'to an extent duplicate the syndrome of insanity' or that might 'permit one's capacities to transcend the limits of the sensorium' have long been in existence, but serious study of them, under the respective classifications of psychotomimetics and psychedelics, has only very recently been started. Most of these latter chemicals, in contrast to the tranquillizers and antidepressants above, come at least originally from natural sources. The pursuit and exploitation of the folk-lore that describes the many intoxicants of Nature has resulted in a disproportionately small number of new structural families. In many instances it has become apparent that the active material in an intoxicating plant is the same as, or is closely related to, a previously known system. Thus a small handful of chemical individuals, disguised by minor chemical distortions, account for the pharmacological effectiveness of a large variety of plants.

Investigations of the Amazon intoxicant ayahuasca (cappi, yaje) have led to a study of the genus *Banisteriopsis*. The analysis of these vines has revealed a series of alkaloids related to harmine which, with its hydrogenation products harmaline and tetrahydroharmine, is claimed to be the central stimulant present in *Prestonia amazonicum*. Harmine has also been isolated from the seeds and roots of the biologically active *Peganum harmala*, of both a different family and a different continent (*Zygophyllaceae*, rather than *Malpighiaceae;* Asia, rather than South America). Two additional intoxicating plants, of yet different genera (*Tetrapterys methystica* and *Mascagnia psilophylla*), probably embody this same alkaloid group.

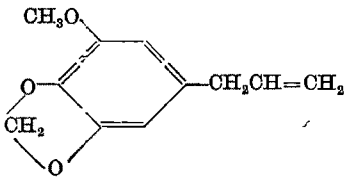
The extracts of *P. amazonicum*, mentioned above, have also been found to contain *N*,*N*-dimethyl-5-hydroxytryptamine (bufotenine). This presumed psychotomimetic also occurs in *Lespedeza bicolor* and is one of the toxic principals in the snuffs made from the seeds of *Piptadenia peregrina*, *P. colubrina* and *P. macrocarpa*. This latter genus serves as yet another connecting link, for from its various species has been isolated *N*,*N*-dimethyltryptamine. The implication of this indole as the responsible agent in a narcotic drink concocted from

the closely related plant, *Mimosa hostilis*, must be questioned, as the purified alkaloid is effective only on parenteral administration.

Mescaline is usually associated exclusively with the peyotl button from *Anhalonium lewinii* from which it was originally isolated, but more recent investigations into other cacti, *Gymnocalycium gibbosum* and *Opuntia cylindrica*, have revealed that here, too, the same phenethylamine is a major component.

The search for the sacred Mexican intoxicating mushrooms known as teonanacatl successfully led to the investigation of several members of the genus, *Psilocybe*. One of the most potent examples, *P. mexicana*, has afforded a new hallucinogenic chemical, psilocybin. This compound, the phosphate of a positional isomer (*N*,*N*-dimethyl-4-hydroxytryptamine) of bufotenine (v. s.), has now been shown to be responsible for the narcotic effects of a large number of active mushrooms of the same genus. It has been shown to be present in *Stropharia cubensis* and is suspected to occur in the genus *Panaeolus*.

d-Lysergic acid diethylamide, LSD, is perhaps the most widely studied of all the hallucinogens and was first prepared by synthetic modification of alkaloids derived from the ergot fungi. The lysergic acid structure was long thought to be unique to this plant phylum, but recent analysis of the native (Mexican) drugs ololiuqui and tlitliltzen has led to the investigation of various *Convolvulaceae* (specifically the morning glory plants *Rivia corymbosa* and *Ipomoea violacea*), wherein the intoxicating chemicals were also found to be amides of lysergic acid.



Thus, research into the active components of a score of psychotropic plant sources has revealed perhaps a half-dozen chemicals and their closely related analogues. It is possible that a similar set of circumstances, outlined later, may implicate the simple chemical myristicin (3-methoxy-4,5-methylenedioxyallylbenzene) in a comparable role.

An intoxicating snuff, yakee or paricá, is used by Indians in Colombia, and the origins of this material have been established to be a species of the genus *Virola*, *vis.*, *V. calophylla*, *V. calophylloidea*, and possibly *V. elongata*. These trees are members of the family Myristicaceae, and the essential oil myristicin has been mentioned as a possible suspect in the explanation of the biological activity. Secondly, increasing attention is being drawn, in the medical literature, to the use of nutmeg as a mentally disorganizing material. The seed of *Myristica fragrans*, on ingestion, produces cycles of delirium and giddiness. The components generally believed culpable lie in the non-terpinacious volatile oil fraction, of which the primary component is myristicin. Very recently a new, synthetic, psychotomimetic has been described, 3-methoxy-4,5-methylenedioxyamphetamine (MMDA). This base possesses the precise carbon and oxygen skeleton of myristicin, from which it can be theoretically derived, by the addition of a molecule of ammonia.

Thus, the natural essential oil myristicin may serve a psychotogen role in being a possible component of the virola tree, as a probable active agent in the nutmeg, and as a potential *in vivo* origin of MMDA. The following discussion is intended to present a complete definition of myristicin, both chemically, botanically, and pharmacologically. Further, the known biological effectiveness of it, its cogeners, its botanically related analogues, and the oils in which these have been found, is outlined and is discussed in the light of possible involvement in human intoxication.

Chemical Definition

In early descriptions of natural products, the name 'myristicin' referred to the solids that crystallized from old samples of oil of nutmeg on prolonged standing. These are now known to be myristic acid, $CH_3(CH_2)_{12}COOH$ (ref. 1). Semmler, in his initial investigations of the structures of components of oil of nutmeg[2], used the term to refer to a substance he had isolated after base isomerization and which is now known to be isomyristicin. The name was then applied to the material as found in nutmeg, and is at present used in this sense to represent 3-methoxy-4,5-methylenedioxyallylbenzene, (I).

I

Myristicin has usually been isolated from natural oils by fractional distillation, as it is crystallized only with difficulty even at very low temperatures. The first insight into its structure was achieved by Semmler, who demonstrated that the base-isomerized material from oil of nutmeg could be oxidized to a nine-carbon aromatic acid, the methoxy methylenedioxy ether of gallic acid. Misleading elemental analyses suggested the presence of a four-carbon olefinic chain. A decade later, Thoms[3], working with material isolated from oil of mace, correctly established the side-chain as being an allyl group, in analogy to the then established ether from parsley, apiole. His confirmation of Semmler's further work established that the latter had been working with the conjugated isomer, isomyristicin.

Two routes have been employed in the synthesis of myristicin. The first, reported in 1939 by Trikojus and White[4], used the monoallyl ether of 3-methoxy catechol. Claisen rearrangement yielded 5-allyl-3-methoxy catechol which on reaction with methylene iodide afforded myristicin. A second synthesis of myristicin used eugenol as a starting material[5]. Reaction with hexamine yielded the corresponding salicylaldehyde which was oxidized to the catechol described above. The over-all yield of myristicin was 8 per cent.

Myristicin reacts with bromine to form a tetrabromo derivative (m.p. 130° C) which is frequently used for characterization; the oxidation with permanganate may yield either myristicin aldehyde (m.p. 130°) or myristinic acid (m.p. 208°–210° C). Interaction with methyl magnesium iodide leads to the opening of the methylenedioxy ring with formation of 3-methoxy-4-ethoxy-5-hydroxy allylbenzene[6]. This substance, myristinol*, retains the allyl group intact as is demonstrated by its normal conversion to the conjugated isomyristinol.

Treatment of myristicin with either potassium hydroxide in alcohol or metallic sodium converts the allylic side-chain into the conjugated propenyl group. This latter compound, isomyristicin (m.p. 44° C), is convertible into both a dibromo (m.p. 109° C) and a tetrabromo product (m.p. 156° C) (ref. 3). The oxidation of isomyristicin with ozone yields myristicinaldehyde; oxidation with permanganate leads to the corresponding acid as well. Reaction with nitrous acid leads to a pseudo-nitrosite, which is further convertible through a β-nitro styrene to the corresponding phenyl acetone[7].

Myristicin is a clear, mobile, colourless oil that does not normally freeze even at very low temperatures, although a recent report[8] describes its purification by repeated crystallization at −30° C. It is best isolated from oil of parsley by vacuum distillation (b.p. 173°/40 mm, 126°/4 mm) and shows an $n_D^{20°}$ 1·5407 and a $d^{20°}$ 1·442. It has a faintly aromatic odour often reminiscent of the botanical origin. This is due, without doubt, to the inefficiencies of

* Myristinol (occasionally mylistinol) is not to be confused with myristicol, the name given to a fraction, b.p. 212°–218°, from oil of nutmeg. This alcohol (Wright, *J. Chem. Soc.*, 26, 549, 1873) has been shown to be a mixture of 1-terpinen-4-ol, borneol, and α-terpineol.

vacuum distillation. Although generally believed to be stable on storage, gradual changes in a synthetic sample have been determined by a bio-assay technique[9]. The physical properties of myristicin as isolated from oil of nutmeg must allow for the presence of elemicin as a concomitant contaminant[10].

Botanical Definition

The most important plant family containing myristicin is the Umbelliferae (syn. Ammiaceae or Apiaceae), which embraces many of the rooty vegetables and common herbs. Of the some 250 genera known in this family, about 10 per cent have appeared in the literature with some form of systematic analysis of components. Myristicin has been shown to be present in the species of each of six of these listed directly below; closely related polyalkoxy aromatics have been observed in at least three additional genera. Several of the parsley plants (*Petroselinum hortense*, *P. sativum*) yield essential oils rich in myristicin, the latter possessing the distinct advantage of yielding a distillation cut, unlike that from oil of nutmeg, that is free of elemicin. The oil of lovage that is derived from the Scotch lovage (or sea parsley) *Levisticum scoticum* contains myristicin as a major component. The rhizomes have been reported to yield well over 1 per cent of their total weight as myristicin[11]. The more common lovage, *L. officinale*, contains eugenol, but no aromatic nucleus more highly substituted. Myristicin has not been reported as a component of most of the more common fennel plants, that is. *Foeniculum vulgare* (in its several varieties, known as bitter, sweet, and Roman fennel), *Crithmum maritimum* (sea fennel), and *Phellandrium aquaticum* (water fennel). The genus *Ridolfia* has been found to be an excellent source, however, in the plant known as harvest fennel (*R. segetum*). After the removal of acidic and carbonyl-containing components, the essential oil consists of 33 per cent myristicin. The commercial dill plant *Anethum graveolens* yields essential oils derived either from the above-ground portions (known as dill-weed or dill-herb oil) or from the seeds. The dill-weed oil contains sizable amounts of myristicin as well as several related aromatics listed below. The edible variety of parsnip (*Pastinaca sativa*) has recently been shown[12] to possess properties of an insecticide and of an insecticide synergist. Analysis of a non-polar solvent extraction revealed that myristicin was the active component, although it was present in the whole parsnip to the extent of only 0·02 per cent. Many species of the genus *Oenanthe* (relatives of the dropwart) have undergone analysis as to their composition, namely, *Oe. crocata*, *Oe. stolonifera*, *Oe. californica* or *sarmentosa*, *Oe. aquatica* and *Oe. phellandrium*. The first of these species has been the most thoroughly studied because of its extreme toxicity to both animals and man (see discussion in the portion on toxicology and pharmacology), although *Oe. crocata* has never been reported to contain myristicin, but *Oe. stolonifera* has[13]. The compound is located in the fruit, and represents perhaps 1 per cent of the total weight.

In the family Labiatae (syn. Lamiaceae or Menthaceae), the genus *Orthodon* alone has been observed to contain myristicin. *O. grosseseratum* Kudo contains about 0·2 per cent volatile oils, which contain a small amount of myristicin. *O. asaroniferum* Fujita, so named because of an appreciable amount of asarone in its 0·3 per cent volatile oil fraction, has been equated to *O. asaniferum* by a virtually identical oil composition, which includes a small amount of myristicin[14].

Analysis of the 'Nepal camphor wood' of India, *Cinnamomum glanduliferum* (fam. Lauraceae), has revealed three components, safrole, elemicin and myristicin[15]. Identification of the latter was made by comparison of the tetrabromide with a reference specimen.

The only plant classified under the family Myristicaceae that has been documented as containing myristicin is the nutmeg tree. This source (*Myristica fragrans* as well as many additional species) yields through its seed (the nutmeg) or the sheath of the seed (mace) a volatile oil fraction that contains about 4 per cent myristicin. If the source of the drug yakee (paricá) can be assigned to trees of the genus *Virola* (as mentioned in the introduction) and the presence of myristicin demonstrated, then the aforementioned species will constitute a second occurrence in the family Myristicaceae.

Within these botanical families there are frequent occurrences of many compounds that may be considered as close analogues of myristicin. The term analogue here defines aromatics containing at least three oxygen functions and a three-carbon olefinic chain. The propenyl analogue of myristicin itself, isomyristicin, is known to accompany myristicin in *A. graveolens*. It is most unlikely that it could be generated from myristicin in the course of isolation of the essential oil fraction, as other oils of the Umbelliferae, isolated in similar ways and containing allyl compounds equally easily isomerized (see following), are not found to contain the propenyl isomer.

Elemicin, 3,4,5-trimethoxyallylbenzene, is the analogue of myristicin, in which the methylenedioxy group has been replaced with two methoxy groups. It has been mentioned earlier as a congeneric contaminant of myristicin in the oil of nutmeg. Further, it is one of the principal components of yet another of the orthodon oils, *O. elemiciniferum*. It has yet to be demonstrated in any member of the family Umbelliferae. The positional conjugated isomer of elemicin, asarone, is 2,4,5-trimethoxypropenylbenzene. It occurs in the orthodon group, as mentioned here, as the definitive component of *O. asaroniferum*. In the family Umbelliferae, it is found in the oil of carrot (*ex Daucus carota*). The strict isomer of myristicin and elemicin, namely, 2,4,5-trimethoxyallylbenzene, is unknown in Nature.

Among the more highly substituted analogues of myristicin, both 2,3,4,5-tetramethoxyallylbenzene and apiole* (2,5-dimethoxy-3,4-methylenedioxyallylbenzene) are observed as components of the oil of parsley, *P. sativum*[3]. The positional isomer of apiole, 2,3-dimethoxy-4,5-methylenedioxyallylbenzene (dillapiole), accompanies myristicin in *Anethum graveolens*. It also occurs in *A. sowa* (dill-seed oil) as well in the sea-fennel *Crithmum maritimum*. In the family Labiatae, *Orthodon formosanum* contains only 0·1 per cent oil, but this is 65 per cent dillapiole.

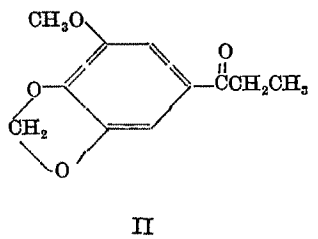
Pharmacological Definitions

The pharmacology of these materials may be divided into three groupings: that of botanicals known to contain myristicin, that of isolated myristicin concentrates, and that of chemicals closely allied (in both molecular structure and in natural origin) to myristicin.

Plants of the genus *Oenanthe* have long been known to be highly toxic both to animals and to man. Oenanthotoxin has been isolated as the toxic principal of *Oe. crocata* and has been established as a multiply unsaturated diol[16]. The toxic symptoms are characterized as initial nervous and intestinal disturbance followed by emesis, mydriasis, cyanosis and convulsions. In humans, a lethal dose is effective within 2 h of ingestion. The purified material, oenanthotoxin, shows a pharmacological spectrum parallel to that of a tincture of the natural tuber but cannot be the sole toxic principle, as the extract devoid of any oenanthotoxin still produces toxic symptoms in man[17]. A non-toxic ketone, crocatone(II), has been isolated which bears a close resemblance to myristicin. Another species of water parsley, *Oe. sarmentosa*, is reported to be non-toxic[18], but no attempt has been made to establish the presence of myristicin. Thus, one must conclude that any responses to myristicin as in these plants would be obscured by the presence of oenanthotoxin.

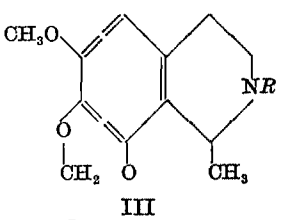
* The term apiole, representing the compound 2.5-dimethoxy-3,4-methylenedioxyallylbenzene, is not to be confused with the same word (often without the final 'e') used to describe the crude green oil of parsley.

The parsnip, *P. sativa*, has only recently been shown to contain myristicin[12]. It has long been known that, in sensitized individuals, contact with the juices leads to actinic dermatitis. Various furocomarins have been isolated and two of them display biological activity; these are pastinacin, which shows spasmolytic and vasodilating properties, and xanthotoxin, which has been used in the treatment of vitiligo (non-congenital leukodermia)[19]. It appears that, here again, any responses of the myristicin present would be masked by active, but unrelated, congenors.



The pharmacology of *A. graveolens* (dill) is virtually unknown. The oil has been recommended as a remedy for hiccoughs and emesis, and as an aqueous solution, as a carminative. Toxicity due to excess is unreported.

The most frequently investigated form of parsley is, rather than the distilled oil, the oleoresin which is obtained by extraction. This fraction is called 'apiol', 'liquid apiol', or green oil of parsley. This natural extract received a clouded reputation in the 1930's when a popular claim of effectiveness as an abortifacient coincided with a commercial product which contained some 30 per cent *o*-cresyl phosphate as an impurity. The polyneurites, paralyses and deaths associated with its misuse during this period have been blamed on this contaminant. The uncontaminated extract produces a fall in blood pressure, tremors, and weakness of extremities similar to nutmeg poisoning. This is discussed later.



Although various fennels have long been established in the medical world, the only one that contains myristicin, *R. segetum*, has a totally unknown pharmacology. Similarly, studies on the genus *Orthodon* have been conducted solely as a guide to taxonomic arrangement. *L. scoticum*, too, is unexplored although the related lovage, *L. officianele*, apparently dates back for centuries in medical history.

The seed of the myristica has long been enveloped in a folklore of emmanogogic and ecbolic potency, and consequently there is a large body of literature available concerning its misuse. As the animal and human pharmacology have recently been reviewed[21], only a generalized syndrome of human intoxication will be described. The ingestion of about 5 g of the whole seed (approximately one large nutmeg) leads after a period of a few hours to a more or less severe physical collapse, characterized by a weak pulse, hypothermia, clamminess of the extremities, giddiness, vertigo, nausea and a feeling of congestion and pressure either in the chest or abdomen. For some 12 h there is an alternation of delirium and stupor, and this is usually resolved by a heavy sleep. For a period of several days there may be headaches and perhaps spells of dizziness. Cases resulting from the ingestion of powdered nutmeg seem to parallel this general syndrome.

It is of interest to note that two of the components of *A. lewinii*, the source of mescaline, possess the same aromatic substitution pattern as that of myristicin. The isoquinolines lophophorine and anhalonine (III; R = CH_3, R = H, respectively) are natural components of the native cactus. Their pharmacologies are virtually unknown.

II

III

The only myristicin concentrates that have received any pharmacological evaluation have been obtained from nutmeg. Animal responses have been summarized[21] and reflect, apart from liver disruption, a modest hypotensive response. The first of the two reports on effectiveness in humans describes a total dose of 400 mg 2 or 3 h following ingestion there were suggestions of elation or of anxiety in several of the experimental subjects[22]. The second report involves a preliminary employment in diagnosed mental illness[23] but does not elaborate on the psychotropic effectiveness.

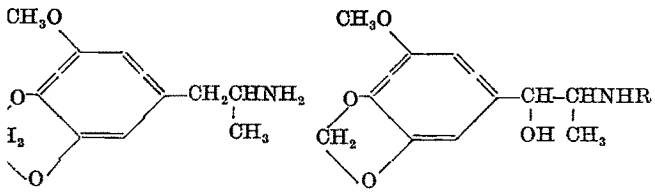
Apiole is the most carefully investigated of any of the related polyalkoxylated aromatic propenes. The syndrome of human poisoning includes, besides a transient intoxication, headaches, indigestion, loss of appetite and fever. The isomeric isoapiole, as a pure chemical, produces similar effects in human subjects. There is heart excitement and an expanded pulse becoming dicrotic on higher dosages (0·6–0·8 g). Again, the intoxication is short-lived although other of the toxic phenomena may persist for several days[24].

Of the several tri- or higher alkoxylated alkyl- or propenyl benzenes mentioned, only isomyristicin, tetramethoxyallylbenzene, and recently *cis*- and *trans*-asarone have received any pharmacological investigation. None of these has been reported to have been explored in human subjects, although recent studies in primates have shown *trans*-asarone to possess tranquillizing effects similar to chlorpromazine. Dosages of 5 mg/kg produced a catatonic indifference lasting several days[25].

Theoretical Modes of Action

The possibility must be considered that myristicin *per se* is not the form in which the substance is found in Nature. Thus, the physical isolation of the oil from nutmeg, parsley, etc., may employ techniques sufficiently strenuous to liberate myristicin from a precursor 'protomyristicin'. This natural form may then be either the actual toxicant in the instance of human ingestion, or may generate the active product *in situ*, perhaps at a site or in a concentration not otherwise attainable. These speculations are in accord with the inability to imitate nutmeg intoxication with synthetic myristicin. On the other hand, the isolated apiole from parsley has an effectiveness not enjoyed by the whole plant. This explanation can only be supported by an increasingly careful analysis of the nature source of these materials.

An appealing explanation of the action of myristicin involves the potential addition of a molecule of ammonia to the allyl chain. Such a reaction would readily explain the position of the synthetic drug MMDA, IV (ref. 26). Amination of the analogous ether elemicin has been shown to yield 3,4,5-trimethoxy amphetamine(TMA) *in vitro* by way of a bromo intermediate[27]. Further, a similar addition with an available substituted amine would lead easily to a corresponding N-substituted amphetamine.



The facile isomerization of an aromatic allyl group to the conjugated propenyl counterpart is assumed to occur in the intact organism[28]. Thus the production of an aromatic acid as a metabolic product of allyl compounds presumes such a preliminary isomerization (that is, safrol → piperonylic acid). The propenyl analogue, isomyristicin, would again be capable of accepting either ammonia or amines as is true with the allyl isomer here, leading to the *in situ* generation of substituted amphetamines. Many other types of reactions at such a double bond are possible, such as oxidation or the addition of non-nitrogenous nucleophiles (alcohols→ethers, mercaptans→thioethers).

Hydrogenation of the double bond in either the allyl or propenyl isomer is improbable. Such a mechanism is not known in human detoxication, and in those instances wherein an olefinic material may be compared directly with the saturated counterpart, the latter is less potent and more slowly acting (for example, anaesthetic ether, barbiturates).

Oxidation could occur either on the ring of myristicin, or on the side-chain with or without chain cleavage. Ring oxidation, a well-recognized biological mechanism, would lead to a demethylated analogue either of apiole or

of dill-apiole. In the light of the known human effectiveness of apiole, this route has appeal, although its mode of action in turn must still be explained in terms of the present discussion of myristicin. Chain oxidation would lead to either 3-methoxy-4,5-methylenedioxyphenyl acetic acid or the corresponding benzoic acid. Both types of products have frequently been observed in the metabolism of three-carbon chains, but in no instance has either type represented anything other than a biological end-product. Hydroxylation of the chain would lead, in the instance of the propenyl isomer, to the enol form of the corresponding propiophenone or the phenylacetone. The former has been mentioned here (crocatone) and is a non-toxic component found in *Oenanthe*. Recently, however, the acetophenone analogue of crocatone was synthesized and found to be of comparatively high toxicity to mice[29]. Using the transaminase enzyme system, the phenyl acetone isomer could easily be converted again to the MMDA. This process has been mentioned in connexion with elemicin[21].

Recently, propenyl aromatics have been found to react readily, after epoxidation, with aliphatic amines, to form various isomers of ephedrine[30]. A parallel reaction with isomyristicin would lead to a mixture of isomers of the corresponding ethanolamines (V):

IV V

Such compounds are not known with the methylenedioxy substitution although analogous trimethoxy compounds have been synthesized[31].

A metabolic pathway which must be considered as a potential explanation of the function of myristicin in the body involves hydrolytic de-alkylation of the ring. Mention has been made here of the easy disruption of the methylenedioxy heterocycle, and a similar reaction *in vivo* employing existing hydrolytic enzymes may explain the increased potency of a methylenedioxy group over the corresponding dimethoxy analogue.

Summary

The purpose of this review has been to delineate the limits of the present knowledge concerning the aromatic ether, myristicin. An appealing suggestion exists that, as a potential factor in two natural intoxicants and as a chemical precursor to a synthetic one, it may be implicated as the responsible agent. Preliminary human pharmacology suggests that it may indeed possess psychotropic properties, but this is yet to be expanded on, and is so far quantitatively inadequate in the explanation of the effectiveness of nutmeg or of paricá.

SYNTHESIS OF VIRUS AND MACROMOLECULES BY RUBELLA-INFECTED CELLS

By DR. R. MAES, A. VAHERI, D. SEDWICK and S. PLOTKIN

Wistar Institute of Anatomy and Biology, Philadelphia, Pennsylvania

RUBELLA virus grows *in vitro* in a wide variety of mammalian cell types. A recent report[1] describes the growth of this virus in clones of a baby hamster kidney cell line (*BHK* 21) with the production of virus titres which permit an investigation of one-step growth and of virus host-cell interaction.

Rubella virus was concentrated from *BHK* 21 or RK_{13} cell supernatants[1,2] by dialysis against 'Carbowax 20-*M*' until an approximately ten-fold concentration was obtained. The virus was then dialysed overnight against phosphate buffered saline and centrifuged for 4 h at 4° C and 25,000 r.p.m. in an '*SW*39' Spinco rotor, on a cushion of 0·7 M sucrose in phosphate buffered saline. In this way, most of the serum was removed. The sucrose as well as 1 ml. of the adjacent supernatant solution were taken out by a syringe and dialysed against phosphate buffered saline. By these concentration procedures, virus titres were increased fifty or one hundredfold, up to between 10^7 and 10^9 TCD_{50}/ml.

The cultures were infected with this virus-concentrated pool at a multiplicity of 5 or 10 TCD_{50} per cell. Fig. 1 shows the growth curves of cell-associated and extracellular rubella virus in two cell lines after infection with 5–10 TCD_{50} per cell. The virus multiplication is presented as an increase of titre above the virus present intracellularly by 10 h after infection. Although the biological characteristics of the two cell lines[3,4] differ considerably, no basic difference was observed in the time-lapse for the appearance of the new virus. It has been shown by Parkman *et al.*[5] that a true diploid cell culture, such as that of an African green monkey kidney inoculated with 10^4–10^5 InD_{50}, responds in the same manner, the end of the eclipse period occurring at about 12 h after infection. This growth curve also seems to be valid for a continuous line of Rhesus monkey kidney cells (LLC-MK_2)[6]. However, with the same input multiplicity of infection, the maximum intracellular titres obtained in the four systems vary considerably, being 10^4 TCD_{50} in green monkey kidney, 10^5 TCD_{50}

in *LLC-MK*$_2$ cells, 10^6 *TCD*$_{50}$ in *RK*$_{13}$, and $10^{6.8}$ *TCD*$_{50}$ in *BHK* 21.

On the basis of the growth curves it was determined that rubella virus synthesis is not inhibited by actinomycin *D* and that infection has little effect on cellular synthesis of macromolecules. When 2·5 γ/ml. of actinomycin *D* (Merck, Sharp and Dohme) were added 3 h after infection of *RK*$_{13}$ cells, no reduction of titre was observed when cells were collected at 18 h, and only a slight reduction at 24 h, when cytotoxicity was beginning to be visible. In green monkey kidney cells the addition of actinomycin at 12 h, at the time of appearance of the first newly formed virus, did not lead to a reduction of titre in material gathered at 48 h, the peak of virus synthesis (Table 1). The concentration of actinomycin used in these experiments, namely 2·5 γ/ml., is sufficient to depress host-cell RNA synthesis, as shown by the lack of incorporation of ^{3}H-uridine (plus a thousand-fold excess of thymidine) into the ribosomal RNA of green monkey kidney cells. In view of the fact that rubella virus has some properties which place it in the myxovirus group, it is interesting that like Newcastle disease virus it is not inhibited by actinomycin.

Table 1. LACK OF EFFECT ON VIRUS SYNTHESIS OF ADDITION OF ACTINOMYCIN *D* TO RUBELLA-INFECTED TISSUE CULTURES

Cell line	Time of drug addition (h after infection)	Stage of growth-cycle	Collection time (h)	Titre (% of control)
RK$_{13}$	3	Eclipse	18	100
RK$_{13}$	3	Eclipse	24	60*
GMK	12	Early exponential	48	100
GMK	24	Middle exponential	48	100

* Visible signs of cytotoxicity.

It is well known that rubella virus can multiply for weeks in a variety of tissue cultures without marked disturbance of cell growth. This has been confirmed on the macromolecular level by experiments in *BHK* 21/*WI* 2 cells[1]. Cells grown on coverslips were infected by rubella virus at an input multiplicity of 5–10 *TCD*$_{50}$ per cell. Infected cells and controls were pulse-labelled for 20 min at various times after infection with 0·5 μc/ml. of ^{3}H-uridine (plus a thousandfold excess of thymidine) or with 5 μc./ml. of ^{14}C-labelled algal protein hydrolysate. Duplicate experiments were processed following the technique of Bablanian *et al.*[9] and the radioactivity

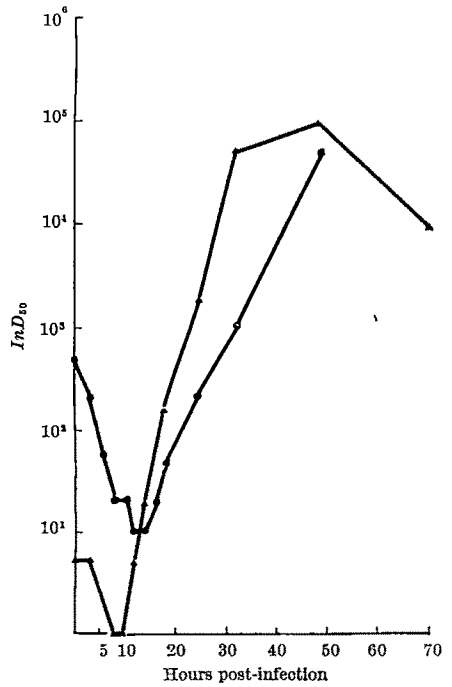

Fig. 1 One-step growth curves of rubella virus in *RK*$_{13}$ cell line grown in monolayer. Titres reported as increase of *TCD*$_{50}$ above the virus intracellularly present during the eclipse period. ▲, Intracellular levels; ●, extracellular levels

Fig. 2. One-step growth curves of rubella virus in *BHK*21/13 cell line grown in monolayer. Titres reported as increase of *TCD*$_{50}$ above the virus intracellularly present during the eclipse period. ●, Intracellular levels; ○, extracellular levels

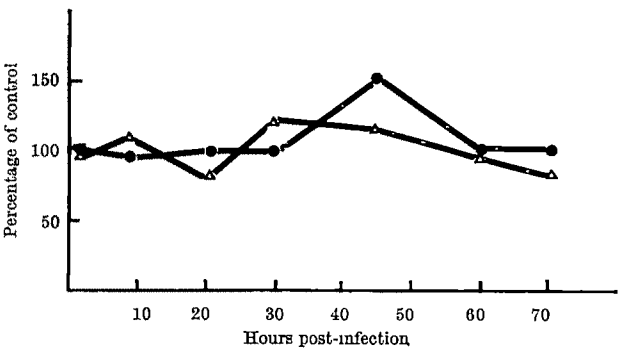

Fig. 3. Lack of inhibition of cellular synthesis of RNA and protein after rubella virus infection. △, ^{3}H-uridine uptake, ●, ^{14}C-protein hydrolysis uptake. For details, see text

measured[8]. No overall inhibition of protein or RNA synthesis was observed during the first 70 h after infection (Fig. 3), at which time the cells started to come away from the glass and the experiment was terminated. It should be noted that the detached cells were still alive as observed by Trypan blue exclusion; the same cell line grown in suspension has, in common with many other systems, the ability to sustain growth of rubella virus without cell destruction for at least several weeks[1,2,5].

This research was supported in part by a grant from the National Institute of Allergy and Infectious Diseases, and by a training grant from the National Institute of General Medical Science and the Joseph P. Kennedy, Jr. Foundation.

EFFICACY OF 'VIRACTIN' IN PREVENTING RESPIRATORY DISEASE

A DISTILLATE of the fermentation products of *Streptomyces griseus* has been named 'Viractin' by Leach *et al.*[1], who suggested that it prevents influenza and upper respiratory tract disease. The claim was based largely on clinical trials, the validity of which has been questioned[2].

This efficacy of 'Viractin' in cultures and laboratory animals has been investigated at the Common Cold Research Unit in Salisbury, England. Since a strong protective effect had apparently been detected in patients we attempted to show an antiviral effect, using laboratory methods, against some of the viruses known to cause the clinical picture of influenza and minor upper respiratory diseases.

In preliminary experiments the minimum toxic concentration of 'Viractin' was first determined using unstained roller tube cultures of various types of cell (Table 1).

Table 1. TOXICITY OF 'VIRACTIN'. MINIMUM CONCENTRATION OF 'VIRACTIN' CAUSING CYTOPATHIC EFFECT AFTER 4 DAYS' INCUBATION WITH INDICATED CELLS

	Human diploid	Human embryo kidney	HeLa	Calf kidney	Chick embryo fibroblasts	Monkey kidney
Concentration in medium	300	300	100	300	300	100

As a result of these tests it was decided to use a concentration of 30 μg 'Viractin'/ml. of medium in tests for antiviral activity. Leach *et al.* postulated that 'Viractin' acted on cell receptors, making it impossible for viruses to attach to cells. Therefore several types of cell in tissue cultures were treated with medium containing 'Viractin'. Control tubes were left for the same length of time in medium without 'Viractin'. Then serial dilutions of virus suspensions were made and added to the appropriate tubes. Following inoculation, the highest dilutions of the virus suspensions which infected the cultures with and without 'Viractin' were found. Table 2 shows that there was no evidence of an antiviral effect in such tests using viruses drawn from all the biological groups which are known to be concerned in the causation of influenza and upper respiratory disease.

Table 2. EFFECT OF 'VIRACTIN' ON VIRUS GROWTH IN TISSUE CULTURE

Virus used	Result of titration (TCD_{50}/ml.) in cultures containing 30 μg 'Viractin'	No 'Viractin'
Rhinovirus *M* (HGP)	$10^{5.5}$	10^{5}
Rhinovirus *H*	$10^{4.5}$	$10^{5.5}$
Influenza *A*	10^{6}	10^{6}
Influenza *B*	10^{4}	10^{5}
Parainfluenza 1	$10^{5.5}$	10^{5}
Adenovirus 5	10^{4}	10^{4}
Adenovirus 7	10^{3}	10^{2}

Leach *et al.* showed no antiviral activity on adeno-measles and polio-viruses in aqueous suspension. However, viruses which infect the respiratory tract are believed to be transmitted as droplets so we tried to detect inactivation of virus in droplets suspended in an atmosphere containing 'Viractin'. Influenza *A* virus was sprayed into a cupboard and later extracted as previously described[3,4], the coarse, more rapidly falling particles, which correspond to the size range trapped in the upper respiratory tract, were collected in a pre-impinger, and the finer, more slowly falling particles in an impinger. The air in the cupboard had a very high concentration of 'Viractin', obtained by putting saturated swabs in the cupboard. Such an atmosphere could not have been tolerated for long by people because of the very unpleasant smell of 'Viractin'. Virus was also sprayed into a cupboard containing a normal atmosphere and collected in the same way. Virus was titrated for infectivity in tissue cultures. The results showed that there was no reduction in the titre of influenza *A* virus extracted from the cupboard containing 'Viractin' compared with the titre of virus recovered from the cupboard without the compound. This experiment was repeated with a representative of the picornavirus group, coxsackie virus *A*21. The titre of the virus exposed to 'Viractin' was ten-fold less than the control. This apparent reduction in virus titre could not be confirmed in a further experiment, in which the concentration of 'Viractin' used was the same as that used in the clinical trials, that is, 80,000 O.D.U./1,000 ft.^{3}. It was concluded that no viricidal effect could be demonstrated (Table 3).

Table 3. EFFECT OF 'VIRACTIN' ON COXSACKIE VIRUS *A*21 IN DROPLET FORM

Material titrated	Virus titre (TCD_{50}/ml.) in sampling fluids collected from virus in atmosphere with 'Viractin'	without 'Viractin'
Tissue culture fluid remaining in spraying apparatus	$10^{5.75}$	10^{6}
Fluids recovered from		
(*a*) Pre-impinger sampler	10^{3}	$10^{1.5}$
(*b*) Impinger sampler	$10^{1.75}$	$10^{1.25}$

Atmosphere treated with 'Viractin' 80,000 O D U./1,000 ft. (ref. 3) overnight before virus sprayed in. Samples collected 10 min later. Bacterial spores were added to the spray fluid as a tracer and showed that identical volumes of fluid were sprayed and recovered in each test.

It was thought possible that 'Viractin' might have an effect on virus growth in ciliated epithelium although it had none on dedifferentiated cells. Organ cultures of ferret trachea were therefore prepared[5] in disposable plastic Petri dishes and maintained in medium 199 with or without 30 μg/ml. of 'Viractin' at 33° C. After several hours influenza *A* and *B* viruses were added. Medium from the dishes was collected and renewed daily and each sample was titrated for infectivity in tissue culture (Table 4). A similar amount of virus was produced by treated and by untreated cultures; in addition, 'Viractin' had no effect on the ciliary activity of uninfected cultures or on the time at which ciliary activity was stopped by the virus.

Table 4. EFFECT OF 'VIRACTIN' IN ORGAN CULTURE. TITRATION OF MEDIA COLLECTED DAILY FROM ORGAN CULTURES INOCULATED ON DAYS WITH INFLUENZA *A* AND *B* VIRUSES

Day	Influenza *A* MEL 'Viractin'	Influenza *A* MEL Control	Influenza *B* 'Viractin'	Influenza *B* Control
1	$10^{1.5}$	$10^{1.5}$	0	0
2	$10^{2.5}$	$10^{2.5}$	0	0
3	$10^{2.5}$	$10^{2.5}$	$10^{2.5}$	10^{2}
4	$10^{1.5}$	$10^{2.5}$	$10^{2.5}$	10^{1}
5	$10^{2.5}$	$10^{2.5}$	$10^{2.5}$	$10^{2.5}$

Although no protective effect of 'Viractin' in cultures had been detected it was possible that inhaled 'Viractin' might alter the host response to a virus. Therefore groups of 12–14 g *Ajax* strain white mice were put into boxes and left in a room with an atmosphere containing 'Viractin' in a concentration of 80,000 O.D.U./1,000 ft.^{3}. Two days later they were inoculated intranasally under light ether anaesthesia with serial dilutions of influenza *A* MEL virus. Almost all the mice died. After 15 days the reciprocal survival times and the means of the reciprocal survival times were calculated (Table 5). There was no evidence that the mice in 'Viractin' atmosphere survived longer than those in an atmosphere without 'Viractin'.

In view of the uniformly negative results of these laboratory experiments it was decided that there was

Table 5. SURVIVAL OF MICE INFECTED WITH INFLUENZA *A* VIRUS IN ROOM CONTAINING 'VIRACTIN'

Virus dilution	Mean survival time in days 'Viractin'	Mean survival time in days Control	Mean of reciprocal survival time 'Viractin'	Mean of reciprocal survival time Control
10^{-1}	1·7	2·5	0·72	0·44
10^{-2}	3·2	3·3	0·32	0·31
10^{-3}	4·2	3·5	0·25	0·29
10^{-4}	6·4	4·9	0·19	0·22
10^{-5}	8·5	(9·5)*	0·12	0·08

THE data presented by Drs. Walker and Tyrrell on their tissue culture and animal investigations of 'Viractin' confirm that this substance has no significant *in vitro* activity by the test systems used. Our similar results were reported in the first publication on this subject[1]. We have another publication in the press giving further data on 'Viractin' in tissue cultures infected with adenovirus[2].

I realize that the preponderance of opinion is such that animal studies must precede clinical trials. This may be thought of more as an ethical rather than a scientific matter. It clearly involves a feeling that efficacy must be proved in some animal species or tissue culture before it can be investigated in man. It is my contention that this is not necessarily true, and this has been demonstrated with 'Viractin' to a limited extent in that the *in vitro* tests have been negative, but the clinical investigations have demonstrated a sufficient degree of efficacy to warrant further investigations. We are continuing our efforts to extend the preliminary investigations reported earlier.

Litchfield[3] points out some of the limitations in our thinking about the correlations of findings between laboratory animals and man. He also feels that the net result of depending on tests in laboratory animals to find compounds for the treatment of diseases in man is that relatively few effective and safe drugs will emerge. Could it be that our screening programmes are not altogether effective?

Looking back over the past fifty years or so it is difficult not to be impressed with the distinct possibility that a number of drugs which are useful and are being used daily would probably have never reached a clinical trial by to-day's standard. Digitalis, without prior knowledge of its pharmacological properties, would probably have been discarded because it had a variety of toxic effects on the heart and a slight overdosage of it would produce fatal cardiac arrest. I would predict that to-day it would never have progressed to the stage of clinical trials. Another very useful drug, quinine, might not have been tested clinically because of its extreme toxicity to dogs. The foregoing are but two examples of valuable drugs that came to use first by observations in man.

I wish to mention one antibiotic which is being used clinically that did not show any significant activity in animals. This is *cyclo*serine; it did not have *in vitro* activity against most bacteria, but was active against *Mycobacterium tuberculosis*. When *cyclo*serine was tested in guinea-pigs infected with experimental tuberculosis, it was inactive. In man it is effective against a wide variety of bacterial infections and is also one of the effective agents against tuberculosis. The reason for the lack of activity in animals is that D-alanine is a specific antagonist for *cyclo*serine, and man does not have this metabolite[4].

It would seem to me that the foregoing illustrations point to the fact that we may be depending too much on our screening methods to select drugs for clinical trials. This may be the case with 'Viractin' since the limited clinical tests have shown that it holds promise as an effective prophylactic agent for upper respiration infections.

HERPES VIRUS SPECIFIED RIBONUCLEIC ACIDS

By J. HAY*, DR. G. J. KÖTELES† and DR. H. M. KEIR
Institute of Biochemistry, University of Glasgow
AND
DR. H. SUBAK SHARPE
Medical Research Council Experimental Virus Unit, Institute of Virology, University of Glasgow

IN general, when a virus particle successfully infects a host cell, the viral genome first initiates synthesis of new nucleic acids, some of which then programme or induce qualitative or quantitative changes in the synthesis of proteins. The metabolism of the cell thus undergoes a sequence of changes which lead to the production of progeny virus particles. As a result, the host cell is usually destroyed.

While most present-day knowledge of this situation is derived from extensive investigations of infection of bacterial cells by *T*-even bacteriophage[1–3], recent work indicates that mammalian cells respond to virus infection in an analogous fashion. Thus, in the case of HeLa cells infected with vaccinia virus, the normal patterns of synthesis of RNA specified by the cell genome is gradually destroyed, while new messenger-RNA functional in the synthesis of virus-specified protein is concomitantly transcribed from the viral genome in the cytoplasm[4,5].

The present article describes the changes in RNA synthesis induced by herpes simplex virus, which grows in the nucleus of the infected mammalian cell.

Earlier investigations with *BHK* 21 cells infected with herpes simplex virus established[6] the time course of certain virus-induced events, in particular the appearance of herpes DNA, virus-specific protein and mature virus particles. It was also observed that the activities of DNA nucleotidyltransferase (*EC* 2.7.7.7) and deoxyribonuclease (*EC* 3.1.4.5) increase markedly after infection[7]. We have recently obtained evidence which suggests that these increased activities are due to virus-specified enzymes[8].

* Medical Research Council scholar.
† Present address: Central Radiobiology Institute, Budapest, Hungary.

Other laboratories have provided evidence that herpes virus codes for or induces a new thymidine kinase (*EC* 2.7.1.21) (ref. 9).

Present-day theory predicts that a DNA virus, like herpes virus, initiates events leading to the manufacture of virus-specified proteins and ultimately to progeny virus, by way of transcription of specific RNA. Preliminary work[10] in *BHK* 21 cells demonstrated that synthesis of rapidly labelled, rapidly sedimenting RNA (45*S*, 35*S*) declined soon after infection with herpes simplex virus, reaching a low value 4–5 h after infection. However, a peak (20*S*) of rapidly labelled RNA, not present in uninfected cells, was observed 90 min after infection. We now have evidence concerning the kinetics of production and the genetic origin of the RNA in the 20*S* peak.

BHK 21 (*C*13) cells[11] grown in monolayer culture[6] were dispersed and infected in suspension with herpes simplex virus (strain α) at a multiplicity of exposure of 16 plaque-forming units (P.F.U.) per cell. After adsorption for 20 min at 37° C standard batches (3×10^7 cells) were plated in flat bottles and gassed with 5 per cent carbon dioxide. At suitable time intervals after infection, batches were exposed to a 30-min pulse of tritiated uridine (200 μc./bottle). The cells were then scraped from the glass, washed in cold buffer and frozen to −70° C in 0·01 M sodium acetate buffer *p*H 5·2 containing 0·11 per cent w/v sodium dodecyl sulphate and 0·2 per cent w/v bentonite. For control cell batches, [^{14}C]-uridine was used instead of tritiated uridine.

RNA was prepared by the method of Eason, Cline and Smellie[12]. Infectivity was measured on parallel cell cultures plated on glass.

Fig. 1 shows that RNA synthesis following infection declines to 60 per cent of the control rate by 1·5 h and

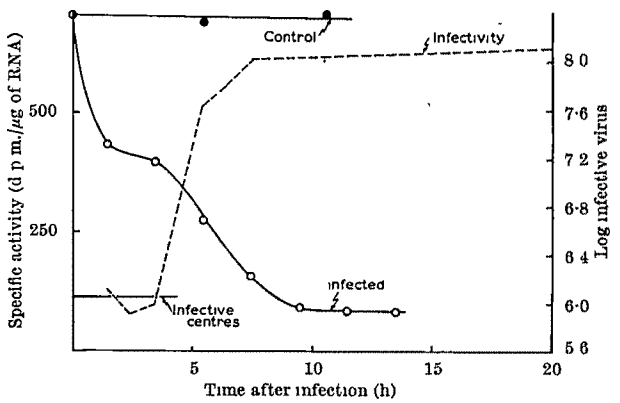

Fig. 1. RNA synthesis and infectious virus synthesis in *BHK* 21 cells infected with herpes virus. RNA synthesis in uninfected cells is also shown. Cells were exposed to tritiated uridine for 30 min and then collected for isolation of RNA. Initial infection was assessed by plating singly dispersed cells for infective centres in the presence of antiserum after mixing with 4×10^6 control cells per plate. Efficiency of plating of washed infective centres was 30 per cent. About 10^4 infected cells were also plated on glass without control cells but with antiserum present, but none formed a colony. Synthesis of infectious virus was assessed by plating batches of $3{\cdot}75 \times 10^6$ infected cells on Petri dishes and incubating in 5 ml. of growth medium. At various times all but 1 ml. of medium was removed from two plates, the cells scraped off the glass, the two 1-ml. portions pooled, the cells disrupted by sonication, and infectivity then titrated (ref 13). ●, Specific activity of RNA from control cells, ○, specific activity of RNA from infected cells; ---, infectivity; ——, infective centres

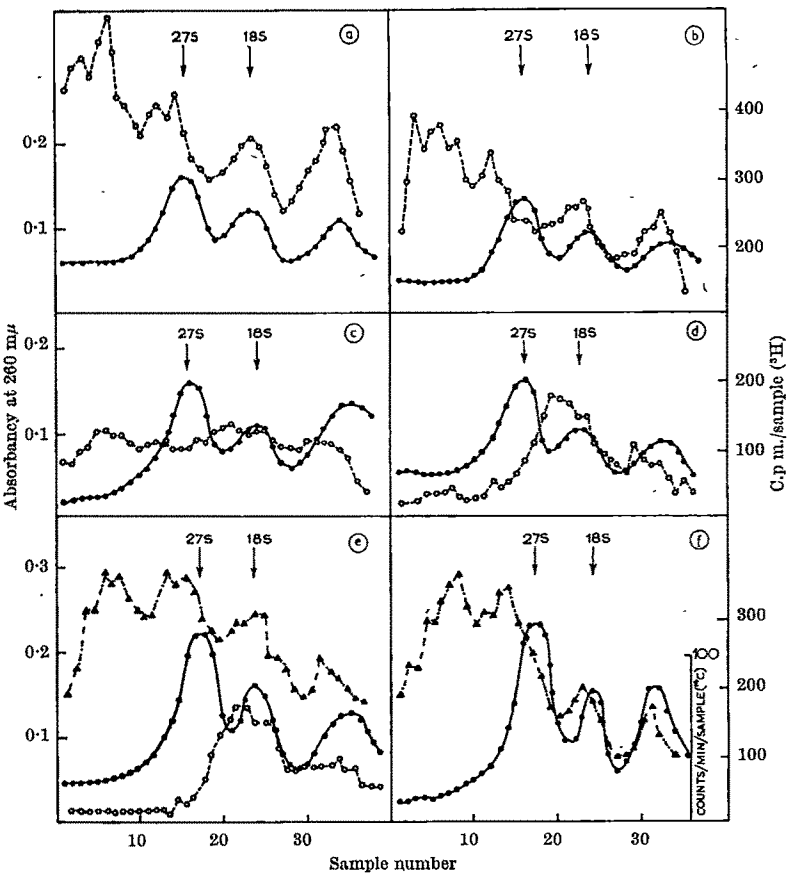

Fig. 2. Synthesis of rapidly labelled RNA in control (*BHK* 21) cells and in cells infected for various times with herpes virus. Infected cells were pulsed with tritiated uridine from: (*a*) 0·75 to 1·25 h; (*b*) 1·25 to 1·75 h; (*c*) 3·25 to 3·75 h, (*d*) 5·25 to 5·75 h; (*e*) 7·25 to 7·75 h after infection. Uninfected cells were pulsed with [^{14}C] uridine from (*e*) 7·25 to 7·75 h and (*f*) 0 to 0·50 h. Part (*e*) of the figure thus represents the sedimentation analysis of [^{14}C]RNA from control cells mixed with an equal amount of [^{3}H]RNA from infected cells. From each pulse sample approx. 300 μg of RNA was layered on to a linear gradient of sucrose (5–25 per cent w/v, pretreated with bentonite) and centrifuged at 21,000 r p m. for 11·5 h. 0 11-ml. fractions collected sequentially from each gradient were measured for absorbancy at 260 mμ, and for radioactivity (ref. 15). Approximate *S* values (see text) were calculated (ref. 16) with reference to ribosomal RNA. ●, Absorbancy at 260 mμ; ○, c p.m. (^{3}H) per fraction (RNA from infected cells); △, c.p m. (^{14}C) per fraction (RNA from control cells)

retains this level until about 3·5 h. A further steady fall occurs up to 9 h when 12 per cent of the control rate is reached, which is maintained for at least a further 5 h. Infective particles first appear between 4 and 5 h and reach the maximum titre at 7·5 h.

RNA samples were analysed by sedimentation through sucrose density gradients[14] (i) to identify the fractions of rapidly labelled cell RNA the syntheses of which declined after herpes infection, and (ii) to characterize any new RNA arising from virus-directed transcription. Results are shown in Fig. 2. The absorbancy patterns indicate the positions of the ribosomal RNA species (27*S* and 18*S*) and of 4*S* RNA. Incorporation of [^{14}C]-uridine into the rapidly labelled RNA of uninfected cells gives rise to a pattern which characteristically involves two main peaks of high specific activity at 45*S* and 35*S*, a peak in the 4*S*–6*S* region, and further peaks of incorporation coincident with the ribosomal RNA components (Fig. 2*e*, *f*). Fig. 2*a*, which presents the analysis of RNA from cells infected with herpes virus and then exposed to tritiated uridine from 0·75 to 1·25 h, is qualitatively the same. A qualitative change in the 20*S* region first appears in the 1·25–1·75 h sample (Fig. 2*b*). By 3·25–3·75 h infected cells show a marked decrease of incorporation into 45*S* and 35*S* RNA (Fig. 2*c*), while a broad peak at 20*S* is now evident; no comparable peak is present in uninfected cells. Two hours later (5·25–5·75 h), RNA synthesis is confined to this broad peak at 20*S*, and to some extent to 4*S* material, while 45*S* and 35*S* RNA synthesis has

fallen to a very low level (Fig. 2*d*). In the 7·25–7·75 h sample (Fig. 2*e*), 45*S* and 35*S* RNA can no longer be detected, and the rates of synthesis of 20*S* RNA and 4*S* have fallen relative to the 5·25–5·75 h sample. This is also found as late as 13·25–13·75 h but with an even lower rate of synthesis (see Fig. 1).

The initial decline in incorporation shown in Fig. 1 is probably due to the fall in synthesis of 45*S* and 35*S* RNA apparent from Fig. 2, whereas the later decline may represent a decrease in the rate of synthesis of the 20*S* RNA species or, more likely, it may reflect the metabolic death of a proportion of the infected cells.

DNA–RNA hybridization experiments. The specific genetic origin of these rapidly-labelled species of RNA formed before and after infection was investigated using DNA–RNA hybridization techniques[17]. DNAs of *BHK* 21 cells and of herpes virus (grown in *HEp* 2 cells) were tested for hybrid formation with RNA from uninfected or infected *BHK* 21 cells.

Uninfected cells. 45*S* RNA from *BHK* 21 cells formed a hybrid with *BHK* 21 cells DNA (Fig. 3*a*) but not with DNA from Landschutz ascites-tumour cells (Fig. 3*b*). This indicates that the rapidly labelled, rapidly sedimenting RNA was transcribed from the *BHK* 21 cell genome; moreover, analysis of its base ratios[20] gave a guanine + cytosine content of 68 per cent, unlike the base composition of *BHK* 21 cell DNA (43 per cent guanine + cytosine), but similar to 27*S* ribosomal RNA from these cells (67 per cent guanine + cytosine); this composition has not altered significantly 3 h after infection.

Infected cells. Analogous DNA–RNA hybridization experiments were carried out using RNA from infected cells (Table 1). Most of the 20*S* RNA which associated with the DNA of herpes virus withstood the action of ribonuclease (*EC* 2.7.7.16). Some of the 20*S* RNA also formed ribonuclease-resistant associations with *BHK* 21 DNA, though not with Landschutz DNA. Hybrid formation with *BHK* 21 DNA was to be expected in this particular experiment as the sedimentation analysis at this sample time showed that some 45*S* and 35*S* material was still being synthesized. (This suggests that not all cells were infected at the beginning of this experiment.) Corroborative evidence of hybridization between 20*S* RNA from infected cells and DNA of herpes virus has also been obtained using the procedure of Becker and Joklik[5]. We conclude that *BHK* 21 cells, 7·25–7·75 h after infection with herpes virus, synthesize virus-specified RNA which sediments as a broad band at 20*S*.

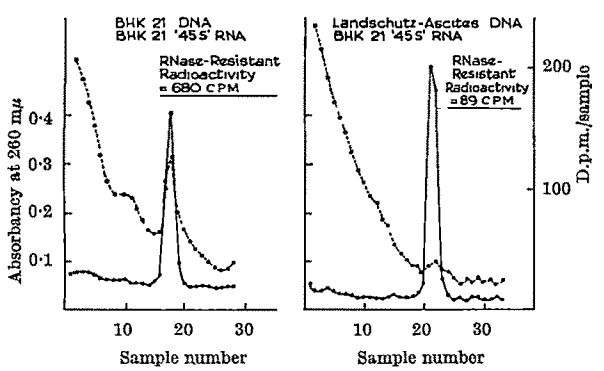

Fig. 3. Hybrid formation between DNA and rapidly labelled RNA from uninfected *BHK* 21 cells. DNA was isolated (ref. 18), and checked for purity (ref. 19) in the Spinco model *E* ultracentrifuge (buoyant density, 1·695 g/cm³). It was then denatured at 100° C. [¹⁴C] uridine-labelled RNA was isolated (ref. 12), fractionated on sucrose density gradients and the 45*S* peak collected. 5×10^4 d p.m. from this peak were mixed with 50 μg of denatured *BHK* 21 cell DNA (or Landschutz ascites-tumour cell DNA), incubated at 65° C for 5 h and then slowly cooled to 25° C during the next 10–12 h. Half of each sample was treated with ribonuclease (free from deoxyribonuclease), then precipitated with acid collected on 'Millipore' filter membranes, washed and counted. The remaining half of each incubation mixture was adjusted with caesium chloride to a density of 1·71 g/cm³ and centrifuged for 60 h to equilibrium. 0·1-ml. fractions were collected sequentially, measured for absorbancy at 260 mμ, and acid-precipitable radioactivity was then counted. ●—●, Absorbancy at 260 mμ; ● - - - ●, d.p.m. per sample

Table 1. HYBRID FORMATION BETWEEN 20*S* RNA FROM CELLS INFECTED WITH HERPES VIRUS AND DNA FROM VARIOUS SOURCES

Source of DNA	Fractions pooled after caesium chloride gradient centrifugation	Total d.p.m. (tritium) in pooled fractions: Before treatment with ribonuclease	After treatment with ribonuclease
BHK 21 cells	Bottom five fractions	390	0
	A_{260} peak fractions	262	40
Landschutz ascites-tumour cells	Bottom five fractions	675	6
	A_{260} peak fractions	75	0
Herpes simplex virus	Bottom five fractions	375	0
	A_{260} peak fractions	225	107

DNA was extracted from purified herpes virus (ref. 21); its buoyant density (ref. 19) was 1·752–1·727 g/cm³. 50 μg portions respectively of denatured *BHK* 21 DNA or Landschutz DNA or herpes DNA were incubated with 20*S* RNA (10^4 d.p.m.) from *BHK* 21 cells exposed to tritiated uridine 7·25–7·75 h after infection. Incubation mixtures were held at 75° C for 1 h, then 65° C for 2 h and then cooled slowly to 22° C. Caesium chloride density gradient centrifugation was carried out on each mixture (see Fig. 3). Fractions from the bottom of each gradient (containing unhybridized RNA) were pooled, and likewise the fractions containing the DNA peak. After dilution to 0·2 M caesium chloride acid-insoluble radioactivity was measured on one-quarter of each pool. After ribonuclease (free from deoxyribonuclease) treatment of the remainder, ribonuclease-resistant material was precipitated with acid, washed and measured for radioactivity.

Table 2. SYNTHESIS OF RIBOSOMAL RNA IN UNINFECTED AND HERPES SIMPLEX VIRUS-INFECTED *BHK* 21 CELLS

Time after infection (h)	Specific activity of ribosomal RNA*: Control ³H	Control ¹⁴C	Infected ³H	Infected ¹⁴C	Infected Control ³H	Infected Control ¹⁴C
0·5–2·0	2·2	1·2	1·6†	1·3	0·73	1·08
2·0–3·5	1·7	1·3	0·92	1·35	0·54	1·03
3·5–6·0	1·8	1·4	0·7	1·45	0·39	1·03

Cells were exposed to [¹⁴C] uridine for 2 h, removed from the glass (ref. 6), infected in suspension with herpes virus, and after 25 min adsorption, plated on glass and labelled with [³H] uridine from 0·5 to 2·0 h, 2·0 to 3·5 h and 3·5 to 6·0 h; control cell samples were treated identically, but were not infected. ¹⁴C and ³H disintegrations were separated as described by Hendler (ref. 15).

* C.p.m. × 10^{-3} per unit of absorbancy at 260 mμ.

† Values for ribosomal RNA synthesis after infection are probably overestimates, because we have evidence that not all cells were infected initially in this experiment.

At present, we cannot rule out that some host-directed synthesis of 20*S* RNA occurs in cells 7·25–7·75 h after infection. Nevertheless, assuming that all RNA elaborated at this time is virus-specified, we can express its amount as a percentage of that formed at the start of the experiment, when all RNA synthesis is cell-specified. The calculation, which relates counts incorporated to the absorbancies of the peaks of ribosomal RNA, yields the following estimate. Between 7·25 and 7·75 h after infection, virus-specified 20*S* and 4*S* RNAs amount to 14 per cent and 4 per cent, respectively, of the total host-specified RNA synthesis under parallel conditions. As this time is probably later than the time of maximum synthesis of virus-specified RNA, these percentages should be considered minimum estimates; for example, it can be calculated from the data in Fig. 2 that virus-directed RNA synthesis between 5·25 and 5·75 h is 23 per cent (20*S*) and 5 per cent (4*S*) of control.

Ribosomal RNA. The stability of ribosomal RNA and the effect of infection on its synthesis have also been investigated. Experimental details are given in Table 2, which shows that ribosomal RNA synthesized before infection was stable up to 6 h after infection (^{14}C specific activities); and that ribosomal RNA continued to be synthesized in the cells following infection. The rate of synthesis rapidly falls as infection proceeds, and reaches 39 per cent of the control-level in the period 3·5–6·0 h after infection (tritium specific activities). This decline paralleled the time course of disappearance of 45*S* and 35*S* rapidly-labelled RNA (Figs. 1 and 2). The rate of incorporation of tritiated uridine into ribosomal RNA of control cells during the period immediately following plating of the dispersed cells (0·5–2·0 h, Table 2) is higher than that found afterwards. This may be a consequence of increased metabolic activity in the cells following dispersal and plating.

S-RNA. The origin of 4*S* RNA labelled after infection of *BHK* 21 cells with herpes virus (see Fig. 2) has also been investigated[21]. The experiments show that 4*S* RNA species with several transfer-RNA properties are specified by the viral genome. At the same time it was demon-

strated that some synthesis of host-specific 4*S* RNA also continued after infection. Assuming that between 7·25 and 7·75 h after infection all 4*S* RNA synthesized is virus-specified, this represents 38·5 per cent of 4*S* RNA synthesized in control cells; between 5·25 and 5·75 h after infection, the figure is 48 per cent.

We thank Prof. J. N. Davidson and Prof. M. G. P. Stoker for their interest and support. The investigation was aided by grants from the British Empire Cancer Campaign for Research and the Rankin Fund of the University of Glasgow. Dr. G. J. Köteles was in receipt of a fellowship from the International Atomic Energy Agency. We also thank Miss H. Moss and Mr. P. Ferry for technical assistance.

EXPERIMENTAL AMYLOIDOSIS AND TOLERANCE

By PROF. E. LETTERER and DR. R. KRETSCHMER*
Institute of Pathology, University of Tübingen, and Universidad Nacional Autónoma de México

RECENT work on experimental amyloidosis (induced by means of repeated antigenic stimulation) has produced general agreement that this lesion is produced during the course of a protracted immune response[1]. However, this statement should be made with caution, since the immune response which is apparently related to experimental amyloidosis does not seem to proceed in the orthodox manner[2]. Investigations of the serological changes that occur during the development of experimental amyloidosis have not clarified the mechanism of formation of amyloid[3], and early experiments that cautiously suggested amyloid substance to be antigen–antibody complexes[4] lost ground as a result of recent chemical[5], histochemical[6] and ultra-structural[7] studies of the lesions. Rather, the indisputable presence of γ-globulin in amyloid seems to correspond to a secondary deposit and not to a determinant factor in its production[8]. Finally, irradiation, treatment with steroid or adrenocorticotrophic hormone (ACTH) and antimetabolite administration increase the frequency of amyloidosis in animals subjected to prolonged antigenic stimulation, particularly when applied after this stimulation has begun[1]. However, if this latter condition is observed, these procedures no longer act as immune depressors, and irradiation may even enhance the immune response[9].

Acquired tolerance constitutes a highly specific depression of the immune response, since it excludes only the response against the antigen used, fully respecting the remaining immunological potentialities of the animal[10]. In order to investigate further the relationship between experimental amyloidosis and the immune response, it seemed of interest to test the possibility of inducing this lesion in animals previously rendered tolerant by exposure to the antigen during the neonatal period.

Non-inbred *NMRI* mice of either sex were used throughout the experiment. New-born mice were kept with their respective mothers until weaning at 3–4 weeks of age. The animals were then sexed and placed in groups of five per cage. All animals with signs of infection were excluded. The following antigens were used: complete Freund's adjuvant (Hyland Laboratories), 'reinforced' Freund's adjuvant[11] (3 g per cent *Mycobacterium butyricum* (Difco Laboratories) in complete Freund's adjuvant) and casein–adjuvant mixture (four parts of 5 per cent casein (Hoffman La Roche *A.G.*) in 0·25 per cent sodium bicarbonate solution to one part of complete Freund's adjuvant). All antigens were kept and injected under sterile conditions. For the induction of tolerance, 0·03 c.c. of either of the three substances was injected subcutaneously under the skin of the back at the day of birth, and at 12 and 24 days of age. Repetitions of antigen administration were carried out, since it is known that the maintenance of a tolerant state requires uninterrupted exposure to the antigen[10]. In order to detect eventual effects of this neonatal treatment, a small number of animals (five) corresponding to each group were killed at the end of this stage of the experiment, and studied histologically as detailed later. No lesions were observed and no further mention is granted them. Induction of amyloidosis was begun at the age of five weeks according to one of the following methods: (*a*) weekly subcutaneous injections (0·3 c.c.) of complete Freund's adjuvant[12]; (*b*) weekly subcutaneous injections (0·3 c.c.) of the casein-adjuvant mixture[13]. A total of eight injections was given in both cases. Table 1 shows the different groups instituted according to the various combinations of new-born (tolerance-inducing) and adult (amyloid-inducing) treatment, as well as the respective control groups. Animals were killed by decapitation one week after the last amyloid-inducing injection. (This corresponds to 14 weeks of age in the groups not receiving the latter treatment.) Blocks for the histological examination were taken from spleen, liver, kidney, lymph nodes, lungs and heart. Organs were fixed in 4 per cent formalin, embedded in paraffin and stained with haematoxylin and eosin. Congo red slides were made with frozen sections and observed under polarized light. Numerical evaluation of the results was assessed on splenic involvement only, since it was found that splenic amyloidosis was the most consistent lesion, never failing in those few cases where amyloidosis was found in other organs. No attempt was made to evaluate the degree of the lesions. The percentage of animals revealing splenic amyloidosis is shown in Table 1. Results were statistically analysed by means of a conditional test of binomial distribution.

As the result for group 1 shows, no spontaneous amyloidosis was found in this experiment. Like some other authors[14], but contrary to the findings of Tal and Laufer[12], we were not able to produce amyloidosis in normal animals

* Present address: The Children's Hospital Medical Center, Boston, Massachusetts.

Table 1. DEVELOPMENT OF SPLENIC AMYLOIDOSIS IN THE DIFFERENT GROUPS

Group No.	No. of animals	Neonatal treatment (tolerance-inducing)	Adult treatment (amyloid-inducing)	No. amyloid	Percentage amyloid
1	16	None	None	0	0
2	22	None	Complete adjuvant	0	0
3	21	None	Casein–adjuvant	14	66
4	15	Complete adjuvant	None	0	0
5	34	Complete adjuvant	Complete adjuvant	0	0
6	20	Complete adjuvant	Casein–adjuvant	19	95
7	20	Reinforced adjuvant	None	0	0
8	12	Reinforced adjuvant	Complete adjuvant	1	8·3
9	9	Reinforced adjuvant	Casein–adjuvant	7	77
10	8	Casein-adjuvant	None	0	0
11	36	Casein-adjuvant	Casein–adjuvant	12	33

by means of repeated injections of complete Freund's adjuvant (Group 2). These authors used a different strain of mice, so the discrepancy could be explained on this ground, particularly after the demonstration that strain susceptibility is a pre-eminent factor in the development of experimental amyloidosis[15]. On the other hand, and in accordance with the results of Christensen[13], normal animals treated with the casein–adjuvant mixture showed amyloidosis in a significant number (Group 3). Neonatal treatment with complete Freund's adjuvant did not modify the outcome of the adult treatment with the same substance (Group 5), nor did it alter the evolution of those animals receiving no further treatment (Group 4). The same is also true for Groups 7 and 8, where neonatal treatment was achieved with reinforced adjuvant. It should be mentioned here that pure complete Freund's adjuvant is in itself antigenic on account of its bacterial content[16] and that it has been possible to induce tolerance to this antigen by injecting complete Freund's adjuvant in neonates[17]. Group 6 revealed a somewhat unexpected result, because neonatal treatment with complete Freund's adjuvant significantly increased the frequency by which amyloidosis was produced in the adult with the injection of the casein–adjuvant mixture. We do not have a plausible explanation for this 'enhancing' effect, but believe it merits further study. On the other hand, neonatal treatment with 'reinforced' adjuvant did not significantly modify the outcome of adult treatment with the casein–adjuvant mixture. This suggests that the aforementioned 'enhancing'-phenomenon does not necessarily depend on the bacterial component of the adjuvant or is limited to an optimal dose of it. Finally, when compared with the results of Groups 3, 6 or 9, Group 11 shows that the neonatal treatment with the casein–adjuvant mixture significantly diminishes the frequency of amyloidosis produced by injections of the same mixture at adult age. The same neonatal procedure, not followed by any adult treatment, failed to produce lesions at all (Group 10).

Usually, such findings would suggest that the phenomena had an immune character[17]. However, in this case one is reluctant to fully accept this in view of the facts mentioned in the introduction of this article. Nevertheless, the results point to the fact that production of experimental amyloidosis requires the existence and function of a specific immune response, since its selective elimination impairs the development of the lesions (Group 11).

According to Teilum[1], experimental amyloidosis represents the deposit of a glycoprotein produced *in situ* by mesenchymal cells at the final or 'exhaustion' stage of an abnormally prolonged immune response. This process follows a stereotyped sequence of events which can be brought about by means of a protracted antigenic stimulation, and can be accelerated through radiation, steroid treatment or antimetabolite administration, particularly when they are applied after antigenic stimulation has begun. Our experiment may bear the interpretation that the frequency of experimental amyloidosis was decreased by a state of acquired tolerance against the casein–adjuvant mixture, although this tolerance state was not tested by other means.

We thank W. Gulbinat (Institut für Medizinische Biometrie, Tübingen) for the statistical analysis of the results, and Dr. K. Willms for her valuable technical assistance.

ANATOMIC ADAPTATION OF THE ALIMENTARY TRACT OF THE RAT TO THE HYPERPHAGIA OF CHRONIC ALLOXAN-DIABETES

By DR. E. LESLY JERVIS and DR. R. J. LEVIN
Department of Physiology, University of Sheffield, Sheffield

CHESLER and Tislowitz[1] briefly mentioned that at autopsy chronic alloxan-diabetic rats had longer intestines and larger stomachs than normal rats. In this communication we would like to document more fully some of the striking changes that take place in the alimentary tract of chronic alloxan-diabetic rats and discuss possible factors that could cause these changes.

A group of young white rats (40–90 g) were injected intravenously with alloxan (60–70 mg/kg body-weight). A number of these rats developed severe chronic diabetes as judged by the criteria of glucosuria, high fasting blood sugar, cataract development and general depression of growth. Those that did not become diabetic were used as controls. Both groups were allowed *ad lib.* access to water and stock diet (Diet 86, 'Oxoid'). After 6–12 months the animals were anaesthetized, their abdominal cavities opened and the stomachs, small intestines and caeca were removed separately. They were then washed free of debris, blotted, and dried in an oven at 100° C for approximately 24 h.

Fig. 1 shows a typical alloxan diabetic rat (*B*) compared with a rat of similar age (*C*) and a rat of similar weight (*A*). The small stunted body of the diabetic rat with its pronounced distended abdomen contrasts clearly with the normal development of either the age or weight control. The abdomens were distended because the

alimentary tracts usually contained large amounts of food and faeces while the intestine itself was grossly enlarged both in diameter and length (control intestines 80–100 cm, diabetic intestines 100–150 cm). The histological sections in the lower part of Fig. 1 illustrate the change in diameter of the diabetic intestine (*b*) compared with that of the age control (*c*) or the weight control (*a*) that has been maximally distended by injection of fixative into its lumen. Further evidence of the large changes in the alimentary tract is seen in Table 1, which shows the dry-weights of the stomachs, small intestines and caeca of the diabetic rats and their controls. Table 1 also includes data from talc-fed rats and their controls, which will be discussed later. The results for the diabetic group show that the largest increase in weight (95 per cent) occurs in the small intestine ($P < 0.001$). There is a small (15 per cent) but significant increase in stomach weight ($P < 0.05$) but the increase in the weight of the caeca (23 per cent) is not significant ($P > 0.05$).

Although it is possible that the endocrine imbalance of chronic diabetes may affect the growth of the small intestine *per se*, this is likely to be of minor importance compared with the effect of the changed dietary intake. Measurements of the food intake of the diabetic rats indicated that they consumed 2–3 times more food per day per rat than did their controls. Because this increase

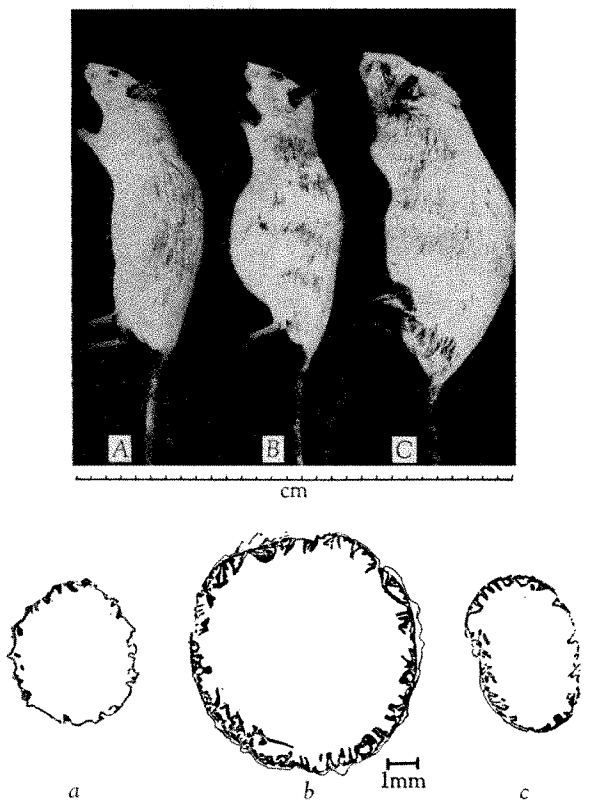

Fig. 1. Photograph shows (*B*) a typical chronic alloxan-diabetic rat compared with (*A*) a rat of the same weight and (*C*) one of the same age. For section *a* the intestine was maximally distended by the injection of fixative into the lumen

in the bulk could induce the changes observed in the small bowel, a group of young white rats (50–60 g) were fed for 6–7 months on a specially prepared bulked-out diet made by adding an equal quantity of talc (B.D.H. acid washed) to the stock diet. At the end of the feeding period both the controls (fed the stock diet) and the rats on the bulked-out diet were anaesthetized and treated as before to obtain the dry weights of the various parts of the alimentary tract. The weights are shown in Table 1. The largest significant increase ($P < 0.02$) was seen in the small intestine but even this was small (10 per cent). It therefore appears that in our experiments bulk is not an important factor in causing gross anatomical changes in the small bowel of the rat. This is similar to the findings of Addis[2] and Wierda[3] but differs from those of Friedman[4], who found that bulked-out diets fed to mice caused a large increase in the weight of the small intestine.

Many other experimental conditions have been shown to cause anatomical or weight changes in the small intestine. The small bowel hypertrophies when food is fed intermittently[5], when appetite is stimulated by insulin[6], by lactation[7] or by keeping rats in the cold[8], when rats or mice are made hyperphagic by lesions in the hypothalamus[9,10] or when rats are made hyperthyroid[11]. Surgical removal of small intestine leads to dilatation and hypertrophy of the remaining bowel in the rat[12] and in the dog[13]. That all these conditions cause hyperphagia and thus induce a work hypertrophy of the intestine does not satisfactorily explain how the increased food intake stimulates intestinal growth. As bulk has little effect on growth our investigations suggest that the stimulus is the presence of increased amounts of nutrients. Campbell and Fell[7] speculated that the "enlargement of the small intestine might be a direct response to the amount and rate of passage of one or more specific dietary components".

In all the cases of work hypertrophy more nutrient than normal is present in the lumen of the gut. To cause growth this material must stimulate mitosis in the crypts of Lieberkuhn. This might be brought about in a number of ways. The nutrient might: (1) enter the crypt cells and directly increase their available energy supply; (2) enter the cells and relieve the effects of intracellular mechanisms that suppress mitosis; (3) increase the removal of extracellular tissue-specific mitotic inhibitors (as postulated by Bullough[14]) from around the crypts by the increased blood and lymph flows generated during absorption.

In the case of (1) and (2) the degree of stimulation of mitosis will depend on the amount of nutrient available to the crypt cells. Increases in food intake would increase the amount of nutrient to these cells, stimulate division and thus the formation of new absorptive cells. These, when functioning on the villi, would compete for the nutrient in the lumen. Thus the amount available for the crypt cells would be reduced and the stimulus to division would fall. The size of the intestine would level out at the point where the 'nutrient/intestinal absorptive surface ratio' was similar to that found in normal conditions. Such a system would provide a means by which the intestine could grow to a size commensurate with the food load presented to it. In the case of (3) a limiting factor controlling intestinal size would be the maximal increase in blood and lymph flows that could be generated during the absorption of food. If the condition of the animal makes it eat continually (chronic diabetes) or if food stored in the stomach is continuously released to the intestines, the increased blood flow would be sustained for long periods and support intestinal growth.

Although the processes we have described for the stimulation of intestinal growth are likely to be oversimplifications as factors other than nutrient intake and blood supply (for example, hormones[15] and intestinal flora[16]) affect the intestine, it is interesting to note that massive resection brings about an increase in the mitotic

index[17]. Such a removal of tissue would cause an increased 'nutrient/absorptive surface' ratio and hence stimulate mitosis. Fasting, on the other hand, causes a decrease in mitosis[18]. This could be explained by the reduction in the ratio and hence lowered nutrient supply to the crypt cells.

EFFECTS OF IRRADIATION ON SYNTHESIS OF DEOXYRIBONUCLEIC ACID AND MITOSIS IN SYNCHRONOUS CULTURES OF HELA CELLS

By T. P. BRENT, Prof. J. A. V. BUTLER and Dr. A. R. CRATHORN

Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, Fulham Road, London, S.W.3

RECENT investigations have indicated that the ability of cells to survive ionizing radiation varies during the cell cycle; for example, Terasima and Tolmach found in HeLa cells that the periods of maximum radioresistance were at the beginning of G_1- and at the end of the S-periods[1], and Sinclair and Morton found in Chinese hamster cells that maximum radioresistance occurred at the end of the S-period[2]. It has not been possible so far to correlate these variations with any biochemical processes. The availability of synchronous populations of HeLa cells as described in our previous article[3] has made it possible to examine the effect of radiation on DNA synthesis at different stages of the cell cycle.

Preliminary observations, with asynchronous cultures, on the colony-forming ability of single cells after γ-irradiation showed the usual exponential relationship between dose and survival with a shoulder at low doses. The biochemical investigations described here were made following doses in the range 500–1,000 rads, with a dose rate of 100 rads/min, at which survival was from 10 per cent to 1 per cent. The changes in rate of DNA synthesis observed after irradiating an asynchronous population of cells with 600 rads are seen in Fig. 1. The cells were irradiated in suspension in spinner flasks and the rate of DNA synthesis was measured by assaying the amount of radioactivity incorporated into the cold acid-insoluble cellular material separated on 'Millipore' filters[3] after incubating the cells for 10 or 15 min with tritiated thymidine. As the rate of thymidine incorporation falls immediately after irradiation, it follows that the rate of DNA synthesis in the cells which are in the DNA synthetic phase must be immediately affected by the irradiation.

That this was a direct effect on DNA synthesis and not an artefact produced by an alteration to the composition of the precursor pool was confirmed by examination of the cold acid-soluble radioactivity where it was found that the nature and size of this pool were unaffected by irradiation of the cells.

This finding was confirmed by irradiating a synchronous population of cells in suspension during the period of DNA synthesis (S), and measuring the rate of thymidine uptake at various times during the cell cycle. An apparently immediate large effect on the rate of DNA synthesis was observed (Fig. 2). On the other hand, when irradiation was carried out at mitosis, that is, immediately after collecting the cells, no marked effect on the pattern of the subsequent DNA synthesis was observed, except for a small dose-dependent delay in the position of the S-period (Fig. 3). Cell division at the end of the same cell cycle was, however, found to be markedly delayed and depressed in a dose-dependent fashion (Fig. 4).

Observations were then made over two complete cell cycles, irradiation being given at mitosis, during the period G_1 (7 h after mitosis) and during the S period (11 h after mitosis). Measurements of the rates of DNA synthesis at various times are shown in Fig. 5. It will be seen that only when the cells are irradiated during the S-period is there

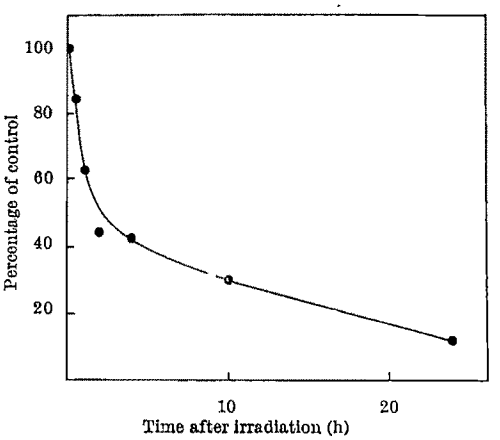

Fig. 1. Incorporation of tritiated thymidine into asynchronous cells in 15 min at various times after irradiation with 600 rads expressed as a percentage of control

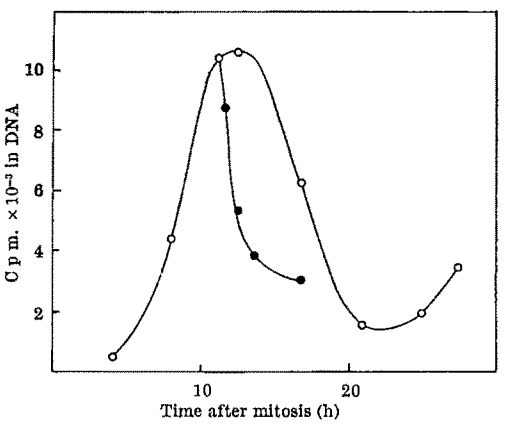

Fig 2 The rate of incorporation of tritiated thymidine in synchronous populations at various times after mitosis —○—, Control experiment; —●—, culture irradiated with 1,000 rads 11 h after mitosis

a marked effect on DNA synthesis during the same cell cycle. In some experiments, such as the example shown, it was noted that there is a small recovery in the rate of DNA synthesis towards the end of the *S*-period. During the second cycle the rate of DNA synthesis is depressed irrespective of the time of irradiation, despite the fact that cells irradiated before the *S*-period have apparently replicated their DNA completely in the first cycle. In the case of the cells irradiated during the *S*-period of the first cycle autoradiographic studies were made from which it was found that during the remainder of the first cycle the percentage of labelled cells was the same as for a control culture (90 per cent at the peak of *S*), but the extent of tritiated thymidine incorporation was reduced. During the second cycle both the percentage of cells labelled and the amount of labelling were reduced compared with a control culture.

The analysis of the situation in the second cycle is complicated by the presence of cells which have not undergone mitosis, but these results clearly indicate that there are two separable effects of radiation: (1) If the cell is irradiated in *S*, DNA replication is largely inhibited; this will prevent cell division and ultimately lead to cell death. (2) If the cell is at mitosis or in G_1 when irradiated, DNA replication in the same cell cycle apparently proceeds normally, but cell division is nevertheless delayed and depressed and only a limited amount of DNA synthesis occurs in the second cycle.

It follows that the DNA replication mechanism is more radiosensitive during the *S*-period than at other times.

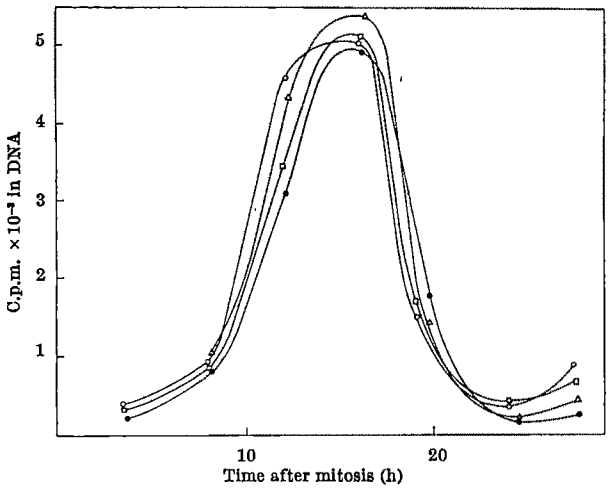

Fig. 3. The rate of incorporation of tritiated thymidine into synchronous populations at various times after mitosis. In all cases the cells were irradiated with various doses immediately after mitosis. —○—, Control, —□—, 300 rads; —△—, 600 rads; —●—, 900 rads

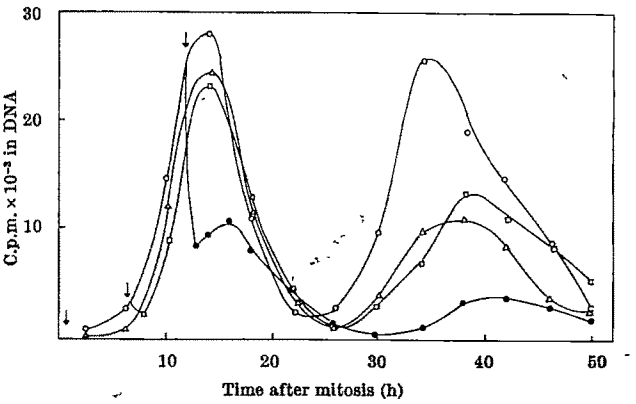

Fig. 5. The rate of incorporation of thymidine in synchronous populations at various times after mitosis. Irradiation with 1,000 rads were carried out at the following times (arrowed): —△—, mitosis; —□—, 7 h after mitosis; —●—, 11 h after mitosis. Control culture, —○—

One possible explanation of this is that the replicating site itself, that is, a region of DNA together with the replicating enzyme, is particularly sensitive at this time. The target size which would be required, however, to account for the sensitivity is large. It can be calculated that a dose of 1,000 rads, which is effective in stopping the synthetic process, provides one 'hit' per 5×10^5 nucleotide pairs (that is, molecular weight $\approx 10^9$). This is much too large to be considered as the system which is at any one moment taking part in DNA replication.

It must therefore be supposed that damage anywhere within a considerable stretch of the DNA twin helix will rapidly block the replicating process. That this is not unreasonable is shown by the following considerations. An estimate of the rate at which a replicating system might move along a DNA molecule can be obtained from the known rate of DNA synthesis in *E. coli*. In this case, a figure of 10^5 nucleotide pairs per minute has been calculated[4]. Thus, on the assumption that synthesis cannot proceed beyond a damaged region, it would be expected that synthesis would cease in a time of the order of 5 min following irradiation with 1,000 rads. A time lag of this order would not be detected in these experiments and therefore the results of these calculations are not incompatible with the 'immediate' effect which is observed.

We have still to account for the lower sensitivity of the replication system when irradiated prior to the *S*-period. This might be due to greater compactness of the DNA at this time. During the synthetic process the DNA fibres must be well dispersed and increased sensitivity might be due to secondary ionizations received from surrounding water molecules. Comparison of these results of irradiation with those obtained with more densely ionizing radiation, where the direct effect will be greater, might clarify this point.

Another possible explanation, which is perhaps more likely, however, is that a repair mechanism exists, such as has been proposed by Setlow and Carrier[5]. This would have to operate rapidly enough to eliminate the damage caused by irradiation in the presynthetic stages in the time available before DNA synthesis begins. So far as the present experiments go, it would appear that damage done 1–2 h before the synthetic period is reached can be repaired. On the other hand, such a process would be too slow to effect repair after irradiation in the *S*-period in the time available before the replicating sites reach the radiation lesions.

It has already been noted that there were some signs of recovery near the end of the synthetic period, after irradiation during the earlier part of this period. This could also be explained by partial repair during the interval. It could, however, be due to imperfect synchrony of the cells, and a more precise analysis would be required to establish this.

It can be concluded that in these experiments it is possible to distinguish two kinds of damage (*a*) to the mitotic apparatus or its precursor, and (*b*) to the DNA in relation to its replication. During mitosis (*a*) is clearly more sensitive to the irradiation than (*b*). During replication of DNA, while the DNA mechanism is clearly more sensitive than it was during the mitotic stage, the sensitivity of the mitotic process at this stage cannot be clearly distinguished.

We thank Miss A. Stephenson for technical assistance.

HAEMOLYMPH PIGMENTS OF APHIDS

By DR. J. H. BOWIE, DR. D. W. CAMERON, DR. J. A. FINDLAY and DR. J. A. K. QUARTEY
University Chemical Laboratory, Cambridge

SOME years ago, an extensive investigation[1,2] by Todd *et al.* directed attention to a range of remarkable colouring matters found in the haemolymph of various species of aphids. These substances were observed to fall into a number of groups, one of which has been investigated chemically in considerable detail and the structures of its components elucidated[3–5]. This group, termed aphins, is of comparatively wide occurrence, having been found in eighteen of the forty-two species of the Aphididae originally examined. Less attention has been paid until recently to the several non-aphin haemolymph pigments, which frequently occur in equally large proportions. This was due, in some cases, to their instability and in others to their relative inaccessibility. Despite these difficulties, enough of these substances has now been obtained for systematic chemical study, which is in progress. Though not yet complete, it has advanced sufficiently far to show interesting structural and biogenetic similarities affecting all groups of aphid pigments and to permit a limited survey of their occurrence to be made. We are concerned here with establishing what these similarities are. It is not proposed to discuss the chemistry of new compounds in detail except in so far as is necessary to characterize them adequately.

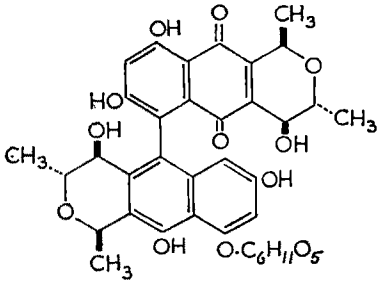
The chemistry of the aphins[3–5] was considered chiefly with reference to the aphins-*fb*, which were obtained from the bean aphid, *Aphis fabae* Scop., and from a number of other species. (Addition of the suffix *-fb* was used to distinguish them from the isomeric aphins *-sl*, obtained from the willow aphid *Tuberolachnus salignus* Gmelin.) These substances occur in the living insect as a glucoside, protoaphin-*fb* (I), $C_{36}H_{38}O_{16}$. After the death of the insect, this compound suffers enzymatic hydrolysis of the glucosidic linkage, together with extensive rearrangement, and is converted successively into xantho-, chryso-, and finally the stable, highly condensed erythroaphin-*fb* (II; R = H).

Careful examination of *A. fabae*, so as to avoid enzymatic decomposition processes, shows that, in addition to protoaphin-*fb*, two other glycosidic components are present in substantial amounts. One of them is a dark blue-green substance, the presence of which was detected in earlier work[2] but which was not then investigated. For this we now propose the name 'aphinin'. The other is a colourless component which fluoresces strongly in ultra-violet light. Protoaphin and aphinin, between them, account for virtually the entire soluble pigment content of the insects. (The small amounts of yellow fat-soluble constituents[2], which are invariably found on extraction of aphids, correspond spectroscopically and in partition behaviour to carotene hydrocarbons. Usually they are present in such small amounts, typically 0·005 per cent of the live insect weight, that we have not examined them in detail.)

Other highly pigmented aphid species, for example, *A. sambuci* L. (elders), *A. rumicis* L. (dock), *A. farinosa* Gm. (*Salix*) and *A. corniella* HRL (dogwood), contain the same three glycosidic constituents as *A. fabae*, but not in the same proportions. In general, black-coloured aphids, for example, *A. fabae* and *A. rumicis*, seem to contain more protoaphin relative to aphinin than dark green species, for example, *A. sambuci*. Variation in pigment content can indeed occur between different individuals of the same species. *A. sambuci*, for example, shows considerable variability in colour, ranging from dark blue-green to reddish-brown, the proportion of each being dependent on external factors, for example, time of season or temperature[6]. Examination of specimens of each of these extreme colour forms shows them to differ only in the relative amounts of the three glycosides already mentioned. A more striking example of colour variation is found in *A. farinosa* which ranges from deep blue-green to dark yellow. Specimens of the former type contain all three glycosides in significant quantities; the latter differ in that the proportion of protoaphin is much reduced, while the amount of aphinin present is so small as to be scarcely detectable.

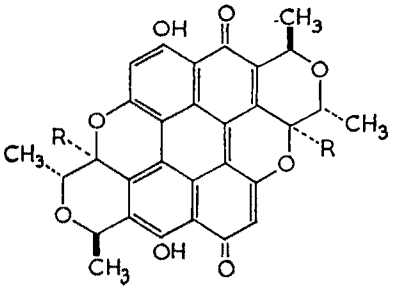
Relatively non-pigmented, pale green insects, for example, *Brevicoryne brassicae* L. (cabbage), *Hyalopterus pruni* Geoffr. (plum), *Macrosiphoniella artemisiae* (*Artemisia vulgaris*) and *Megoura viciae* Buckton (bean), chemically fall into the same category as those already discussed. Not surprisingly, they contain little protoaphin or aphinin. Indeed, the presence of the former cannot be detected; the latter, for which more sensitive methods of detection are available, is present to the extent of only *c.* 0·02 per cent of the live insect weight. The main component of such species is the colourless, fluorescent glycoside, chromatographically similar to that in *A. fabae* and present in substantial quantity (up to 1 per cent of the live insect weight).

A sufficient quantity of aphinin for chemical study is most conveniently obtained from *A. sambuci*, whence it can be isolated to the extent of 0·2 per cent of the live insect weight. In the solid phase aphinin-*sm* is dark blue-green, almost black, and, in solution, absorbs strongly at 638 mμ. It is exceedingly unstable towards heat, light and most oxidizing conditions. It readily undergoes reversible reduction to a yellow hydroquinone. It can be separated from protoaphin by virtue of its greater acidity. On mild treatment with acid it is hydrolysed to the corresponding aglucone and glucose. Unlike protoaphin it is not hydrolysed enzymatically by extracts of crushed insects. Its probable molecular formula is $C_{36}H_{36}O_{16}$ and its structure almost certainly is based on the extended quinone (III; R = glucose). A compound based on the system (III; R=H) has been synthesized in connexion with other work[7]. It is spectroscopically almost identical



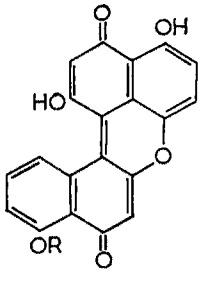
with aphinin, and the chemistry of the two compounds, inasmuch as it affects their chromophores, is completely parallel. For example, very mild, controlled oxidation of either leads to the chromophore (IV). The product obtained from aphinin-*sm* in this way has the formula $C_{36}H_{36}O_{16}$ and absorbs at 590 and 628 mμ. The corresponding aglucone, $C_{30}H_{26}O_{11}$, being less unstable and more symmetrical than its precursors, is more suitable for further chemical study which is in progress. The nature of the non-aromatic residues which substitute the aphinin nucleus (III) has not been established. Spectroscopic considerations, however, strongly suggest that they are closely related to the aliphatic side-chains in protoaphin (I).

The colourless, fluorescent glycosidic component, which accompanies protoaphin and aphinin in the insect species so far considered, has as yet been examined only cursorily. It has not been obtained pure, nor has its homogeneity been established. It is most conveniently isolated from relatively non-pigmented species, for example, *H. pruni*. It is very unstable towards oxidation and less acidic than either of its congeners. Its light absorption is that of a hydroxylated naphthalene, being somewhat similar to the spectrum of derivatives of 1,3,8-trihydroxynaphthalene, obtained by degradation[3] of protoaphin (I).

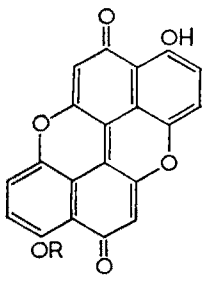


In addition to these substances, two other series of aphid pigments have been found. These were confined to specific genera, although the possibility that they may occur elsewhere cannot be excluded in view of the geographical limitations that attended collection of insects. The pigments derived from two species of *Hormaphis* (previously known as *Hamamelistes*) have already been described[8]. A red glycosidic heteroaphin, present in the living insects, is converted enzymatically after death into a red fluorescent aglycone, rhodoaphin. Recent work suggests that the latter has the molecular formula $C_{30}H_{22}O_{10}$ and confirms that it is closely related to dihydroxyerythroaphin-*fb* (II; R = OH).

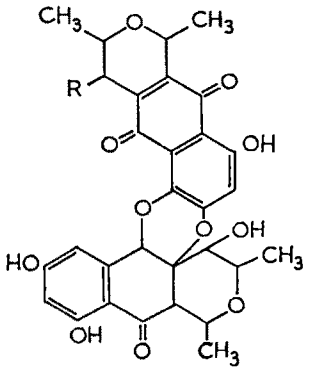
A second series of pigments is evidently restricted to the genus *Dactynotus*. They have been found in *D. jaceae* L. (knapweed), *D. cirsii* L. (thistle)[1,2], *D.* (*Uromelan*) *taraxaci* Kaltenbach, *D. tenaceti* L.[9] and in the North American species *D. rudbeckiae* Fitch and *D. ambrosiae* Thomas[10]. *D. jaceae* has been examined in greatest detail. It contains aphinin and a colourless fluorescent glycoside, but no protoaphin. Instead, a new glucoside and its enzymatically derived aglucones constitute a complex series of pigments for which we propose the name 'dactynaphins'. These amount to 0·75 per cent of the live insect weight. Using similar conventions of nomenclature as for the aphins, we refer to the glucosidic precursor as protodactynaphin-*jc*-1, $C_{36}H_{38}O_{17}$. This compound on enzymatic hydrolysis yields a mixture of two aglucones, a reddish orange rhododactynaphin-*jc*-1 and a yellow xanthodactynaphin-*jc*-1, each having the molecular formula $C_{30}H_{28}O_{12}$ and convertible one into the other. Smaller amounts of an analogous pair of aglucones are also isolable from *D. jaceae*. These are termed rhodo- and xantho-dactynaphins-*jc*-2, $C_{30}H_{28}O_{11}$. The properties of the former are similar to those reported for a substance, rhododactynaphin A, which was obtained by Weiss and Altland[10] from the two North American species mentioned. Through the courtesy of Dr. U. Weiss we have been enabled to compare these two compounds. They are indeed identical, as are rhododactynaphin-*jc*-1 and Weiss and Altland's rhododactynaphin *B*. Rhododactynaphins are readily and reversibly reduced to pale yellow hydroquinones; xanthodactynaphins, on the other hand, are stable to mild reduction. The chemistry of these substances is exceedingly complex and is not to be discussed at length here. Evidence is available, however, to support the structure (V; R = OH) for rhododactynaphin-*jc*-1 and (V; R = H) for -*jc*-2. Alkaline degradation of the former leads to the naphthaquinone (VI; R = H), the structure of which has been unambiguously established. For present purposes it is sufficient to note that the major chromophore in rhododactynaphin-*jc*-1 is (VI), linkage of which to a further C_{15} unit is effected through ethereal oxygen.



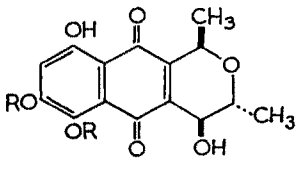
Despite the considerable structural variety in these haemolymph pigments, certain unifying features are, nevertheless, already apparent. All occur in the insects as glycosides, hydrolysis of which invariably leads to C_{30} aglycones. All are quinones or close relatives, as evidenced by their redox properties and general chemistry. All can



I



II



III

IV

V

VI

be visualized as derived formally by oxidative coupling of two C_{15} naphthalenic units, in particular derivatives of 1,3,8-trihydroxynaphthalene. Indeed, the structural variety that occurs is evidently the result of the various possible ways that this coupling process can be effected. In the aphins, aphinin and rhodoaphin, coupling involves carbon–carbon bond formation, in the dactynaphins, carbon–oxygen. In indirect support of these conclusions, similar reactions leading to syntheses of proto- (I) and erythroaphins (II) and several related systems have readily been effected *in vitro* under exceedingly mild conditions[7]. Further, the presence in aphids of colourless glycosides possessing hydroxynaphthalene spectra is of considerable interest. They may be regarded either as pigment precursors or as close relatives formed by similar processes. Besides testing these hypotheses, the completion of structural work in this general area may also provide a basis for speculation on a more fundamental question, namely, the function played by such substances in the insects themselves.

We are grateful to Lord Todd for his interest and encouragement in this work. We thank Mr. H. L. G. Stroyan for identification of aphid specimens and helpful advice, and also Fisons Pest Control, Ltd., Mr. R. N. B. Prior, and Dr. H. Descimon for specimens of *M. viciae*, *A. farinosa*, and *M. artemisiae*, respectively.

'SKIN DIGESTION' AND EPIDERMAL ABSORPTION IN IRREGULAR AND REGULAR URCHINS AND THEIR PROBABLE RELATION TO THE OUTFLOW OF SPHERULE-COELOMOCYTES

By E. PEQUIGNAT
Zoology Laboratory, University of Caen

(1) *Echinocardium cardatum* (Pennant)

When analysing the sand content of the gut of *Echinocardium cordatum*, Lafon[1] was surprised to find how little organic matter was present. Certainly what was present was inadequate for the metabolism and growth of the animal. I endeavoured to determine how *Echinocardium* gathers and absorbs its food by carrying out some investigations on specimens at the Marine Laboratory of Luc-sur-Mer. The specimens had been collected from the same beach as Lafon had collected his; it was possible to keep them for some months in good condition in a sand aquarium supplied with aerated sea-water. In their active state, the animals would push their funnel through the surface: it was obvious that Yonge[2] was right in considering it as a trap for organic particles which, exciting the movements of the dorsal podia, are sucked down into that tunnel of dorsal spines vaulting over the odd ambulacral furrow. There the small prey is mixed with superficial sand (often replaced in my experiments by crushed red brick) and an abundant mucus produced mainly by the clavulae of the internal fasciole. Whenever I tried to trace the trapped particles later on, I was not able to find them, so that the possibility of a superficial 'predigestion' had to be considered. I then carried out some experiments on individuals incompletely buried in the clean sand of a glass vessel continually percolated with sea-water. A great variety of food particles were introduced into the dorsal furrow and I endeavoured to follow their transportation and transformations, for several hours, under a binocular lens. Among the material given were thin pieces of gelatine, egg-white, agar, pieces of worm or mollusc, muscles of crustaceans, crumbs of bread or cheese, flakes of *Ulva lactuca*, and surgical cat-gut soaked in antibiotics. All these were successfully 'dissolved' by the animals provided they were active and the food particles very small or very thin. The particles were impelled along the dorsal furrow by the beat of its small bottom-spines, but being stopped for a time behind the barrier of the internal fasciole where digestion appeared to be especially efficient. If the pieces were too large to be fully digested there, they were sorted out at the frontal notch and rejected laterally into the limy mucus cap which covers the flat dorsal spines. The mucus runs around the frontal humps of the test, comes up the anterior petals and flows backwards over the posterior ambulacra, becomes mixed with the mucus production of the anal and sub-anal fascioles and ends its course in that sticky trail with Nichols[3] calls a 'sanitary drain'. These 'flow-lines' were detected by means of various techniques using crushed brick, carmine, methylene blue, sudan-coloured oil emulsions, etc. They did not fit in with Nichols's description of a diverging flow from the apex. In the 'limy cap', digestion, as well as absorption, proceeded especially in the region of the periproct and the sub-anal tuft and podia. But the dissolved nutrients sometimes slid down the lateral spines to the cocoon of clear mucus which is centred around the mouth, enriched with the secretion of the forty papillate podia of the floscelle.

(2) *Coloured reactions on living heart-urchins. Behaviour of the coelomocytes.*

(*a*) *Proteins.* Egg-albumen, slowly combined with acid fuchsin, turns on heating into a white coagulum which gives a red colour as soon as it is digested. Such coagulum flakes were laid into the dorsal furrow or on the clavulae of an *Echinocardium*; they became light orange while a red tinge appeared in the podia, spines and clavula tips. That general tinge had to be distinguished from the appearance or accentuation of many tiny red spots due to a rush of red spherule-coelomocytes through the epithelia on alimentary excitation. They 'crept' out by means of their mobile lobed pseudopods to reach the external mucus where they eventually disintegrated into red small debris which blackened on treatment with hydrogen peroxide. Kindred[4] had observed this phenomenon in the 'branchial' tufts of *Arbacia*, but I witnessed it everywhere with a feeding urchin—on spines, pedicellariae, podia or clavulae. Other pale coelomocytes with bulky lemon-yellow spherules (responsible for the general colour of *Echinocardia*) behaved in just the same way. The 'sally' of both these cells could be easily observed in the transparent tip of a clavula. A third type of spherule-

coelomocytes showed rounded granules of a greeny-brown tint: but these soon disintegrated under the epithelia into bunches of spherules. Some of the latter were ochre-coloured and might well be pycnotic nuclei. These fragile coelomocytes and their rounded debris were the first to redden when fuchsin-albumen was digested nearby. If the experiment was continued for a sufficient length of time, the connective fibres also reddened and finally the epithelial cells took on a yellowish tinge. It was difficult, however, to be certain that the red coelomocytes grew redder than before and the lemon-coloured ones sometimes showed two or three coloured spherules.

Analogous results were obtained with gelatine flakes soaked with 5 per cent ninhydrin. While they were slowly turning purplish-brown, the neighbouring spines, podia or clavulae showed purple spots and a violet hue; here also the microscope revealed that the greeny-brown spherules were the first to stain dark purple followed by the connective fibres—the other spherule-coelomocytes and even epithelial cells turned violet later on.

To meet the possible objection that bacteria present in the mucus might be the real cause of that proteic liquefaction, pieces of sterile cat-gut or pieces of well-washed annelids were dipped into a solution of penicillin + streptomycin + 'Moldex' + methylene blue + ninhydrin. Half of each piece was left in putrid sea-water to act as a control (where it remained unaltered for weeks), while the other half was given as food. After losing its methylene blue through diffusion, this material gradually turned violet-purple before being dissolved in the limy mucus.

To detect the proteolytic enzymes involved was not easy, yet I was able to detect leucine-aminopeptidase in living material by a histochemical technique. Folk and Burstone's substrate[5] (leucyl-beta-naphthylamide) was incorporated into gelatine flakes deposited in the dorsal furrow. After an hour, the animal was placed in sea-water with a little fast blue *B*. The expected diazonium reaction occurred dyeing the mucus of the furrow, on the neighbouring spines, podia and clavulae an intense red colour. Under the microscope it could be seen that on living transparent clavulae the red colour was first associated with the greenish granules of the disintegrating coelomocytes and possibly the red ones (these turned violet with copper sulphate); later a red dye diffused into the connective tissue and the external mucus.

(*b*) *Glucides.* Agar pieces and small blades of algae, the hardy cuticle of which had been stripped off, were attacked. Filter-paper and starch were more slowly attacked than algal galactosides and polyuronides. When agar gel was added with Schiff reagent it was quickly dissolved, and a cloud of red fuchsin was released.

(*c*) *Lipids.* A greasy mixture of cream cheese, peanut oil and black sudan when dabbed in the dorsal furrow proceeded along the aforementioned flow-lines, turning into a homogeneous emulsion which eventually covered the spines with a thin continuous film. Under the microscope, dark droplets could be seen in the epithelial cells while many disintegrated spherules became purple or reddish. Later on, this red metachromasy appeared even more conspicuously in the muscular and connective fibres of the oesophagus.

(*d*) *Translocations within the body.* Animals which had been submitted to coloured nutrients for some hours were dissected in order to determine the manner in which any absorption had occurred. The oesophagus, the vertical mesentery and the oval gland, the rectum and the clogged coelomocytes spotting the ampullae were densely stained. while the ampullae and the intestine were but lightly tinted. Thus, the intensity of the coloration seemed to be proportional to the density of spherule-coelomocytes. That would support Liebman's view[6] concerning the role of the spherule-coelomocytes (called by him 'trephocytes') in the elaboration and translocation of nutrients. The greeny-brown ones may play such a part, but the red and lemon-yellow cells which do not disintegrate before they are taken up by the external mucus would seem to act as a digestive vanguard.

(3) *Psammechinus miliaris*

Although regular urchins live in the open sea, their podia and epiderm also produce a thin mucous coating which the ciliae push along the spine-grooves. In *Psammechinus*, it has strong digestive powers for artificial food with coloured reagents as well as for living prey. Pieces of egg-white gelatine, crustacean or molluscan tissues, agar, or bread, deposited on the epiderm were soon enclosed by the convergence of the neighbouring spines and soaked with mucus. They were dissolved within 24–48 h. If the prey was too cumbersome or solid, such as a coverslip with coagulated fuchsinated egg-white or the frond of an *Ulva*, the podia would take hold of it, draw it against the spine-tops and the organic matter would be attacked both by the spines and the podial disks, leaving their hollow prints in it. Those prints were sharply brought out in orange-red if fuchsin-albumen was used; and when a frond of *Ulva* had been kept tight for several days, it was possible to observe, using a low-power microscope, several holes and rounded prints where the 'attacked' cells showed a pinkish hue. In aquaria, the urchins are said to be 'disguised' with shells, stones, algae, polyzoa, etc. After some time the shells become cleared of the polyzoa, barnacles or organic detriti which they previously 'wore'. Even a mussel shell itself is attacked, and if its margin comes in contact with the test it becomes as jagged as an old knife. I was able to follow the process of digestion of a small *Natica catena*: within 2 days only a very clean empty shell was left. Still quicker was the skin-digestion of a commensal, *Flabelligera affinis*, provided the worm was removed from its mucous protective bag, which forced it to become attached to the test. When the skin is half destroyed a red stomach can be observed to be still reacting; but soon it loses its colour and becomes dissolved (2·5 h). Here, too, an alimentary excitation of the tegument provokes an outflow of coelomocytes. The red spots on the spines and pedicellariae grow in number and density. Under the microscope, the gradual emergence of red spherule-coelomocytes as well as of colourless spherule-coelomocytes (which replace the lemon-yellow cells of the heart urchin) can easily be observed in podia, pedicellariae, branchial tufts and small crushed spines. Here too the greenish-brown spherulocytes disintegrate in the connective tissue and their diffused pigment can be fixed in the skeletal rods of the spines as 'spinochromes', which are chemically similar to the echinochrome of the red cells. Debris of the latter can only be found on the epithelial surface. But despite this strange 'aboral feeding', regular urchins are essentially 'oral' grazers. Sticking to the bottom with many podia and short spines, they surround a real 'digestive pouch' between their oral surfaces and the floor. In this, the so-called branchial tufts emit large quantities of spherulocytes. So do the lips and the buccal pouches with their mucus-producing villi. The organic matter on the floor can thus be digested externally before being sucked in, the lantern intervening only for cracking hard material. I have stuck the teeth of a sea-urchin together with plastic dental cement ('Ivoclar Justi', kindly supplied by Dr. Bourdin), and although its lips and persistomial podia were injured in the operation, the specimen was able to survive for 16 days. But 24 h sufficed to dissolve out an empty circle under its whole oral face in the coagulated albumen coating a Petri dish, and podial prints were visible in the thinned albumen all around.

A search for leucine-aminopeptidase by means of Burstone's substrate and fast blue *B* gave results similar to those obtained with *Echinocardium* (reddening of the mucus, of the disintegrating cells and possibly the red coelomocytes).

For lipids, I used the same sudan-blacked greasy mixture. The thin black emulsion obtained was pushed up the spines and the same metachromatic colorations were observed inside.

Must one conclude from all this that the gut of the sea-urchin is a useless 'luxury'? Actually, the thick folded epithelium of the pharynx and oesophagus is rich in mucus cells as well as in pervading coleomocytes, so that Stott[7] was able to claim that these wandering cells come out into the lumen to pick the food and then return to the coelom with their 'shopping'! However, although I observed hundreds of red and colourless spherulocytes 'creeping out', I never saw one on its way back. They disintegrate while probably releasing digestive enzymes. The pharynx and oesophagus keep up the epidermal digestive work and probably more efficiently. But in the 'stomach' very few coelomocytes are to be seen either in sections or on the living tissue among the long loose cells of the epithelium. Some of the latter become rather club-shaped and become filled with granules and large vacuoles. Yet they have a ciliate brush like their leaner sisters and do not show the reactions of muco-polysaccharides. Therefore, their content seems to be absorption products rather than secretions. Farman-farmaian's experiments[8] on *Str. purpura-tus* buccally fed with carbon-14 labelled red algae show that the stomach walls are an important seat of reserves, while Lasker and Giese[9] have shown on that same species that digestion was completed in the first two loops—it is possible that this may be a belated digestion due to the action of mucus and coelomocytes proceeding from the oesophagus. The siphon which directly connects the oesophagus to the upper intestine allows some already digested nutrients and also oxygen to reach the festooned loops surrounding the genital glands—the only really internal organs of an urchin.

(4) *Asterias rubens*

Cuénot[10], in his early work, noticed that small annelids could be captured by the rosettes and their pedicellariae and were soon killed. But he went on to comment that the dead prey was then released as it was of no use as food. Actually, if one manages to keep in close contact with the tegument pieces of worms, molluscs, bits of ninhydrinated gelatine, threads of cat-gut, etc., an epidermic digestion will be observed within a few hours. Whenever ninhydrin is used, a violet tinge appears in the tegument which is more conspicuous in the thick epithelium covering the rosettes. If the organic pieces are set into an ambulacral groove where they are soon shut in by the lowering of adambulacral plates over the contracted podia, digestion will be still quicker and if ninhydrin is used at a sufficient concentration several podia turn violet. With Burstone's substrate and fast blue *B*, an intense reddening is obtained in the mucus, the podial mucus-glands and the mucus-cells of the epithelium of the pedicellariae. The 'secretory packets' of Chaet and Philpot's electron microphotographs[11] might be a source of digestive enzymes. They originate from vacuolary cells situated under the epithelia of the disks, which it is possible may act as some kind of spherule coelomocytes. The host of strong active podia surrounding the everted stomach of a feeding starfish may help cardiac digestion chemically as well as mechanically. I gave specimens of *Asterias* living mussels with bolted shells and others enclosed in nylon bags. All were completely digested without being pulled open, for either the dorsal ligaments or the conchyolin margins on the ventral side of the valves had been dissolved. All this is in agreement with J. C. Ferguson's[12] results with *Asterias forbesi* fed with radioactive clams. The study of autoradiographic sections demonstrated that "large quantities of nutrients are absorbed directly from the external medium by epidermal cells, especially those of the tube feet and aboral body-wall": my findings are in agreement with these conclusions.

(5) *Ophiothrix fragilis*

In aquaria, the long spined arms of these ophiurids are either stretched to catch passing particles or tightly fixed to mussels, patellae, lime-covered stones or shells which they eventually clear up. When kept in Petri dishes smeared with egg-white, agar or decked with filter-paper, they leave the bottom clean within a week. To eliminate any gastric emanation through the mouth, I enclosed the disk of a specimen within the cavity of a plastic stopper pressed against a coverslip: five marginal notches allow the arms free movement on the nutritive smear of a Petri dish under sea-water. If that smear consisted of ninhydrinated albumen or gelatine soaked with Burstone's substrate and fast blue *B*, not only did the arms, within a few days, dig their print in it, but staining appeared on their ventral side, the cores of the barbed spines, and more especially in the podia. In them these golden disintegrating granular cells, which grew darker on alimentary excitation and showed a green metachromasy with toluidine blue, were the first to take the dye. Further research is needed to determine whether Buchanan's '*A*' and '*B*' bodies[13] play a part in the production of digestive enzymes. In one experiment, the distal articles of an arm were cut off, and the animal withdrew the proximal part of it within the stopper. The latter, like the disk, was not stained. This indicates brachial digestion and absorption. Large diatoms deposited on the oral surface of an arm, next to a podion and observed for several hours under a lens eventually faded away.

(6) *Conclusions*

I have not yet tested holothurians or crinoids. But there is no reason for these 'ciliary mucus feeders', which have about the same type of coelomocytes as urchins, to behave differently. The large surface area for catching in the case of a crinoid, with its forked arms bristling with pinnules and podia, is out of proportion with the small U-shaped gut of the animal and should have a greater nutritive efficiency. When it is considered that most of the tissues of echinoderms are exoskeletal and that the animals have only a very simple digestive tube without differentiated glands, the necessity of an epithelial nutrition and respiration can be understood. For the fragile unprotected skin, devoid of any cuticle or shell, digestive 'aggressiveness' provides the animal with a means of defending itself against prospective parasites. Actually, the superficial mucus of a living urchin is poor in bacteria and ciliates. Only a few specific commensals (*Urceolariae* for ciliates, a few copepods and amphipods) are to be found. Real digestive organs, respiratory chambers or gills require a circulatory system to drain them; but in this respect M. Burton[14] has shown that the haemal system is not a circulatory network. If a diffuse type of digestion and absorption were to be found with all echinoderms, it can be claimed that evolution shows a tendency to an 'oralization' of the digestive process. It is evident in regular urchins, the Aristotle's lantern of which may be an adaptation to coralligenous environments, and in the large predatory starfish that succeed in engulfing large prey (*Luidia* and *Marthasterias*) and store their gains in their long folded caeca.

MEMORY AND SPONTANEOUS ALTERNATION IN THE RAT

By A. W. STILL*
Psychological Laboratory, University of Cambridge

IT is well known that rats have a tendency to alternate their choices in a T-maze; that is, if given two choices in succession, they tend to choose first one arm of the maze, then the other, rather than the same arm on both choices. They do not, of course, always choose according to this tendency since, for example, a rat rewarded in one arm only will usually choose that arm. We may thus regard choice in a T-maze as being determined in two possible ways, depending on whether or not the rat is choosing according to the alternation tendency.

There are several experiments showing that when rats alternate they usually vary the places they go to, rather than the responses they make[1,2]. Therefore, in order to alternate, the rat must, in some sense, remember which arm of the maze was last entered, and this has led Dember and Fowler[3] to suggest that spontaneous alternation might be used to study memory. This suggestion has not yet been explicitly followed up, though some of the studies on spontaneous alternation *per se* are relevant to the question of memory. In particular, the delay between trials has been varied and, with one pair of trials per day, alternation shows a positively accelerated decline when plotted against delay or log (delay)[4,5].

A positively accelerated decline would be predicted from the following trace decay theory (which owes much to a theory of forgetting put forward by Brown[6]): A trace is laid down when a rat enters a T-maze arm, and this declines in strength with time; following an arm entry there will also, unless the rat is experimentally naïve, be a trace resulting from the last entry to the other arm, and the rat, when it is choosing according to the alternation tendency, will choose the arm with the weaker trace.

Definitions: $\log n_1$ and $\log n_2$ are the strengths, which decline with time, of the traces corresponding to the two arms, $\log n_2$ corresponding to the arm most recently entered. t_1 and t_2 are the respective times since the traces were laid down. $N = \log n_2 - \log n_1 = \log n_2/n_1$. P_a is the probability of alternation, and P_r $(= 1 - P_a)$ is the probability of repetition. The following assumptions are made: (1) when a rat is choosing according to the alternation tendency it will alternate if N is positive, repeat its previous choice if N is negative; (2) N is a random sample from a hypothetical population of values normally distributed about a mean $\bar{N}$ with standard deviation σ_N; (3) $\bar{N}$ is a decreasing function of t_2; (4) σ_N is independent of the value of $\bar{N}$.

From these assumptions it follows that P_r is $\bar{N}/\sigma_N$ expressed as a normal probability integral. Thus if $\bar{N}$ were a linear function of t_2 over some of its range, P_r plotted against t_2 would be part of the lower half of a normal ogive, so that P_a would be positively accelerated over this range. In general, P_a against t_2 will be positively accelerated provided that t_2 is not too large, $\bar{N}$ is sufficiently large when $t_2 = 0$, and $\bar{N}$ is not an extreme negatively accelerated function of t_2.

The following experiment carries the theory a step further: Twelve hooded rats were used; they were highly experienced, having had several hundred rewarded trials in a T-maze. The apparatus was an alley T-maze of aluminium, with the walls of one arm painted grey, the other black; the arms and stem were 2 ft. long, 4 in. wide, and 5·25 in. high. One pair of trials was given per day; the first was forced (access to one arm being prevented by means of a guillotine door), the second free. The delay between forced and free trials was 5 sec, 25 min, 2 h, or 10 h; every day each of these delays was given to three rats, and during the experiment each rat was tested at each delay twelve times. For the 10 h delay the forced trial was in the morning; for the shorter delays pairs of trials were given equally often in the morning and evening. The rats were fed for 2 h every evening, 15 min after all rats had been tested; they were allowed to eat in the maze for 15 sec following every choice.

Since the rats were fed after the evening testing session they were hungrier on evening than morning trials, which might have given rise to a difference in choice behaviour; however, examination of the results for the three shorter delays reveals no significant difference, so morning and evening results were combined. In Fig. 1 mean percentage alteration is plotted against $\log t_2$. The 48 days of the experiment were divided into three blocks of 16 days, and an analysis of variance was performed, using stages of training, individual rats, and delays as the three criteria of classification; the effects due to both delays ($F = 10{\cdot}00$, $P < 0{\cdot}001$) and individual differences ($F = 3{\cdot}21$, $P < 0{\cdot}05$) were significant, but the effect due to stages of training was not ($F = 0{\cdot}82$). The interaction between individuals and stages of training was significant ($F = 1{\cdot}82$, $P < 0{\cdot}05$), which appears to be due to some rats increasing, some decreasing, their general rate of alternation over the course of the experiment. No other interaction approached significance.

The initial flat part of the curve in Fig. 1 would be predicted from the foregoing trace decline theory provided that $\bar{N}/\sigma_N$ is sufficiently large when $t_2 = 0$. However, if $\bar{N}/\sigma_N$ is large, $P_r \simeq 0$, but in fact P_r is initially nearly 0·2. Before trying to reconcile the theory with this finding, let us consider the nature of the individual differences. There are two possibilities: (*a*) Individual differences lie in the function $\bar{N} = f(t_2)$. This possibility may be subdivided further; for example, if $\bar{N} = f(a(t_2 + b))$ we might consider whether the individual differences are in a (which would be the time constant if the function were exponen-

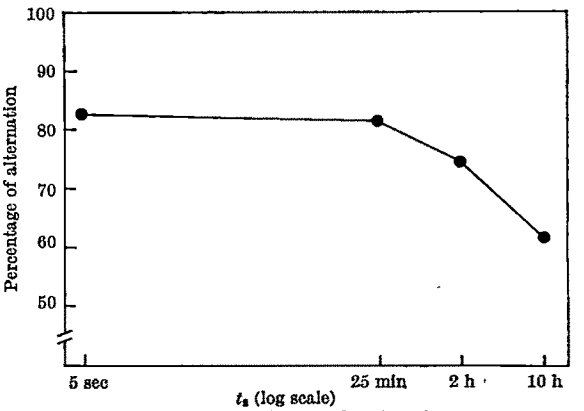

Fig. 1. Alternation as a function of t_2

* Present address: Department of Psychology, University of Durham.

trial), or in b (that is, differences in the value of $\bar{N}$ when $t_2=0$). If individual differences were of this form, an interaction between individuals and delays would, in general, be predicted. (*b*) Individual differences are in the probability of choosing according to the alternation tendency. It has been shown[7] that, where all choices are rewarded, rats choose sometimes according to an alternation tendency, sometimes according to a turn preference, and the respective probabilities of these two types of choice might vary among individuals. Thus, independent of the value of N, there might be a certain probability that the choice will not be according to the alternation tendency. Let this probability be q, and let P_a' be the probability that N is positive (that is, $P_a'=P_a$, the probability of alternation, if $q=0$). Then, if the rat is forced equally often to each arm, so that half the choices according to the turn preference will be alternations:

$$P_a=P_a'-\tfrac{1}{2}q\ P_a'+\tfrac{1}{2}q.\ (1-P_a')$$
$$=P_a'\ (1-q)+\tfrac{1}{2}q$$

Now P_a' varies systematically between delays (thus the effect due to delays), and q varies systematically between individuals (thus the effect due to individual differences); but P_a' and q are independent, and therefore there should be no interaction between individuals and delays.

Thus the absence of an interaction in the foregoing experiment supports *B*, that individual differences in alternation are due to differences in q. The existence of q can, in addition, explain why P_a, as estimated from Fig. 1, is not approximately 1 when the curve is flat. We may conclude that it is necessary to introduce q into the theory in order to explain both individual differences, and the absence of 100 per cent alternation at any delay; parameters such as a and b, already defined, cannot, of course, be rejected as potential intervening variables since they may well prove important in other contexts.

In the next experiments an attempt is made to infer certain characteristics of the assumed underlying trace decline (that is, the decline in $\log n_2$ and $\log n_1$). In order to do this two further assumptions are made: (*a*) that the traces corresponding to the two arms decline in strength with time in the same way, and in mutual independence. (*b*) That the general relation between trace strength, $\log n$ and time, t, since the last arm entry may be expressed in the form:

$$n=g(t)$$

Let $n_2/n_1=z\ (=e^N)$, and let $t_d=t_1-t_2$; then:

$$z=g(t_2)/g(t_2+t_d)$$

Regard t_d as a constant and differentiate.

$$\mathrm{d}z/\mathrm{d}t_2=\frac{g'(t_2).\ g(t_2+t_d)-g(t_2).\ g'(t_2+t_d)}{(g(t_2+t_d))^2}$$

Now $g(t_2+t_d)$ and $g(t_2)$ must always be positive (in order for trace strength to be of the form $\log n$), $g'(t_2+t_d)$ and $g'(t_2)$ are negative and $g(t_2)>g(t_2+t_d)$ (since $\log n_2$ declines with time). Furthermore, where the trace decline against t is positively accelerated, $|g'(t_2+t_d)|>|g'(t_2)|$. Thus, if the trace decline is positively accelerated, $\mathrm{d}z/\mathrm{d}t_2$ will be positive, and z (and therefore alternation) will increase as t_2 increases.

Let us suppose, as a working hypothesis, that the underlying trace, n, tends to an asymptote at 0, as $t\to\infty$, and $g(t)$ is either negatively accelerated throughout, or positively accelerated when t is small, and then negatively accelerated. Which of these possibilities is likely to be correct is tested in the following experiments, in which an attempt is made to find out whether or not the underlying trace decline is positively accelerated over the first few minutes.

In both experiments rats were given three trials per day. The first choice was forced to one arm, the second choice to the other arm, and the third choice was free. In the first experiment t_2 and t_d could be either 15 or 45 sec (yielding four possible combinations, each being used equally often); in the second experiment they could be 15 or 90 sec. Details of apparatus and procedure were the same as in the previous experiment. There was significantly less alternation at $t_d=15$ sec, compared with $t_d=45$ or 90 sec. In the first experiment alternation was about the same at $t_2=15$ sec as at $t_2=45$ sec; in the second experiment it was slightly (though not significantly) less at $t_2=15$ sec.

If the underlying trace decline were positively accelerated over the range tested there should be more alternation at $t_2=15$ sec than at the larger values; the failure to find this in the foregoing experiments thus supports the hypothesis that $g(t)$ is negatively accelerated throughout, as against the hypothesis that there is an initial positive acceleration.

The theoretical analysis of this report has been in very general terms, and the theory put forward and its assumptions can only be regarded as mildly strengthened by the demonstration that this analysis is possible. However, with greater precision in the results it should be possible to test between different mathematical formulations of $g(t)$. Consider, for example, a formula suggested by London[8] for memory in general. He supposed that the engram involved in memory is a complex of activated units, and that forgetting occurs through the inactivation of units with time. If it is assumed that the rate of change in the percentage of units still active at time t is proportional to the percentage active, n, out of the number of units initially active, $g(t)$ will be an exponential function. Thus:

$$\mathrm{d}n/\mathrm{d}t=-an$$

therefore

$$n=ce^{-at}\qquad (c \text{ is a constant})$$

Now, when $t=0$, $n=1$, therefore $c=1$. Thus:

$$n=e^{-at}$$

Suppose three trials are given per day as in the foregoing experiments; then at time t_2+t_d after the first trial:

$$n_1=e^{-a(t_2+t_d)}$$
$$n_2=e^{-at_2}$$

therefore

$$z=\frac{e^{-at_2}}{e^{-a(t_2+t_d)}}$$
$$=e^{at_d}$$

Thus z, and therefore alternation, will increase as t_d increases and will be independent of t_2. In the experiments already described there was indeed an increase in alternation with t_d, but also some evidence of a decrease with t_2 (since there was less alternation at $t_2=15$ sec than $t_2=90$ sec); if the latter result is substantiated, we may reject London's theory as an account of the memory trace involved in alternation, provided of course that the assumptions that have led us to this point are justified. These assumptions may be buttressed by finding a mathematical function that does fit the data with precision; or it may be found necessary to modify the assumptions, for example, by allowing some dependence between traces. At present more data are being gathered by means of experiments along the lines of those described, in order to find such a mathematical function, and show its applicability in as many situations as possible.

I thank the Medical Research Council for financial support, Mr. A. J. Watson for much helpful discussion and advice, and Prof. O. L. Zangwill for his continued encouragement.

LETTERS TO THE EDITOR

ASTROPHYSICS

Meteor Luminosity and Meteor Ionization

In two earlier communications[1,2] I drew attention to the fact that the discrepancy between theory and observation in respect of the light curves of meteors pointed out by Hawkins and Southworth[3] apparently necessitates a modification of the conventional theory of meteor luminosity. There is a better fit between theory and observation if the luminous efficiency factor is assumed to be proportional to the atmospheric density at every point of the meteor trail. However, no physical justification was adduced for such an assumption.

The conventional equation for meteor luminosity/ionization is:

$$I = \frac{1}{2}\left(\frac{dm}{dt}\right) v^2 \tau \qquad (1)$$

where I is the luminous/ionization intensity at any point of the trail, dm/dt is the rate of ablation of the meteor at that point, v is the velocity of the meteor and τ is an efficiency factor that determines what fraction of the kinetic energy of the ablated atoms is converted into luminous/ionization energy. At first sight it is not clear why τ should depend on atmospheric density, although it can have a functional dependence on v.

It is therefore important to enquire whether an explicit dependence of I on ρ in equation (1) can result from the factor dm/dt which is the rate of ablation of the meteor. With a spherical meteor of radius r falling through the atmosphere, the equation for ablation is:

$$L\, dm = \Lambda\, (\pi r^2 dz\, \rho)\, \frac{v^2}{2} \qquad (2)$$

where ρ is the atmospheric density, dm the mass ablated in falling through the height interval dz, L the heat of ablation per unit mass and Λ the heat transfer coefficient.

As has been pointed out by Thomas[4], Λ may be expected to be a function of the speed v and the air density ρ, although in the usual theory it is assumed to be a constant for a given meteor. Let us assume that:

$$\Lambda = \lambda \rho^{\alpha} \qquad (3)$$

where λ and α are constants.

Making use of the hydrostatic equation and the gas equation we readily obtain from equations (2) and (3):

$$dm = -\frac{\lambda}{Lg}\left(\frac{1}{RT}\right)^{\alpha} (\tfrac{1}{2}\pi r^2 v^2)\, p^{\alpha} dp \qquad (4)$$

where g is the acceleration due to gravity, T is the atmospheric temperature, and R the gas constant.

If dr is the decrease in radius of the meteor due to ablation while falling through the height dz, and ρ_m is the density of the meteor, we have:

$$dm = 4\pi r^2 dr\, \rho_m \qquad (5)$$

From equations (4) and (5) we obtain:

$$dr = -Kp^{\alpha} dp \qquad (6)$$

where, to the first approximation, K can be regarded as a constant for a given meteor. From equation (6) we readily obtain the two relations.

$$r = \frac{K}{\beta}(p_e^{\beta} - p^{\beta}) \qquad (7)$$

and:

$$m = K'(p_e^{\beta} - p^{\beta})^3 \qquad (8)$$

Here $\beta = \alpha + 1$ is a constant for a given meteor and p_e is the atmospheric pressure at the end of the meteor trail.

From equation (8) it can be shown that:

$$\frac{dm}{dt} = K_1(1 - \zeta)^2\zeta \qquad (9)$$

where K_1 is a constant for a given meteor to the first approximation, and $\zeta = x^{\beta}$, where $x = p/p_e$.

If H is the atmospheric scale height (assumed constant to the first approximation) at meteor levels, then:

$$x = \frac{p}{p_e} = \exp\left(-\frac{h}{H}\right)$$

where h is the height interval between the instantaneous level of the meteor and the level corresponding to the end of the meteor trail. From equation (9) it is readily seen that dm/dt is a maximum for $\zeta = \frac{1}{3}$ and:

$$\left(\frac{dm}{dt}\right)_{max} = \frac{4}{27} K_1 \qquad (10)$$

If τ is constant, we obtain from equations (1), (9) and (10):

$$I/I_{max} = \frac{27}{4}(1 - \zeta)^2\zeta \qquad (11)$$

This is the equation for the normalized light/ionization curve of the meteor. The corresponding equation expressed as magnitude difference is:

$$\Delta M = M - M_{max} = -2{\cdot}5 \log (I/I_{max})$$
$$= -2{\cdot}5\left[2 \log (1 - \zeta) + \log \zeta + \log\left(\frac{27}{4}\right)\right] \qquad (12)$$

Equation (12) is similar to equation (4) in my earlier note[1] except that ζ now occurs in place of x. Since $\zeta = x^{\beta}$, it follows that for $\beta = 1$, equation (12) becomes identical to equation (4) of the earlier note which is the equation for the light/ionization curve given by the conventional theory. From equation (3) it is seen that in this case Λ is independent of ρ.

When $\beta > 1$, the light curves given by equation (12) and the conventional theory are different. For increasing values of β the ascending and descending branches of the

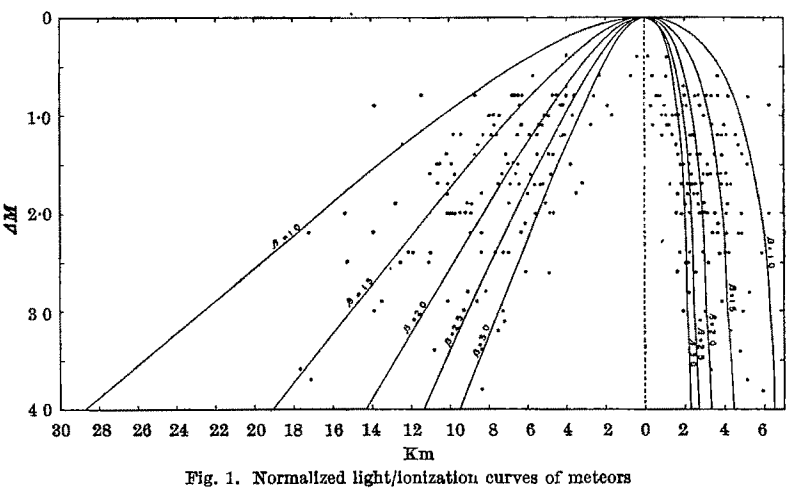

Fig. 1. Normalized light/ionization curves of meteors

light curve become progressively steeper so that the meteor trail becomes shortened. For a given value of ΔM, however, the ratio of the lengths of the ascending and descending branches is independent of β.

Fig. 1 shows the normalized light/ionization curves corresponding to $\beta = 1{\cdot}0$, $1{\cdot}5$, $2{\cdot}0$, $2{\cdot}5$ and $3{\cdot}0$, respectively, assuming[2] a value of 6·38 km for the atmospheric scale height. Fig. 1 also shows the plot of the points corresponding to the beginning and end of the meteor trails in the random sample listed by Hawkins and Southworth[3] after eliminating the majority of the fragmented meteors[2]. There appears to be definite evidence for the dependence of Λ on atmospheric density. The light curve obtained previously, by assuming that τ is proportional to ρ, lies between the light curves corresponding to $\beta = 1{\cdot}5$ and $2{\cdot}0$. This assumption must be rejected because it lacks physical basis. The assumption that the heat transfer coefficient Λ is dependent on the atmospheric density ρ, which is plausible on physical grounds, can explain the major discrepancy between theory and observation in respect of meteor luminosity/ionization.

PHYSICS

Electric Strength of Compressed Air in a Uniform Field

IN a uniform field, Paschen's law, namely, breakdown voltage $V = f(p.d)$ (where p is the gas pressure and d is the gap distance), holds for values of p up to about 10 atm., beyond which the improvement in electric strength of air becomes progressively less than would be expected from this relationship. Most published data extend only up to some 1,200 lb./in.^{2}, and beyond this pressure information is sparse and predictions of the electric strength, E, are difficult as a result of the lack of experimental data. The cause of this departure from Paschen's law may be attributed to the nature of the electrode surfaces. At high pressures, the electric strength of air is dependent on the shape, disposition and material of the electrodes and also on the degree of smoothness of their surfaces[1-3].

Aluminium electrodes give markedly lower values of electric strength at high pressure than, for example, stainless steel, and the material forming the cathode has greater influence than that of the anode[4,5]. Felici and Marchal suggest that the electric strength of air is dependent on the work function φ of the electrode material, metals with high values of φ giving high values of electric strength. Although φ for stainless steel is not exceptionally large, they attribute the high values of E obtained with this metal to its oxide film, which acts as a barrier to cold emission.

According to Llewellyn-Jones[6], a new ionization process must come into play at high pressure which cannot be any of the 'normal' low-pressure gas-collision processes. Furthermore, this process must be cathode-dependent and the Townsend type of mechanism assisted by field emission has been proposed as this ionization process. Other investigators have attributed deviations from Paschen's law to the action of space charges in the gas. Llewellyn-Jones points out that, if this were true, E would be independent of the nature of the cathode. In addition, he found it difficult to accept the cold emission theory since the Fowler-Nordheim theory requires fields ~ 10 MV/cm to produce significant cold emission.

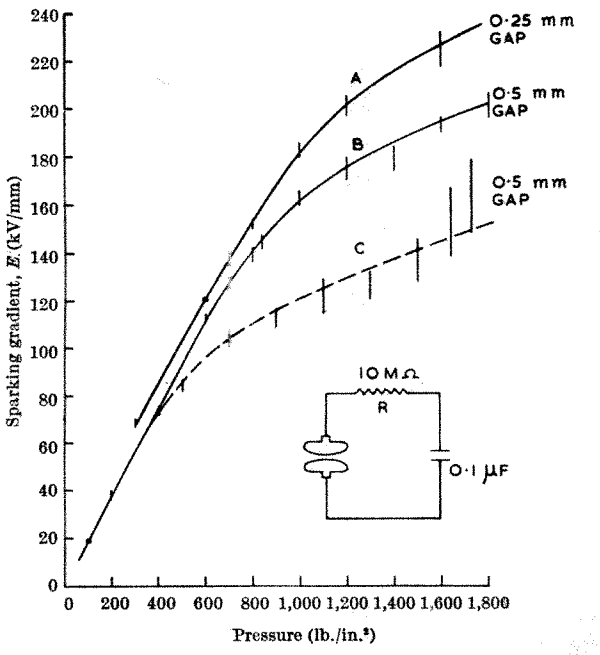
Assessment of the merits of compressed air insulation at pressures $\geqslant 1{,}200$ lb./in.^{2} is of technological importance. However, more experimental information is necessary and, in particular, it is necessary to know how E varies with change in pressure. If E becomes independent of change in pressure, at what pressure does this take place and how important are the shape, disposition and material of the electrodes?

Recent work in our laboratories has demonstrated that there is, in fact, a continuous upward trend of E up to 1,750 lb./in.^{2}. A few preliminary results will now be discussed.

Stainless steel electrodes, 1 cm in diameter, having profiles suggested by Bruce[7], were used in the tests. Three test runs were made using new electrodes for each run (Fig. 1, curves A, B and C). For tests A and B, the electrode surfaces were carefully machine-polished using successively finer grades of emery paper, then Selvyt cloth impregnated with fine alumina, followed by degreasing, washing and drying. The electrodes used for test run C underwent a slightly inferior process. They were simply hand-polished (after the emery paper process) using metal polish, and then degreased. This treatment is believed to be responsible for the marked difference in curves B and C in Fig. 1 at pressures in excess of 400 lb./in.^{2}.

Air having a moisture content < 200 p.p.m. was passed through a silica-gel drying unit before being admitted to the test chamber. The sequence of tests was from high to low pressure and the vertical lines embrace ten consecutive breakdowns. Determination of the electric strength of gases is usually made after a number of breakdowns to condition the electrode surfaces. This process, referred to as 'conditioning', infers the removal by breakdowns of microscopic irregularities and dust particles. Hence, the number of conditioning breakdowns required reduces with improvement in the electrode surface finish.

In the tests described, the first application of voltage gave a value some 25 per cent lower than the final average value in the conditioned range reached after about five breakdowns. Voltage was raised quickly to about 90 per cent of the breakdown voltage, then very slowly up to break-



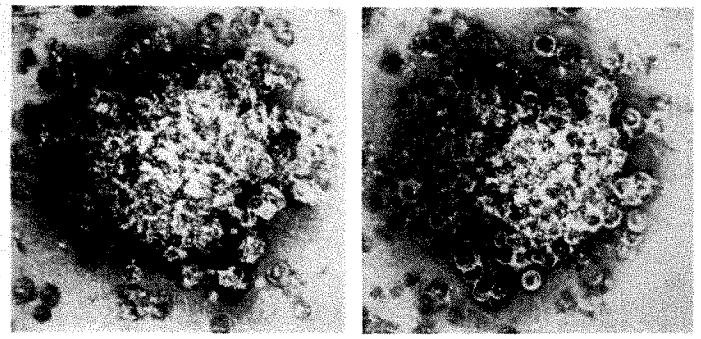


Fig. 1. Direct current sparking gradient of compressed air in a uniform field using stainless steel electrodes (20° C)

Anode Cathode

Fig. 2. Photomicrograph of central area of uniform-field stainless steel electrodes. Test *A*. (× 16)

down. It was found that the 1-min withstand value was within 5 per cent of the minimum breakdown value obtained by raising the voltage slowly. Since conditioning depends partly on the degree of smoothness of the electrode surfaces, it follows that the value of the current-limiting resistance R is also important. To limit damage to the electrodes caused by sparking, a 10 MΩ current-limiting resistance was used. Micrographs of the electrode flats taken after test run *A* are shown in Fig. 2. The pattern of spark roots on each electrode is clearly shown. The peripheries of the cathode roots are more clearly defined than those on the anode.

At pressures in excess of 1,000 lb./in.² other workers appear to have found no appreciable gain in the electric strength of air. Zeir[8] gives values up to 1,760 lb./in.² for gaps up to 0·5 mm and direct voltages up to 100 kV. His results are plotted to a $p.d$ scale and are in general agreement with the present work.

The preliminary results described indicate that if, in fact, there is a levelling-off of electric strength at high pressure, then the critical pressure is well beyond 1,000 lb./in.² for the present test conditions.

We thank Messrs. P. Headley and D. G. McCulloch for advice and assistance in the preparation of the test arrangement.

Properties of Synthetic Good Conductors of Electricity

For both theoretical and practical reasons, it is of considerable interest to develop synthetic good conductors of electricity. From a theoretical point of view, these could serve as interesting alternative model substances by which to test various theories of electric current flow in solids. From a practical point of view, synthetic good conductors might for some purposes become useful rivals to the best natural good conductors, such as copper or silver.

One route to synthetic good conductors of electricity lies in the properties of charge transfer compounds, and in particular in the crystal compounds of graphite. As has been known for some time, good conductors of electricity can be formed both by intercalating electron donor atoms such as the alkali metals (n-type) and electron acceptor groups such as bromine or iodine monochloride (p-type)[1]. Electrolytic formation of acid salts, such as the bisulphate[2], the perchlorate[3] and many other acid derivatives[4], likewise leads to electron acceptor compounds that are good conductors of electricity.

However, to use these crystal compounds as model good conductors of electricity, in addition to achieving optimum stoichiometry it is essential to control the defect concentration, which has a powerful effect on scattering charge carriers in the transport of electricity. Considerable advances in this direction were achieved by replacing polycrystalline graphite[1,2] by well-aligned pyrolytic graphite formed by cracking hydrocarbons[3], but for fully informative investigations it is essential to use near-ideal graphite, such as the material formed from pyrolytic graphite by stress-annealing at high temperatures under moderate pressure[5]. Quite large pieces of such near-ideal graphite can now be formed; the best of these materials can be selected by various non-destructive techniques[6].

Fig. 1 illustrates a specimen of near-ideal graphite cut and mounted preparatory to transforming it into various graphite nitrates by exposing it to the vapour of nitric acid under appropriate conditions[7]. With suitable precautions, nitration proceeds smoothly, and can attain the stoichiometry of the different sequences without introducing specimen distortions or additional crystal disorder to any marked extent.

mm

Fig. 1. Specimen of graphite cut and mounted with leads

Resistivities of the resulting specimens of graphite nitrate of the (black) second sequence, and of the (deep blue) first sequence, were measured down to the freezing point of nitrogen. With rising or falling temperatures, electrical resistances were found to be reversible within experimental error, except through the order–disorder transformation at about −20° C (ref. 8). In the lambda region, a hysteresis loop is clearly apparent, particularly for the first sequence compound (Fig. 2). The steep drop in resistance below the lambda point (Fig. 3) is probably due to increased mobility of the charge carriers in the ordered state of this crystal compound.

Temperature coefficients of electrical conductance of different specimens can be compared in a reduced plot of ρ_T/ρ_0. A similar trend is found for all these preparations. A steep drop occurs in all cases on passing through the lambda point. For the ordered crystal compounds below their lambda points, the rate of change with tem-

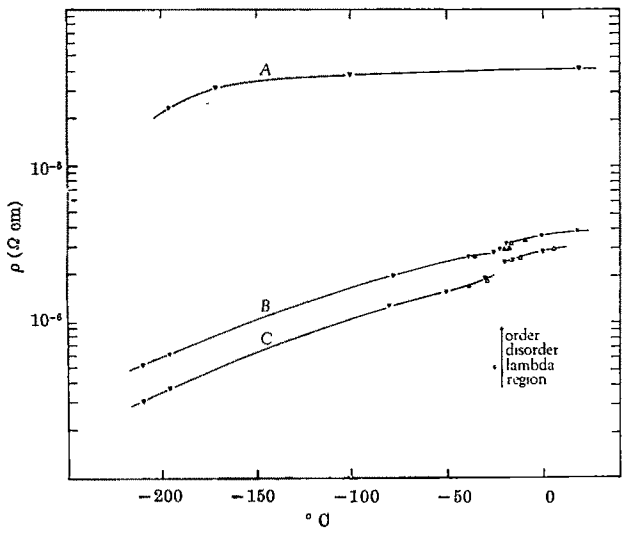

Fig 2. Resistivity of graphite nitrates *A*, Graphite (stress-annealed); *B*, graphite nitrate, second sequence; *C*, graphite nitrate, first sequence. ▼, Descending *T*, △, ascending *T*

perature is comparable with that of natural metallic conductors, such as silver, plotted for comparison in Fig. 3. The influence of residual crystal defects leading to some temperature-independent scattering can, however, be detected in the graphite nitrates, particularly at the lowest temperatures.

On conversion of the original graphite specimen to the nitrate at room temperatures, the crystal expands in the *c*-axis direction but remains unchanged in dimensions parallel to the *a*-axis. Corresponding resistivities for the disordered state, and for the ordered crystals below the lambda point, are recorded for a number of specimens in Table 1. It can be seen that values for the ordered first sequence of graphite nitrate are close to those of copper or silver at comparable temperatures.

Black-body Radiation Law deduced from Stochastic Electrodynamics

SOME years ago, one of us developed, in collaboration with M. Spighel and C. Tzara, a stochastic version of Wheeler and Feynman's 'absorber' theory of radiation, with a classical 'zero-point' fluctuating field corresponding to residual interactions of all charged particles[1]. The energy spectrum was derived and found to be proportional to a universal constant—identifiable with Planck's constant *h*. In the framework of this stochastic electrodynamics it was possible to deduce results of a typically quantum flavour, such as the existence of a stationary ground-level for the harmonic oscillator[2]. A weaker but similar result was announced later by T. Marshall[3,4].

Recently, we showed that a new (apart from a very brief suggestion by A. Sokolov and V. Tumanov[5]) but rather natural definition of momentum and energy would dispense with any substrating or 'cut-off' procedures. In this manner further results were obtained in the stochastic model, such as a 'Lamb-like shift' without any *a priori* quantification[6].

Now Planck's energy distribution for thermal radiation within a black-body can be viewed as the energy spectrum of a random electromagnetic field in the body[7]. Therefore it seems natural to look for a derivation of this law based only on the assumptions of our model.

In the search for such a derivation it must be remembered that classical statistical mechanics applied to thermal radiation phenomena lead to an 'ultra-violet catastrophe' as a consequence of the theorem of equipartition

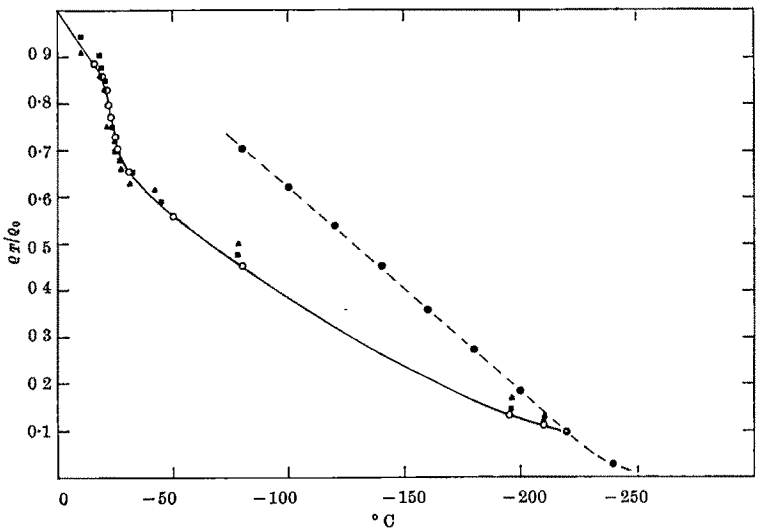

Fig. 3. Resistivity ratio at temperature *T* relative to 0° C First sequence graphite nitrate. Specimen: ○, 31(2)1; ▲, 31(4)5; ■, 31(2)4; ●, silver

of energy. But the theorem itself results from a computation of the average energy which strongly depends, through the canonical distribution, on the classical Hamiltonian. This Hamiltonian is the sum of individual particle Hamiltonians and neglects interactions, while it is understood that a very small interaction still exists and is responsible for the existence of an equilibrium[8].

Now as the black-body to be described here is a system of charged particles in motion, our definitions in ref. 6, equation (5), apply and we can write:

$$P_{\text{electrokinetic}} = m\dot{x} - \frac{2e^2}{3c^3}\ddot{x} + A_{\text{random}} \quad (1)$$

$$E_{\text{electrokinetic}} = (P_{\text{electrokinetic}})^2/2m \quad (2)$$

$$E_{\text{tot}} = E_{\text{electrokinetic}} + E_{\text{pot}} \quad (3)$$

where the symbols have their normal meaning.

The use of equation (3) for the computation of total energy eventually changes the issue of the equipartition theorem. An interaction term which can no more be neglected is to be added to the standard kinetic energy term, namely $kT/2$ per degree of freedom. It is hoped that divergences will be eliminated with the help of our new definition of total energy in the same way as they have been eliminated for the case of an isolated harmonic oscillator.

Therefore our procedure consists of finding a direct evaluation of the interaction energy in the case of a system of linear harmonic oscillators in thermal equilibrium with a black-body at the temperature T. Assuming a body large enough to justify a dipolar approximation, and calling $E_i(\nu)$ and $\overline{E_i}(\nu,T)$ the maximum interaction energy and the average interaction energy, respectively, of an oscillator of natural frequency ν, we have the classical formula:

$$\overline{E_i}(\nu,T) = \frac{c\int_0^{\pi} e^{E_i(\nu)\cos\theta/kT}\, E_i(\nu)\cos\theta\sin\theta\,d\theta}{c\int_0^{\pi} e^{E_i(\nu)\cos\theta/kT}\sin\theta\,d\theta} \quad (4)$$

where θ is the angle of the axis of the oscillator with the direction of the field[9].

Straightforward integration leads to:

$$\overline{E_i}(\nu,T) = E_i(\nu)\, L\,(E_i(\nu)/kT) \quad (5)$$

where:

$$L(x) = \coth x - \frac{1}{x} \quad (6)$$

is Langevin's function, which makes apparent the analogy between this derivation and the classical theory of paramagnetism as already had been suspected in 1913 by Benedicks[10].

If $\overline{E_{\text{tot}}}\ (\nu,T)$ is the average of the total energy for an oscillator, and if one writes:

$$\overline{E_{\text{electrokinetic}}}(\nu,T) = \overline{E_{\text{kinetic}}}(\nu,T) + \overline{E_i}(\nu,T) \quad (7)$$

knowing that, for each degree of freedom:

$$\overline{E_{\text{kin}}}(\nu,T) = \overline{E_{\text{pot}}}(\nu,T) = kT/2 \quad (8)$$

one obtains from (3), (6), (7), (8) applied to (3):

$$\overline{E_{\text{tot}}}(\nu,T) = E_i(\nu)\coth\,(E_i(\nu)/kT)$$
$$= E_i(\nu)\left(\frac{2}{e^{2E_i(\nu)/kT} - 1} + 1\right) \quad (9)$$

A basic property of our model, ref. 6, equation (11), is that to the first approximation:

$$\overline{E_{\text{tot}}}(\nu,0) = \frac{h\nu}{2} \quad (10)$$

On the other hand, we have from equation (9):

$$E_{\text{tot}}(\nu,0) = E_i(\nu) \quad (11)$$

This gives:

$$E_i(\nu) = \frac{h\nu}{2} \quad (12)$$

which, added to equation (9), implies:

$$E_{\text{tot}}(\nu,T) = \frac{h\nu}{2}\left(\frac{2}{e^{h\nu/kT} - 1} + 1\right) \quad (13)$$

The central part played here by $\overline{E_{\text{tot}}}(\nu,0)$, which corresponds to the 'zero-point' field, is noteworthy. This, in addition to the elimination of the ultra-violet divergence, ensures self-consistency to our model, and answers positively a question raised by Einstein and Stern[11].

Finally, equation (13) leads, of course, to the black-body energy distribution law by well-known arguments (see, for example, ref. 12).

METEOROLOGY

Formation of Depressions in the Indian Seas and Lunar Phase

IT was recently shown[1] that the occurrence of heavy rainfall (10 in. and above in 24 h) is related to lunar phase. It will be evident that such heavy falls are mostly associated with depressions, some of which intensify into cyclones and severe cyclones. A study was therefore undertaken to examine the dates of formation of depressions in the Indian Seas *vis-à-vis* the lunar phase. This communication was prompted by Bradley's article "Tidal Components in Hurricane Development"[2] and is intended to provide some additional information to support his conclusions.

The data for this investigation were taken from a publication issued by the Indian Meteorological Department[3] which catalogues depressions formed in the Indian Seas, and gives the date on which the depression stage was reached and its corresponding position.

The phase of the Moon for each day is given in terms of synodic decimals (hundredths of a synodic month) in the ephemeris by Carpenter[4]. The synodic decimal corresponding to each date was taken from that source and the frequency of formation of depressions corresponding to each synodic decimal was found. Successive ten-unit moving totals of the frequencies were then made, and of the hundred such totals thirty were chosen to correspond to the thirty days of the lunar month. For purposes of comparison the frequencies were expressed as percentages of the mean.

Fig. 1 shows the curve, prepared in this manner, of depressions which formed in the latitude band 19° N–22° N in the Bay of Bengal and Arabian Sea during the period 1877–1960. Fig. 2 shows the frequencies of occurrence of heavy rainfall (10 in. and more in 24 h) along the latitude band 20° N–22° N during the period 1891–1950, and is reproduced from my recent article[1]. A similarity is noticed in the trends of the curves in Figs. 1 and 2; their range is also comparable. The correlation between the two curves is 0·50. The correlation between the curves with 1 day

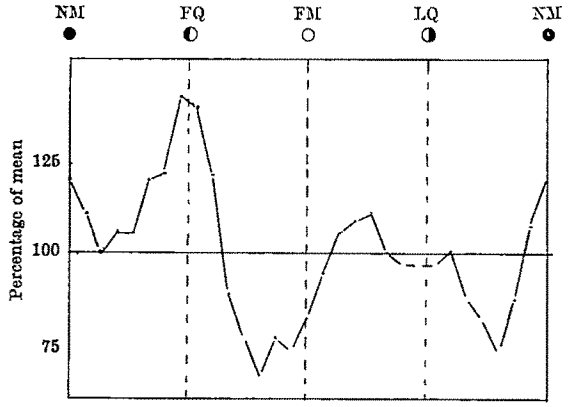

Fig. 1. Frequency of depressions (1877–1960) in the latitude band 19° N–22° N in the Bay of Bengal and Arabian Sea

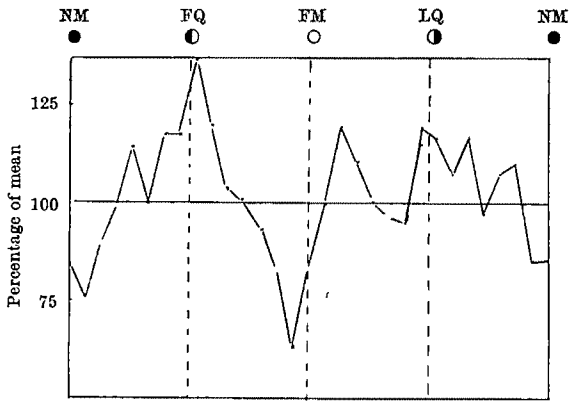

Fig. 2. Frequency of occurrence of heavy rainfall (10 in. and more in 24 h) along latitude band 20° N–22° N, India, 1891–1950

lag (heavy rainfall following depressions) is 0·57 with $\varphi = 0{\cdot}07$. There is a strong indication that the heavy falls were associated with depressions. The tidal influence on the formation of depressions is also indicated, as in both the curves the 14·765 day wave accounts for 48·1 of the total variance and is the largest component.

Any extra-terrestrial effect on meteorological phenomena should be established on a global scale. This calls for an analysis of data pertaining to various parts of the globe. This note, it is hoped, will stimulate interest in further studies of this kind.

METALLURGY

Some Problems in the Use of Solid-state Galvanic Cells at Low Temperatures: the Determination of the Eutectoid Temperature of the Iron–Oxygen System

THE use of solid-state galvanic cells to obtain thermodynamic information is now well established, and the present work was carried out to obtain experience in the use of zirconia doped with lime, as solid electrolyte for oxygen ions only, at low temperatures. Previous experience with this electrolyte has been above 700° C, below which the resistance of the electrolyte rapidly increases and it becomes correspondingly more difficult to obtain information with useful accuracy. The major cause of inaccuracy at low temperatures is non-attainment of equilibrium in the electrodes. This can be severe where alloys are involved and may limit the lowest temperature at which reliable equilibrated results can be obtained.

In order to test the accuracy of the results obtained within the temperature range 400°–600° C, the eutectoid temperature of the Fe–O system was measured by two methods involving galvanic cells. The first method involved measurements between 400° and 1,000° C, while the second involved measurements between 600° and 1,000° C, and, as will be seen, is inherently more accurate. By comparing the results of both methods some idea can be gained of the accuracy or reliability of the results obtained in the range 400°–600° C.

The electrode systems involved (Ni + NiO, Fe + Fe_3O_4, Fe + FeO) were either so rigidly stoichiometric or of such high diffusion properties that equilibrium was quickly established, only at the lowest temperatures used was the time to reach equilibrium greater than a few hours.

If the standard free energies of formation of FeO and Fe_3O_4 are plotted against temperature, the two curves cross at the eutectoid temperature, that is, the temperature of the Fe–O system at which Fe, FeO and Fe_3O_4 exist together in equilibrium. As may be seen from the phase diagram Fig. 1*A*, the oxides FeO and Fe_3O_4 are stable above and below the eutectoid temperature, respectively, in the simple Fe–O system. Experimentally it is more convenient to consider the free-energy change when nickel oxide is reduced by iron to nickel and iron oxide according to the equations:

(above eutectoid temperature)

$$NiO + Fe = FeO + Ni \qquad \Delta G_1^0 \qquad (1)$$

(below eutectoid temperature)

$$NiO + \tfrac{3}{4}Fe = \tfrac{1}{4}Fe_3O_4 + Ni \quad \Delta G_2^0 \qquad (2)$$

The standard free-energy change of this reaction can be studied following Kiukkola and Wagner[1] by using an electrolytic cell with mixtures of iron and iron oxide, nickel and nickel oxide as electrodes and zirconia doped with 15 mol per cent calcium oxide as solid electrolyte, that is:

(above eutectoid temperature)

$$Ni + NiO \mid ZrO_2 + 0{\cdot}15\ CaO \mid Fe + FeO \qquad (I)$$

(below eutectoid temperature)

$$Ni + NiO \mid ZrO_2 + 0{\cdot}15\ CaO \mid Fe + Fe_3O_4 \qquad (II)$$

On passing 2 farads through these cells the displacement reaction (1) and (2), respectively, is caused to occur and the free energy associated with the reaction may therefore be measured under open circuit conditions as a function of the electromotive force of the cell:

$$\Delta G_1^0 = -2FE_I$$

or

$$\Delta G_2^0 = -2FE_{II}$$

Obviously the eutectoid temperature is just as easily detected if E instead of ΔG were plotted against temperature.

The cells were made up quite conventionally, the electrolyte disks being prepared according to the method proposed by Kuikkola and Wagner[1]. The electrodes were made by pressing pellets of mixtures of metal and metal oxide powders. Spectrographically pure iron, nickel, iron oxide and nickel oxides were used and the experiments were carried out under an atmosphere of purified nitrogen[2].

Below 700° C the initial experiments showed lower values of electromotive force than predicted from known thermodynamics, although the same cells had repeatedly

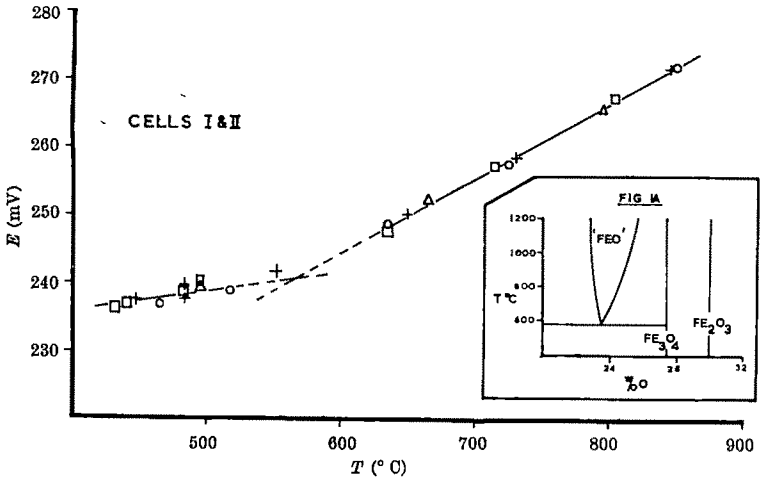

Fig. 1

given correct values at higher temperatures. This result would be expected, however, if the electrolyte were porous, thus allowing oxygen to diffuse as gas from the high oxygen potential electrode. Unless interdiffusion processes are swift enough to maintain equilibrium throughout the electrodes, such permeation of oxygen could cause an oxygen-rich layer to be established at the interface between the electrolyte and the low oxygen potential electrode (Fe + FeO) and, possibly, also an oxygen-depleted zone at the interface between the electrolyte and the high oxygen potential electrode (Ni + NiO). The electromotive force measured under these conditions would be lower than expected from the known thermodynamics—as observed.

This explanation was tested in two ways. First, a new batch of electrolyte was fired to 1,600° C instead of 1,450° C, and this proved to give more reliable results at low temperatures, probably due to more extensive sealing of the pores and consequent elimination of many of the direct migration paths for oxygen gas molecules through the electrolyte. Secondly, the suspected porous electrolyte was used to make a cell of lower electromotive force:

$$Fe + FeO/ZrO_2 + CaO/FeO + Fe_3O_4 \qquad (III)$$

In this case the driving force for diffusion of oxygen through the pores is lower, also the interdiffusion processes in the FeO/Fe_3O_4 electrode are faster than in the Ni/NiO electrode; consequently the results were as predicted from thermodynamics right down to the eutectoid temperature where the electromotive force of cell (III) becomes zero.

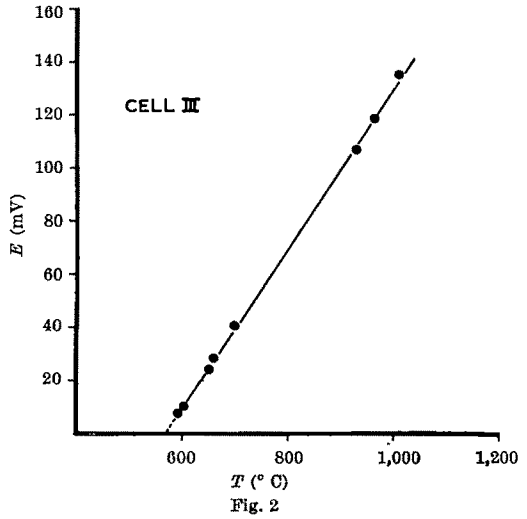

Fig. 2

Subsequent experiments were made using electrolyte tablets about 1 mm thick and 10 mm diameter (giving 10^6 ohms at 400° C), fired at 1,600° C, which produced an electrolyte sufficiently dense for reliable results to be obtained down to about 400° C.

By using a Cambridge 41127/2 galvanometer, readings could be made to within about ±1 mV at 400° C where the cell resistance was about 10^6 ohm.

Fig. 1 shows the results of several runs made using cells (I) and (II), the lines through the points being drawn according to statistical least squares analysis. According to these results the eutectoid temperature lies at 565° C.

The data of Fig. 1 show that reliable results may, with care, be obtained from this type of galvanic cell, at temperatures down to 400° C; however, the plot of Fig. 1 is not ideal for determination of the eutectoid temperature since it involves the extrapolation of two lines (one of which is not very well defined) to meet obliquely. A better method would be to use the cell:

$$Fe + FeO/ZrO_2 + CaO/FeO + Fe_3O_4 \qquad (III)$$

the electromotive force of which is zero below the eutectoid temperature since then both electrodes consist, at equilibrium, of $Fe + Fe_3O_4$. This cell was investigated down to the triple point and the data are plotted in Fig. 2. In this case only a short extrapolation of one well-defined line is required and the intersection with the temperature axis at $E = 0$ gives the eutectoid temperature, which in this case is also given to be 565° C. This is in excellent agreement with 565° C from Fig. 1 and the value of 560° C given by Darken and Gurry[3].

The aim of this report, however, is not simply to provide an alternative estimation of the eutectoid temperature of this system but to emphasize that such determinations may be carried out relatively easily. Using this technique, all that is required is an impervious furnace tube and an inert atmosphere, that is, by removing oxygen and the gases involved in redox systems, such as hydrogen water vapour, carbon monoxide and carbon dioxide, from argon or nitrogen. Under these conditions the galvanic cells used here will operate reliably for days or weeks on end; to obtain results the temperature is simply changed and the system allowed to equilibrate; the time for this process depends on the system under investigation and cannot be improved by alternative methods of measurement.

Most of this work was carried out at the United Steel Companies, Swinden Research Laboratories.

CHEMISTRY

A New Calcium Silicosulphate

A COMPREHENSIVE investigation is in progress of high-temperature phase equilibria in the system $CaO—SiO_2—SO_3$ which is important in the chemistry of cements. A new compound has been located of molar composition at present best represented as $(2CaO.SiO_2)_2.CaSO_4$. This compound has been prepared from calcium carbonate (99·9 per cent pure), crushed quartz (99·95 per cent pure) and AnalaR $CaSO_4 2H_2O$ by ignition for 150 h at 1,150° C

in platinum boats in a platinum-rhodium resistance furnace. For successful preparation the mixture has to be finely ground to pass a 300-mesh sieve in between periods of heating. The X-ray diffraction pattern of the new compound first became discernible after about 2 h of heating. On continued heating, the X-ray diffraction patterns of the reactants and of dicalcium silicate became progressively weaker until, after 150 h, they reached intensity-levels representative of trace quantities.

The X-ray diffraction pattern of the new compound is given in Table 1. These measurements were made at room temperature using a Guinier-type focusing camera, 114 mm diameter with copper-$K\alpha$ radiation. Relative intensities (I) were estimated visually on an arbitrary scale from 1 (very weak) to 10 (very strong). Reflexions of intensities 2 or less have not been included in Table 1.

Table 1. ROOM TEMPERATURE X-RAY POWDER MEASUREMENTS FOR A NEW CALCIUM SILICOSULPHATE

d	I	d	I	d	I	d	I

4·24	3	2·611	8	2·015	4	1·698	6
4·08	7	2·564	9	1·958	6	1·676	3
3·95	7	2·479	4	1·947	3	1·668	4
3·85	3	2·382	3	1·926	3	1·614	3
3·60	3	2·354	3	1·895	9	1·576	3
3·34	7	2·287	5	1·891	9	1·563	3
3·19	9	2·230	4	1·848	3	1·551	3
3·12	7	2·201	4	1·837	5	1·528	6
3·04	7	2·169	5	1·820	4	1·512	3
2·99	7			1·804	5	1·489	3
2·98	7			1·780	4	1·385	3
						1·367	5

The preparation was in the form of small anhedral equant grains. The refractive index of the material in bulk was 1·635 and of isolated elongated grains slightly lower than 1·635. Birefringence of these crystals was very low and this, together with the very small size of the crystals, has so far prevented a more accurate estimation of optical properties. The density of the new compound is 2·95 g cm^{-3}.

The X-ray diffraction pattern in Table 1 resembles that of a compound detected by Sundius and Peterson[1] as a green mineral which colours the sulphate rings accumulating in cement rotary kilns. Differences between the two patterns include the recognition of doublets in place of single high-intensity lines reported by these authors. The high resolution attainable with the focusing X-ray camera used in the present work may account for this difference. The pattern in Table 1 is also richer than that reported by Sundius and Peterson, although low-intensity reflexions have been excluded from the present report. Sundius and Peterson ascribed to their compound the formula $Ca(Na_2K_2)\ SO_4$: silicate = 1 : 1·75 in which the silicate component was given the formula $Ca(MgFe)O{:}SiO_2 = 2{\cdot}17{:}1$. Their synthetic preparation contained 1·4 per cent MgO, 1·4 per cent alkalis and 0·1 per cent FeO. In the present work the preparation believed to lie in the ternary system $CaO—SiO_2—SO_3$ contained $< 0{\cdot}02$ per cent MgO, $< 0{\cdot}01$ per cent alkalis and 0·01 per cent FeO.

The optical properties of the two compounds are also similar and both materials are coloured green in ordinary light. It is probable that the compound found in the kiln rings is an impure form of the calcium silicosulphate which has been isolated.

The new compound has been detected in a range of compositions in the system $CaO—SiO_2—SO_3$ in preparations of carefully controlled composition which were annealed at approximately 1,100° C in platinum capsules fully sealed by welding. The phase assemblages between $(2CaO.SiO_2)_2.CaSO_4$ and adjoining compounds are being investigated. It has been established that the X-ray diffraction pattern of the new phase is the same in these different compositions in agreement with the proposal that this phase is a compound and not, for example, a solid solution. This calcium silicosulphate has been examined in a high-temperature X-ray camera[2] in a stream of pure nitrogen at successively higher temperatures and its X-ray diffraction pattern recorded up to 1,150° C. The present evidence indicates decomposition not far above this temperature.

Performance of Oxygen Fuel Cell Cathodes catalysed with Boron Carbide

THE development of suitable inexpensive electrode catalysts is one of the major tasks confronting fuel cell technologists. The platinum group metals have received considerable attention as catalysts, despite their high cost, because of their combination of stability and high catalytic activity. It has been pointed out[1], however, that only a small amount of the world demand for power could be generated by hydrogen/oxygen fuel cells using the entire world production of platinum. The situation is equally unattractive for the other platinum-group metals. Consequently, for any broad-based terrestrial application of fuel cells, it is necessary to find a cheaper and more readily available material. There have been several publications describing some anode[2–6] and cathode[7,8] catalysts that are cheaper than the platinum-group metals.

This report presents some results with boron carbide as a cathode catalyst in alkaline fuel cells. Boron carbide is an electronic conductor, is available inexpensively in powder form, and is resistant to corrosion by fuel cell electrolytes. It also has been reported to be resistant to electrochemical oxidation[9].

The catalyst mixture, containing a 1:1 by weight ratio of boron carbide of 9·5-μ average particle size (obtained from the Norton Company) and 'Teflon' from the *TFE* 3170 dispersion (obtained from E. I. du Pont de Nemours and Co., Inc.), was applied to porous nickel plaques which were afterwards made waterproof by a method similar to that of Niedrach and Alford[10]. The geometric area of the electrode exposed to the 94° ± 2° C 45 per cent potassium hydroxide flowing electrolyte was 48 cm^2. Electrode spacing was 3 mm. Electrode potentials were measured against an external mercuric oxide reference electrode and included a small IR loss of about 40 mV at 100 m.amp/cm^2.

The results of cathodic polarization measurements taken after about 40 h of operation at 50 m.amp/cm^2 are presented in Fig. 1 as open symbols. The closed symbols represent data taken after a minimum of 320 h continuous operation at 50 m.amp/cm^2. Curves A and B are for standard supported precious metal catalysed carbon and uncatalysed carbon electrodes, respectively, and are given for reference purposes. Curve C shows the polarization for boron carbide at three different catalyst loadings—1·5, 4·4, and 9·2 mg/cm^2. It is very unusual that the catalyst loading should have no influence on the polarization. The performance of the electrodes with 1·5 and 9·2 mg/cm^2, when operated at 50 m.amp/cm^2 continuously, however, does diverge at operating times in excess of about 50 h. Curves C and D of Fig. 2 show how these electrodes perform at constant current density as a function of time. The polarization of these two electrodes, measured at times in excess of 320 h, is shown in Fig. 1 by curves E and F. The electrode with the least amount of boron carbide (curve F) changes most with time. Thus it appears that the catalyst loading does influence the electrode performance even though it takes some time for such differences to become evident.

The cause of this decay in performance with time may be due to an impurity in the boron carbide. Consequently,

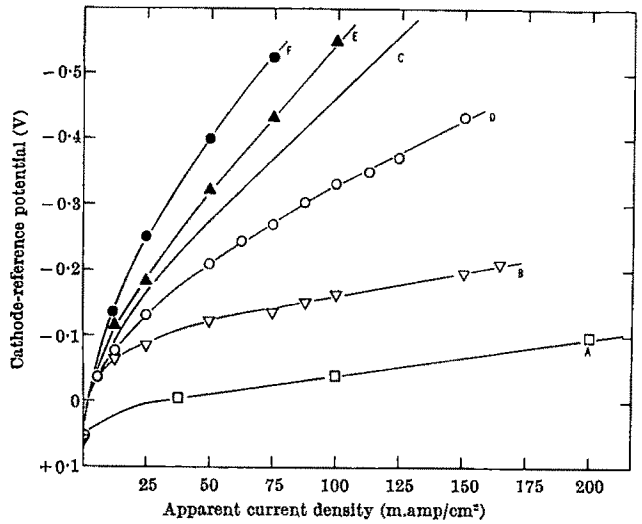

Fig. 1. Cathodic polarization for electrodes in KOH solution, $T = 94 \pm 2°$ C; open symbols, data taken after 40 h at 50 m.amp/cm²; closed symbols, after 320+ h. Curve *A*, catalysed carbon; *B*, uncatalysed carbon; *C*, electrodes containing 1·5, 4·4 and 9·2 mg/cm² boron carbide; *D*, potassium hydroxide washed boron carbide electrodes containing 2·0 and 4·4 mg/cm² catalyst; *E*, electrode containing 9·2 mg/cm² boron carbide after 380 h at 50 m amp/cm²; *F*, electrode containing 1·5 mg/cm² boron carbide after 325 h at 50 m amp/cm²

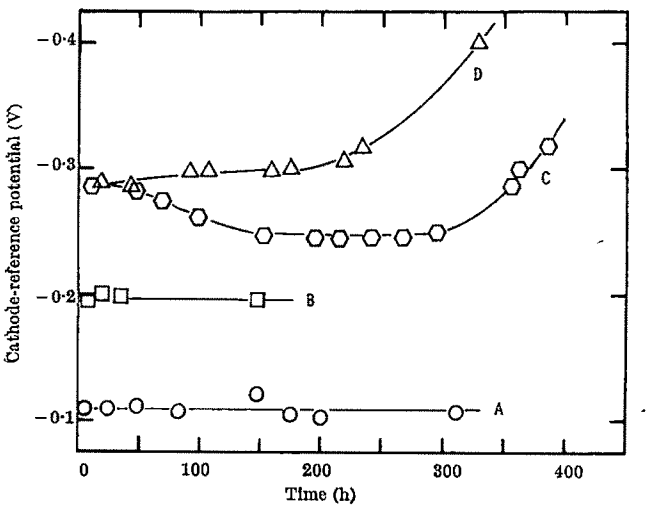

Fig. 2. Cathodic potential-time variation for electrodes operated at 50 m.amp/cm² at $T = 94 \pm 2°$ C, Curve *A*, uncatalysed carbon; *B*, washed boron carbide electrode containing 4·4 mg/cm² catalyst; *C*, unwashed boron carbide electrode containing 9·2 mg/cm² catalyst; *D*, unwashed boron carbide electrode containing 1·5 mg/cm² catalyst

some boron carbide was washed in the following manner before electrode preparation. First, the material was given four 24-h soakings in 6 M potassium hydroxide followed by repeated water rinse to remove potassium hydroxide, and then two 2-h soakings in 30 per cent sulphuric acid followed by several water rinses. It was then dried overnight in a vacuum desiccator. The potassium hydroxide solution, in which the boron carbide powder had been soaked, turned yellow. No attempt was made to analyse this coloured solution. Analyses of the powder, however, revealed that the iron, copper and sulphur content were reduced about an order of magnitude to 0·2 per cent, 0·01 per cent and 0·02 per cent respectively.

The cathodic polarization for electrodes containing 2·0 and 4·4 mg/cm² of the washed boron carbide taken after 40 h of operation at 50 m.amp/cm² is shown in Fig. 1 as curve *D*. Considerable reduction in polarization was achieved by lowering the amount of impurities in the boron carbide sample, but the polarization did not depend on the catalyst loading. A life test of an electrode containing 4·4 mg/cm² of boron carbide was terminated at only 150 h because of the hydrogen anode failure. No change occurred in the performance of the washed boron carbide cathode during that time (curve *B*, Fig. 2). It appears that washing the boron carbide in potassium hydroxide before electrode preparation will improve the initial performance as well as the lifetime of the electrode. Further reduction in the polarization might be possible by further reduction of impurity content.

Optical examination of the boron carbide powder at 400 magnification showed that the sample had many particles in the 0·5 to 2·0μ range as well as some as large as 40μ.

From these data on polarization and lifetime, one would not expect the boron carbide catalyst to replace the usual precious metal catalysts commonly being used. Because of inert electrochemical behaviour, however, boron carbide might be advantageously used as a catalyst support.

Possible Role of Supercooling in the Spearpoints observed during the Combustion of Zirconium Droplets

RECENTLY, I reported on the spear-like images that appear on photographic time exposures of zirconium droplets burning in free fall[1]. The experiments indicated that the spearpoints coincided with solidification of the incandescent droplets.

I suggested that the sudden intensification at the shoulder of the spearpoint might be caused by a large increase in emissivity as the droplet crystallized. This was supported mainly by the change in the colour at room temperature of droplets quenched in liquid argon slightly above and below the shoulder; those quenched above were black while those quenched below were grey. By comparing the colours with those described in the literature, the composition of the droplets was estimated to be approximately $ZrO_{1.97}$ at the point of solidification.

There is another possible explanation of the spearpoints. The gradual decrease and sudden increase in intensity may be caused by a supercooling of the glowing oxide droplets before they solidify. Rapid release of the heat of crystallization may then raise the temperature of the droplets to the normal freezing point, and yield a more intense thermal emission at this new, higher temperature. A similar process, known as recalescence or the 'blick' effect, occurs when droplets of metal solidify[2,3]. Supercooling is particularly favourable in small droplets because a molten mass is progressively less likely to contain nucleation singularities as its size decreases[3].

This communication reports new experiments involving vibrational nucleation of burning zirconium droplets which suggest that supercooling may participate significantly in the formation of spearpoints.

An attempt to distinguish between intensification by solidification after supercooling and an increased emittance on freezing was made by causing the burning droplets to collide with an aluminium plate at various times during fall. This was accomplished by suspending an aluminium

plate inclined a few degrees from the vertical in the combustion chamber[4]; the plate was arranged so that the burning droplets would strike it at a glancing angle and travel down the chamber with only slight deviations from their original paths. (They did not adhere to the plate at any stage of combustion.) Experiments were performed with 525μ droplets of zone-melted zirconium burning in ultra-pure oxygen at 625 torr as described earlier[1]. The burning droplets were photographed simultaneously with both a still camera and a high-speed ciné camera. With the latter, it was possible to time events to ±0·1 msec.

Without collision, the shoulders of the normal spearpoints formed reproducibly at 217 ± 6 msec after the heating flash. When the droplets struck the plate between 74 and 152 msec after ignition, spearpoints formed at 169 ± 10 msec in twelve out of eighteen experiments; the other six droplets intensified at the normal time. When the collisions occurred between 152 and 200 msec, only three out of thirteen droplets intensified at the normal time. In the remaining ten experiments, the spearpoints were completely suppressed; that is, after collision, the droplets lost intensity smoothly and more slowly until the images disappeared at about the same time as the non-colliding droplets. This is interpreted as indicating that solidification occurred without appreciable supercooling during this time interval. Collision with the plate after 200 msec did not affect the formation of spearpoints.

These results suggest: (1) that nucleation was induced with high probability by deflecting the burning droplets from an aluminium plate; (2) that the droplets had cooled to the true freezing point at 152 msec, the earliest time at which solidification could be induced by mechanical shock.

Assuming that only supercooling was involved in the intensifications, I estimated the amount of supercooling, $\Delta T_- = T(\text{solid}) - T(\text{liquid})$, from the densities of the photographic images. Six separate experiments were performed with 525μ droplets of zone-melted zirconium burning in ultra-pure oxygen at 625 torr (again the same conditions as in ref. 1). The droplets were photographed on Kodak 'Plus-X Pan' sheet film through a 4·01 mm-thick Corning *CS*2-64 filter (transmittance less than 0·5 per cent at wave-lengths less than 620 mμ). The films were calibrated by passing the radiation from a xenon flash lamp through the same filter and a step tablet with known neutral densities. After careful development, the films were scanned 2-mm above and below the shoulders of the spearpoints normal to the direction of fall with a photoelectric densitometer.

The ratio of peak intensities obtained this way, $I(\text{solid})/I(\text{liquid})$, was 3·93 ± 0·26. If it can be assumed that the emittance of the droplets does not change during freezing, then the ratio of absolute temperatures at the shoulder becomes $T(\text{solid})/T(\text{liquid}) = (I(\text{solid})/I(\text{liquid}))^{1/4}$. If T(solid) can be taken to be approximately the melting point of stoichiometric zirconium dioxide, 3,100° K (ref. 5), T(liquid) is approximately 2,200° K. The supercooling, ΔT_-, then, is about 900° K, based purely on radiation intensities. (A rise in temperature of this magnitude is not forbidden from the point of view of energy. Taking the heat of fusion to be 20·8 kcal/mole (ref. 6) and the heat capacity of the melt to be 17·8 cal/mole deg (ref. 6), the temperature rise of molten zirconium dioxide on nucleation could be as large as 1,169° K.)

Using the foregoing assumptions for these combustions, $\Delta T_- \approx 0{\cdot}29\ T(\text{melting})$ (in °K) for the freezing oxide. This value should be compared with the supercooling which holds for the solidification of many metals[3], $\Delta T_- \approx 0{\cdot}18\ T(\text{melting})$.

As yet, it has not been possible to determine the relative importance of either supercooling or changes in emittance on the images of the solidifying droplets. Supercooling, however, is probably the dominant effect. This statement is supported by measurements above 2,200° K on stoichiometric zirconia[7], which indicate that at 6,500 Å, the spectral emittance of the solid is actually somewhat less than that of the liquid. It is also supported by the observation of spearpoints in burning droplets of many other metals as different as strontium[8], barium[8], calcium[8], manganese[8], tantalum[8], iron[8,9] and many ferrous alloys[9]. It thus seems more plausible to attribute spearpoints to supercooling—an effect which should be relatively insensitive to chemical composition—rather than to large emittance changes, which should strongly depend on the chemical nature of the system.

This work was supported by the U.S. Atomic Energy Commission. I thank Dr. R. E. Luna for valuable discussions and Mr. N. L. Richardson for his assistance.

Heat of Combustion of Benzoic Acid under Thermodynamic Standard Conditions

BENZOIC acid is widely used in thermochemistry as a calorimetric standard substance. This widespread usage as a standard means that benzoic acid is normally combusted in nearly identical bomb calorimeters. As a consequence it has become common practice to quote its heat of combustion under standard bomb conditions (ΔQ_B) as suggested by Washburn[1], rather than under thermodynamic standard conditions ($-\Delta E^\circ$), as this often eliminates the necessity for lengthy thermodynamic conditions. At present the standard bomb conditions for the combustion of benzoic acid are[2]: (*a*) The combustion reaction is referred to 25° C. (*b*) The sample is burned in a bomb of constant volume in pure oxygen at an initial pressure of 30 atm. at 25° C. (*c*) The number of grammes of sample burned is equal to three times the internal volume of the bomb in litres. (*d*) The number of grammes of water placed in the bomb before combustion is equal to three times the internal volume of the bomb in litres. For certain other applications, notably when benzoic acid is used as a starter for the combustion of a less easily combusted material, it is necessary to know its heat of combustion under thermodynamic standard conditions. Such a case arose recently at Harwell in a re-determination of the heats of combustion of natural and artificial graphites.

It is common practice to regard ΔE° as the gain in intrinsic energy on combustion of the benzoic acid in pure oxygen at 1 atm. pressure and 25° C (ref. 3), and as such its numerical value takes a negative sign. This definition is not strictly in accord with current thermodynamic usage which reserves the superscript zero for substances in their modern thermodynamic standard states. For a gas the standard state is defined as the pure substance in the ideal gas state at 1 atm. pressure, that is unit fugacity (internal energy content that of the real gas at zero pressure)[4]. Thus the symbol ΔE° strictly applies to the gain in intrinsic energy on combustion with the products and reactants in their thermodynamic standard states. Numerical values for ΔE° and ΔQ_B are calculated from the experimentally observed heat of combustion by the application of thermodynamic corrections. This method of derivation for ΔQ_B and ΔE°

requires that the difference between them (ΔQ_B – (– $\Delta E°$)) should be a constant since it depends on the thermodynamic corrections applied and not on the experimental values of the heat of combustion. The difference between ΔQ_B and – $\Delta E°$ has been calculated by me by the application of a suitable thermodynamic correction. The method used was a modified Washburn correction as described by Prosen[4] and the calculations were carried out on an I.B.M. 7030 ('*STRETCH*') computer. This calculation yielded a value for (ΔQ_B – (– $\Delta E°$)) of 20·3 J/g.

Values for ΔQ_B, the heat of combustion under standard bomb conditions, are always referred to 25° C, and it is conventional but not obligatory to refer values for $\Delta E°$ to the same temperature. The failure to refer values of $\Delta E°$ to 25° C has been the source of some confusion in the chemical thermodynamic literature. Two estimates of $\Delta E°$ for the combustion of benzoic acid have been published in the literature, one due to Fraser and Prosen[5] of – 26,411·6 J/g (corresponding to ΔQ_B = 26,434·7 J/g) and the other of – 26,418·6 J/g (ΔQ_B = 26,438·1 J/g) due to Gundry and Meetham[3]. These figures apparently lead to markedly different values for the thermodynamic correction (ΔQ_B – (– $\Delta E°$)). A close examination of the paper of Fraser and Prosen shows that their value for $\Delta E°$ is referred to 28° C and not 25° C. Correction of this figure to 25° C yields a value for $\Delta E°$ (25° C) of – 26,414·8 J/g. As discussed here the difference between ΔQ_B and – $\Delta E°$ should be a constant and, in fact, the figures are now seen to be in agreement. Fraser and Prosen find the difference to be 19·9 J/g, Gundry and Meetham 19·5 J/g and I find 20·3 J/g. In addition to these estimates of the Washburn correction, Jessup[6] has calculated it to be 20·0 J/g.

Absolute values for the heat of combustion of benzoic acid are normally quoted in the literature under standard bomb conditions (ΔQ_B). There have lately been a number of accurate determinations of this quantity[4,6–9] and before a value can be assigned to $\Delta E°$ some mean value must be assigned to ΔQ_B. This is necessary because few authors have calculated values for $\Delta E°$ from their experimental results, preferring to present them under standard bomb conditions. At present the best method for obtaining a mean value for ΔQ_B appears to be that advocated by Gundry and Meetham[3], who suggest the use of a weighted mean of the latest determinations. Table 1 is a summary of the latest information on the heat of combustion of benzoic acid under standard bomb conditions. It follows closely the approach of Gundry and Meetham with the following important exceptions: (i) The 1946–48 data of Coops *et al.*[8] have been omitted on account of the acknowledged incompleteness of some of their combustions[10]. (ii) The means were stated by Gundry and Meetham to have been weighted according to their standard errors. A re-examination of the original papers showed that the figures quoted by Gundry and Meetham are not always the standard errors. As a consequence of this the overall mean calculated by them contains an artificial bias. Accordingly, the errors quoted in Table 1 have been recalculated, where necessary, to the common basis of the 'uncertainty interval' as advocated by Rossini[11].

Table 1. HEAT OF COMBUSTION OF BENZOIC ACID

	Benzoic acid batch No.	Heat of combustion (ΔQ_B) J/g	Assigned uncertainty interval
Jessup, 1942 (ref. 6)	*N.B.S.* 39e	26,432·1	2·7*
	39f	26,434·2	2·7*
	"Specially purified"	26,434·7	3·8*
Prosen and Rossini, 1944 (ref. 7)	*N.B.S.* 39e	26,434·7	2·6
Coops and Adriaanse, 1954 (ref. 8)	*N.B.S.* 39f	26,433·9	4·9
	V.U.S.	26,438·1	7·8
Challoner, Gundry and Meetham, 1955 (ref. 9)	*B.D.H.* 692,782	26,436·4	4·4
Gundry and Meetham, 1957 (ref. 3)	*N.B.S.* May, 1949, Calorimetry Conference	26,438·1	5·4

* Calculated by me from data in Jessup's paper.

The overall weighted mean calculated from the data in Table 1 then becomes 26,434·4 J/g with an estimated overall uncertainty of ± 1·25 J/g. In accordance with normal practice the overall uncertainty interval ($2\sigma_m$) is estimated as:

$$\frac{1}{2\sigma_m} = \sqrt{\sum_1^n \frac{1}{(2\sigma_i)^2}}$$

where $2\sigma_i$ is the uncertainty interval for the ith set of observations. Estimation of the error through the foregoing formula suffers from the defect that it fails to distinguish any systematic errors in the means from one set of observations to another. An alternative estimate of the uncertainty interval may be made as:

$$2\sigma_m = 2\sqrt{\frac{\sum_1^n \left(\frac{1}{2\sigma_i}\right)^2 (\bar{x}_i - \bar{x}_m)}{(n-1)\sum_1^n \left(\frac{1}{2\sigma_i}\right)^2}}$$

where $\bar{x}_m$ is the overall mean. This second formula yields a value of ± 1·22 J/g for $2\sigma_m$. The close agreement between these two estimates for the overall uncertainty interval shows that there is no evidence of a significant bias in the data from the various sources.

It is therefore concluded that at present the best estimate for the heat of combustion of benzoic acid under standard bomb conditions (ΔQ_B) is 26,434·4 J/g with an estimated overall uncertainty of ± 1·2 J/g. The corresponding heat of combustion under thermodynamic standard conditions (that is, gain in intrinsic energy on combustion) is 26,414·1 J/g with an overall uncertainty of ± 1·2 J/g.

π-Bonded Olefines and Olefine Hydrogenation

ALTHOUGH the catalysed hydrogenation of ethylene and other olefines has been a favourite reaction for investigation for many years, it has, in general, proved vastly more complicated than would appear from the simple stoichiometry of the reaction. Continuing investigations are, however, giving more insight into the numerous possible elementary steps involved in the overall reaction. In a recent review[1] Bond has emphasized the role of π-bonded olefines in the metal-catalysed hydrogenation of unsaturated compounds, although he points out that there is no evidence as to whether say π-bonded ethylene will react with hydrogen to give ethane directly, or whether a σ-diadsorbed olefine is a necessary intermediate.

It was therefore thought to be worthwhile to determine whether ethylene platinous chloride $(PtCl_2.C_2H_4)_2$ possessed any catalytic activity for the hydrogenation of ethylene;

it is accepted[2] that in this compound the ethylene is bound to the platinum by σ–π bonding, and might therefore serve as a crude model for ethylene adsorbed on platinum.

Ethylene platinous chloride was prepared according to the method of Anderson[3] from sodium chloroplatinate and ethanol: for ease in subsequent handling the compound was supported on alumina by adsorption from benzene solution. The ethylene used was taken from a cylinder, and was purified by repeated low temperature distillation. Hydrogen was standard tank electrolytic grade, and was passed through a 'Deoxo' unit and a trap at −196° C before use. The reactor was essentially a 'Pyrex' test-tube of approximately 5 ml. capacity, attached to a conventional high-vacuum system by means of a 10/30 standard taper joint.

In a typical run, approximately 0·5 g of the alumina-supported ethylene platinous chloride was weighed accurately into the reactor tube, which was then attached to the vacuum system. The reactor was rapidly pumped down to zero pressure, as measured with a di-*n*-butyl phthalate manometer, the reactor surrounded by an ice bath at 0° C, and ethylene added to a pressure P_E cm of di-*n*-butyl phthalate: hydrogen was then added to a total pressure $(P_E + P_H)$, with the hydrogen pressure P_H always being less than P_E. The change in pressure with time was followed and, in all cases, the pressure decreased by an amount P_H, after which the pressure remained constant. The only hydrogenation product detected by gas chromatography was ethane. During such a run there was no visible colour change in the compound (the alumina-supported material was pale yellow), and on subsequent reweighing no detectable weight change.

If hydrogen alone was added to the reactor under the same conditions rapid decomposition of the ethylene platinous chloride occurred, and black metallic platinum was obtained.

It may be concluded that in at least one case, π-bonded ethylene may react with hydrogen to form ethane without the need or possibility of a σ-diadsorbed intermediate. A quantitative investigation of this and similar reactions is in progress at the present time, and the results will be reported in detail elsewhere.

BIOCHEMISTRY

Bone Lysozyme: Partial Purification, Properties and Depression of Activity by Parathyroid Extract

DURING an investigation of the metabolism of bone, high levels of lysozyme activity were found which could be markedly decreased by parathyroid extract, an agent known to induce fundamental changes in this tissue[1]. It was also observed that parathyroid extract caused the lysozyme content of other tissues to change. This report details these findings and describes a partial purification of the bone enzyme.

Weanling, fasted, male white rabbits, in groups of 2–4, received a subcutaneous injection of parathyroid extract (Lilly) 18 h before being killed by exsanguination. Similar groups of animals served as controls. The shafts or distal or proximal ends of the femurs were frozen in dry ice and pulverized. The powders were exhaustively extracted with ten volumes of M/15 phosphate buffer (*p*H 6·2) at 3° C. Soft tissues and marrow from the femur shafts were homogenized in the phosphate buffer. Blood was laked by shaking. After centrifugation, the supernatant fluids were assayed for lysozyme[2] with crystalline egg white lysozyme (Sigma) serving as standard. Enzymatic activity was expressed as μg of crystalline enzyme. Deoxyribose was determined by the method of Schneider[3]; in the case of bone, the tissue was first decalcified in 10 per cent trichloroacetic acid. Protein was assayed by the method of Lowry[4], nitrogen by a micro-Kjeldahl procedure[5] and serum calcium by flame photometry.

Depression of lysozyme activity by parathyroid extract. The greatest concentration of lysozyme on a fresh weight basis was found in distal femur and shaft marrow with smaller amounts in the proximal end and shaft (Table 1). The enzyme content of distal femur per μmole of deoxyribose was about five times that of marrow. In parallel studies the concentration of lysozyme per μmole of deoxyribose was equal to that of kidney and spleen and twice and three times that of lung and liver, respectively.

After administration of parathyroid extract, serum calcium increased by 0·5–2·3 m.equiv./l. indicating that the hormone was active. This treatment had no effect on total deoxyribose content, extracted protein and extracted nitrogen of any tissues studied. The dry weight and histological appearance of the bone did not change. The lysozyme activity, on the other hand, decreased from control-levels in every one of twenty experiments in all tissues except lung, where it increased. The greatest decrease in lysozyme activity occurred in proximal femur. On average, for all our experiments, the percentage changes in lysozyme content were as follows: proximal femur, −68; blood, −51; distal femur, −46; liver, −31; spleen, −30; marrow, −16; and lung, +45.

Table 1. LYSOZYME CONTENT OF NORMAL FEMUR*

Tissue	No. of samples	μg lysozyme per g	μg lysozyme per μmole deoxyribose
Distal femur	23	100 ± 25	13 ± 6
Proximal femur	5	53 (33–80)	—
Shaft	2	7·5 (5–10)	—
Shaft marrow	8	81 ± 18	2·7 ± 1·0

* 'g' refers to grams fresh weight of tissue. Standard deviation follows ± symbol; range is shown in brackets.

Depression of lysozyme activity in rabbit tissues induced by the *in vivo* administration of parathyroid extract is similar to the results of Litwack[6], who found that thyroid hormone depressed the level of lysozyme in rat kidney. He reported degrees of depression from 27 to 49 per cent which were generally less than the effects reported herein for bone. One explanation for the change of lysozyme activity by parathyroid extract might be the direct interaction of lysozyme with parathyroid hormone such as has been reported by Litwack[7] for thyroxine. Alternatively, there might be an interaction between the enzyme and products released from the tissue by the action of parathyroid extract. Another possibility is that, in bone at least, the change in lysozyme activity is secondary to an alteration in cellular type and/or a consequent shifting of enzymatic patterns[8].

Partial purification and properties of bone lysozyme. Distal femurs from mongrel rabbits were obtained commercially in frozen form and were extracted as already described. These extracts contained from 4 to 10 μg of lysozyme per mg of protein. The activity did not sediment after 60 min centrifugation at 144,000*g*. Under pressure it diffused through a 'Cellophane' membrane, which retained protein of greater than 30,000 molecular weight, at a rate equal to that of crystalline egg-white lysozyme. The crude extracts were stored at −12° C for more than 2 weeks with no loss of activity; heating at 100° C, *p*H 8, for 2 min destroyed all the activity.

The crude extracts were lyophilized and resuspended in one-tenth volume of distilled water and centrifuged. The pellet was discarded. This procedure resulted in complete recovery of activity with a two- to eight-fold purification. The supernatant solution was then passed through a column of 'Sephadex *G*-75' (10–30 ml. of gel

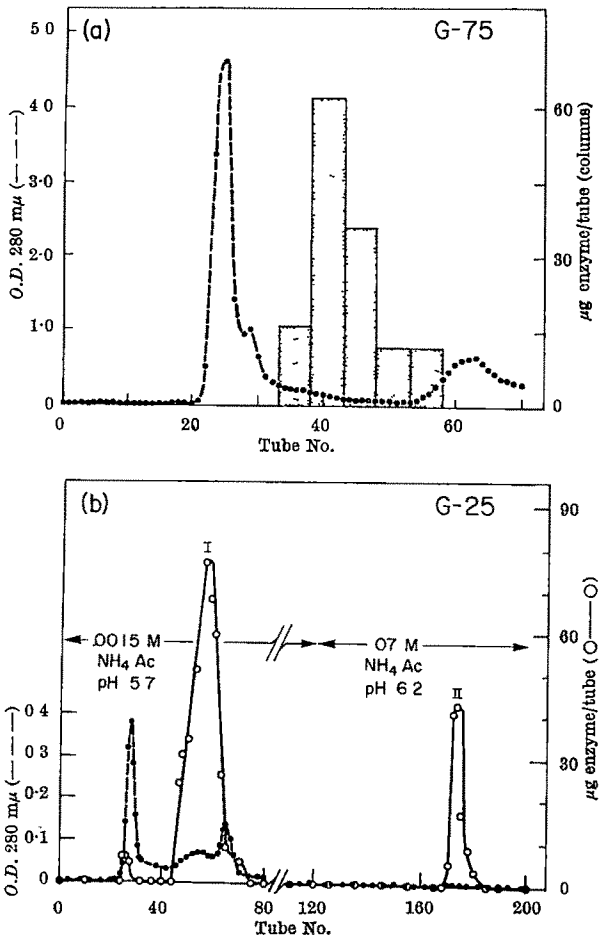

Fig. 1. Purification of bone lysozyme by gel filtration on 'Sephadex *G*-75' and '*G*-25'. The flow rate was 20 ml./h and the fraction size was 5 ml. *a*, Twenty-five ml. of solution containing 1,850 μg of lysozyme with a specific activity of 15·3 μg/mg protein was passed through the gel. The eluted lysozyme fraction contained 105 per cent of the starting activity with a specific activity of 107 μg/mg protein. *b*, Ten ml. of solution containing 1,290 μg of lysozyme with a specific activity of 177 μg/mg protein was applied to the gel. The specific activity of species I was 541 μg/mg protein and that of species II was 1,700 μg/mg protein (minimum)

bed volume per ml. of sample). The gel was eluted with M/15 phosphate buffer, *p*H 6·2, at 3° C. A typical elution pattern is shown in Fig. 1*a*. The enzymatic activity emerged from the column in a broad band following the elution of most of the protein (280 mμ). This procedure led to a fifteen-fold to twenty-five-fold purification with yields from 100 to 150 per cent—suggesting that a lysozyme inhibitor was removed during the procedure.

The pooled fraction, following concentration by lyophilization and a 4–6 h dialysis against distilled water, was applied to a 'Sephadex *G*-25' column and eluted with 0·0015 M ammonium acetate buffer, *p*H 5·7 (Fig. 1*b*). About two-thirds of the activity (species I) emerged from the gel after passage of an effluent volume about twice that of the void volume of the column. The remaining activity (species II) was next eluted with 0·07 M ammonium acetate, *p*H 6·2. This procedure resulted in an essentially complete recovery of activity. Species I was three-fold and species II ten-fold more pure than the starting material for this step. In four such procedures overall recovery, referable to the crude extract, was at least 100 per cent with a purification of about fifty-fold for species I and 200-fold for species II. The specific activities of species I and species II were about one-half and twice that of crystalline egg-white lysozyme, respectively.

Both species of lysozyme lysed *M. lysodeikticus*, *S. lutea* and *B. megaterium*. The optimal *p*H for activity against *M. lysodeikticus* for both was 6·1. That the species were dissimilar was indicated by a marked difference in heat stability. Both species retained full activity after heating at 88° C for 15 min at *p*H 2·5. At *p*H 8·0, however, species II was completely inactivated while species I retained 65 per cent of its activity.

In one investigation the procedure for isolating bone lysozyme was applied to shaft marrow. In elution from 'Sephadex *G*-25' and heat stability, marrow lysozyme resembled species II. Additional studies must be performed, however, before it can be concluded that marrow lysozyme and species II are identical.

This investigation was supported in part by the National Institute of Dental Research, U.S. Public Health Service.

Active Copper Transport in Mammalian Tissues—a Possible Role in Wilson's Disease

IT has long been known that there are two major circulating fractions of serum copper. In the normal person, 95 per cent of the copper is carried by the alpha$_2$-globulin copper oxidase, ceruloplasmin, and the remainder was said to be 'free' or albumin-bound. A previous report[1] demonstrated a third physiologically important dialysable fraction of serum copper bound to amino-acids which facilitated the transport of copper across a semi-permeable membrane *in vitro*. The present investigation shows that there is an active transport mechanism for copper which operates in a metabolically active cell system. The findings lend themselves to interesting speculations with regard to the pathogenesis of Wilson's disease.

The uptake of copper-64 acetate by mammalian tissues was investigated, using fresh liver and kidney cortex slices from decapitated male Wistar rats. Ehrlich mouse ascites carcinoma cells grown in strain *A* mice for 6 days were also studied since they are known to concentrate amino-acids, using an active transport system. The technique of Christensen[2] was followed closely. Groups of liver slices (weighing 200 mg), rat kidney cortex slices (100 mg) or packed ascites cells were pre-incubated for 15 min in a freshly oxygenated Krebs–Ringer bicarbonate (KRB) buffer, *p*H 7·4. A purified 4 g per cent human albumin solution in KRB buffer of *p*H 7·4 was used as basic medium. Labelled cupric acetate was added to the medium in physiological concentration or in excess, with L-amino acids, individually or in combination, in equimolar concentration. The flasks were then incubated in a Dubnoff metabolic shaker, at 37° C, for 30, 60, 90, 120 and 180 min in a 95 per cent oxygen–5 per cent carbon dioxide atmosphere. Similar experiments were done at 20° C and with varying concentrations of oxygen.

Following incubation, the slices were immediately removed, or cells separated, washed three times with 20 ml. ion-free water, blotted, and counted in a Picker scintillation counter.

The ability of amino-acids, particularly histidine, to enhance the uptake of copper into liver slices and Ehrlich

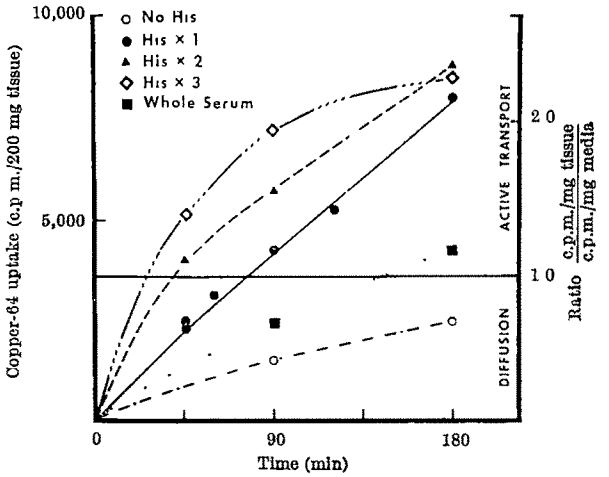

Fig. 1. The effect of histidine on copper-64 uptake into rat liver slices. Histidine (4, 8, and 12 μmoles); copper (10 μmoles); *p*H 7·4, 37° C, 95 per cent oxygen–5 per cent carbon dioxide atmosphere

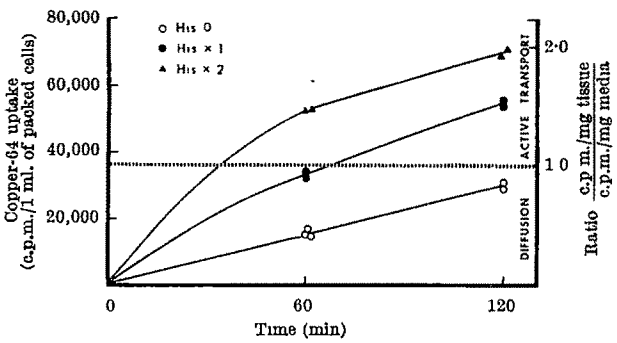

Fig. 2. The effect of histidine on copper-64 uptake into Ehrlich mouse ascites carcinoma cells, *p*H 7·4, 37° C, 95 per cent oxygen–5 per cent carbon dioxide atmosphere. Histidine (4 and 8 μmoles) and copper (10 μmoles) in each medium

mouse ascites tumour cells is shown in Figs. 1, 2, 3 and 4. The ratio of c.p.m. per mg tissue to c.p.m. per mg medium is also shown in each figure. Since a ratio less than unity means simple diffusion and one greater than unity suggests transport against a concentration gradient, the results indicate an active transport mechanism for copper facilitated by amino-acids, especially histidine.

In all experiments the rate of copper-64 uptake was related directly to the initial copper concentration in the medium; the more copper added, the more was taken up by the cells.

4-μM L-histidine significantly increases the uptake of copper-64 into rat liver slices (Fig. 1). Doubling and tripling the histidine concentration resulted in a further proportionate increase of copper-64 uptake until 2 h. However, at 3 h there is a maximal uptake, indicating that the transport system has reached its capacity, which is not related to copper but to the concentration of histidine.

The same results are obtained when Ehrlich mouse ascites cancer cells are used (Fig. 2).

Fig. 3 again shows the marked enhancing effect on copper-64 uptake of histidine (his). Glutamine (glu), threonine (thre), and asparagine (asp) show little effect. The combination of histidine, particularly with glutamine (his + glu) results in greater uptake of copper-64 than the sum of their individual effects. Amino-acid combinations not containing histidine (glu + thre, glu + asp, thre + asp, glu + asp), were relatively ineffective.

The subcellular distribution of copper-64, determined (by the technique of Hogeboom)[3] on liver slice homogenates after 2-h incubation, showed 69 per cent of their activity in the microsomes (38 per cent), mitochondria (25 per cent), and supernatant (6 per cent), confirming that the transported copper-64 was indeed inside the cell.

The transport, as facilitated by histidine and other amino-acids, was found to be dependent on temperature and oxygen. The uptake of copper-64 was significantly reduced at 20° C, and abolished in an anaerobic atmosphere. Atmospheric conditions reduced by 35 per cent the uptake of copper-64 into liver slices, but did not change uptake into the Ehrlich mouse ascites carcinoma cells.

Similar studies indicated that copper-64 was accumulated against a concentration gradient by slices of rat kidney cortex, facilitated only by histidine and not by its combinations, or other amino-acids (Fig. 4).

A cellular transport mechanism for copper has been shown to be linked with amino-acids, especially histidine. It fulfils the criteria and characteristics of an asymmetrical active transport system[4], that is, dependency on temperature, oxygen, concentration, and operation against a chemical concentration gradient.

This transport system appears to be similar in rat liver slices, tumour cells, and rat kidney cortex slices.

In recent years, some doubt has been cast on the aetiological theories for Wilson's disease. The 'ceruloplasmin deficiency theory'[5] fails to explain the disturbances in

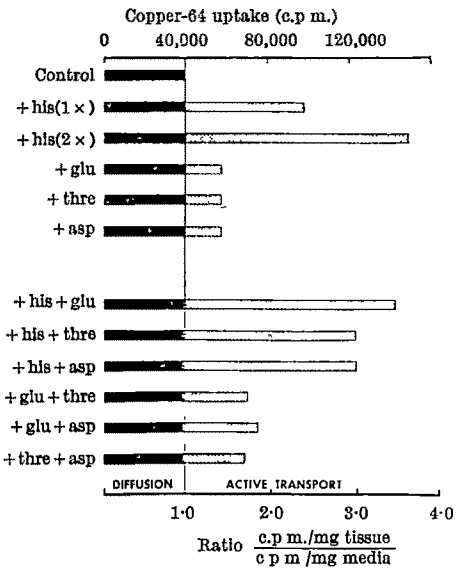

Fig. 3. The effect of different amino-acids and some of their combinations on copper-64 uptake into rat liver slices. All amino-acids are in equimolar (4 μmoles) concentrations. Incubation time was 2 h at *p*H 7·4, 37° C, and 95 per cent oxygen–5 per cent carbon dioxide atmosphere

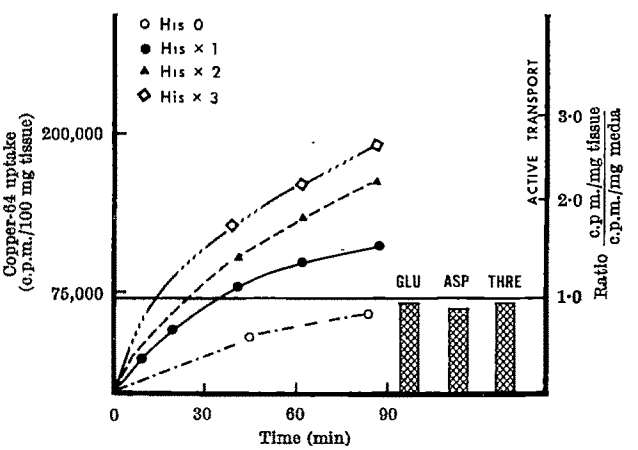

Fig. 4 The uptake of copper-64 into rat kidney cortex slices as facilitated by histidine (4, 8, 12 μmoles). The bars on the right show that glutamine (glu), asparagine (asp), and threonine (thre) are ineffective; *p*H 7·4, 37° C, 95 per cent oxygen–5 per cent carbon dioxide, copper concentration (5 μmoles)

amino-acid metabolism, and the complete lack of correlation between the degree of ceruloplasmin deficiency and the severity of the clinical findings. The failure to determine any genetic relationship in heterozygotes, using ceruloplasmin as the variable, has further weakened this viewpoint. The theory postulating an abnormal tissue protein with a high affinity to copper[6] has had only one proponent, and the findings have never been duplicated[7,8].

The oft-reported[9–11] delayed and diminished uptake of intravenously administered radioactive copper by the liver in patients and heterozygotes, and the elevation (6–20 times normal) of non-ceruloplasmin-bound serum copper[11], suggest that a defective transport mechanism for copper may be the underlying disturbance in patients with Wilson's disease.

The present investigations demonstrate the presence in tissues of an active transport system for copper which is dependent on histidine and perhaps other amino-acids. Impairment of this transport system is postulated as the basic metabolic defect in Wilson's disease. An investigation is now in progress on a patient with Wilson's disease and the related heterozygotes.

We thank Drs. E. Harpur, P. Schofield, C. Giroud, and A. Gold for their help and criticisms, and George Klein and Mary Harbert for technical assistance.

Isolation of Δ^7-Cholesten-3-one from Butterfat

THE direct reaction of butterfat with 2,4-dinitrophenylhydrazine has resulted in the identification of a number of previously undescribed carbonyl compounds[1,2] from dairy products. During the course of those investigations a 2,4-dinitrophenylhydrazone (hereafter abbreviated to DNPhydrazone) was observed with chromatographic properties similar to the aldehyde DNPhydrazones but differing in light absorption properties. Initial studies revealed that the unknown DNPhydrazone gave a positive response to the Liebermann-Burchard reaction. This communication presents some investigations in which the compound has been identified as the DNPhydrazone of Δ^7-cholesten-3-one.

500 g butterfat was dissolved in 1·5 l. of carbonyl-free hexane[3]. The solution was divided and each half was passed through a 10 g 2,4-dinitrophenylhydrazine reaction column[4]. The DNPhydrazone monocarbonyl fraction was isolated from the fat by adsorption chromatography on magnesia ('Seasorb 43') and alumina columns according to the method of Schwartz *et al.*[4]. The saturated aldehyde DNPhydrazone fraction (tan in colour) was isolated from the monocarbonyl DNPhydrazones by adsorption chromatography on a 'Seasorb 43': 'Celite 545' column using 2 per cent methanol in chloroform as the eluting solvent[5]. The DNPhydrazone giving a positive Liebermann-Burchard reaction was separated from the long-chain aldehyde DNPhydrazones on a reverse phase partition chromatographic column prepared from 8 g of dodecane mechanically ground into 15 g of silanized 'HyFlo Super-cel' and packed into the column as a slurry. The eluting solvent was acetonitrile saturated with dodecane. The sample was dissolved in the eluting solvent by gentle heating and placed on the column. Several such columns were necessary to accommodate the quantity of DNPhydrazones obtained from 500 g of milkfat. The major band following the elution of the long-chain aldehyde DNPhydrazones was collected and evaporated to near dryness on a steam bath with the aid of a stream of nitrogen. The residue was taken up in chloroform and the residual dodecane removed from the DNPhydrazone by adsorption of the latter on a 'Seasorb 43': 'Celite 545' (4 g : 8 g) column. The DNPhydrazones adsorbed on the column were washed with 50 ml. of chloroform and the grey band eluted ofrm the column with 2 per cent methanol in chloroform. The effluent containing the Liebermann-Burchard positive DNPhydrazone was evaporated to dryness under nitrogen and the parent compound regenerated from the reagent by allowing a solution of the unknown in 30 ml. acetone containing 1·2 ml. of 5 N sulphuric acid to stand overnight at room temperature. The parent compound was recovered from the acetone solution as follows. Water (5 ml.) was added to the solution, which was then evaporated on a steam bath under nitrogen to approximately 10 ml. The precipitate was recovered by extracting twice with 20 ml. portions of carbonyl-free hexane, and these extracts were combined, dried with sodium sulphate, filtered and evaporated to dryness. The residue containing the unknown was separated from the acetone DNPhydrazone resulting from the renegeration by chromatographing a 5 ml. chloroform solution of the residue on a column containing 2 g of 'Seasorb 43' and 4 g of 'Celite 545' in chloroform. The column was washed with 25 ml. of chloroform and the effluent, containing the steroid, collected. The steroid was further purified by thin-layer chromatography on silica gel *G* using 0·5 per cent methanol in benzene as developing solvent. Development and recovery of the unknown (approx. 1 mg) from the glass plates were accomplished as previously described[6]. The compound crystallized from acetone and water has a melting point of 128°–130° C. Two additional recrystallizations in the same solvent system resulted in fine needles having a melting point of 138°–140° C.

The recrystallized sample was analysed by mass spectrometry. The molecular ion at *m/e* 384 and the peak at *m/e* 271 (loss of alkyl side chain) indicated that the unknown is a mono-unsaturated keto steroid of the cholestane series. Ultra-violet analysis in absolute ethanol revealed a maximum absorption at 202 mμ, which was in keeping with the previous observation that the DNPhydrazone had a maximum absorption at 365 mμ in chloroform indicating the double bond was not conjugated to the carbonyl group.

The steroid gave a 'fast acting' reaction to the Liebermann-Burchard test, a positive Zimmermann test, a negative Salkowski test, positive Tortelli-Jaffé test and a positive selenium dioxide test. These observations were in agreement with those reported and observed for Δ^7-cholesten-3-one prepared and purified according to Busch[7] (m.p. 145° C) (reported: 146°–148°).

Confirmation of the identification of the steroid as Δ^7-cholesten-3-one was obtained from studies of its

Table 1

m/e	Percentage of peak height relative to molecular ion: Authentic Δ^7-cholesten-3-one	Isolated Δ^7-cholesten-3-one
217	12·5	10 6
229	25	25·5
245	16·9	17
247	14·3	16
271	50	47
369	19·5	19 1
384	100	100

infra-red spectra, mass spectra, and melting point. Fig. 1 is a partial reproduction of the infra-red spectra of (*A*) authentic Δ^7-cholesten-3-one and (*B*) the steroid isolated from butterfat. The identical spectra were obtained on a Beckman *IR-5A* infra-red spectrophotometer using micro-potassium bromide disks.

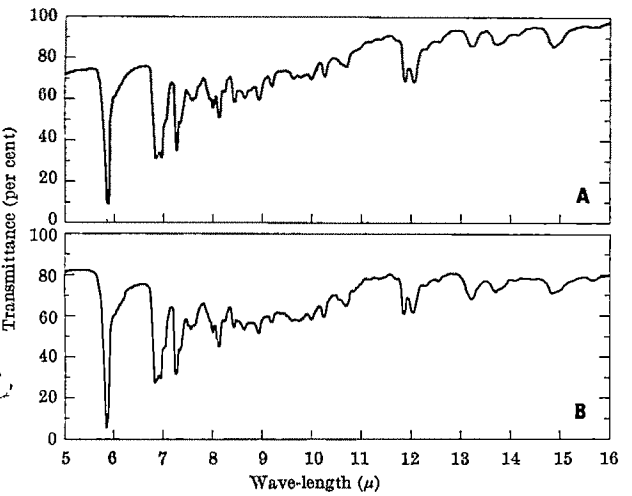

Fig. 1. Infra-red spectra of micro-potassium bromide pellets of (*A*) authentic and (*B*) isolated Δ^7-cholesten-3-one

Table 1 is a comparison of the peak heights of the molecular fragments in the high mass range, relative to the molecular ion, of the authentic and isolated steroid. The spectra were obtained on a Bendix (model 14) 'time of flight' mass spectrometer with a vacuum locked direct inlet system (Bendix Corporation model 843*A*). A temperature of approximately 100° C was used to obtain a good quality spectra.

Recrystallization of the authentic steroid (m.p. 145°) from acetone-water, as was necessary with the isolated steroid because of the minute quantity of sample available, resulted in a lowering of the melting point to 138°–140° C. A mixed melting point with the isolated steroid (m.p. 138°–140° C) resulted in a melt at 138°–141° C. A mixed melting point between the DNPhydrazone of the authentic (m.p. 210°–212° C) and the isolated (210°–213° C) steroid crystallized from acetone–water occurred at 210°–212° C.

The presence of Δ^7-cholesten-3-one in butter fat is, so far as it is known, the only report of its occurrence in nature. Its significance as an intermediate or by-product of cholesterol biosynthesis is speculative.

Correlation between Resistance to Stem Rust and the Concentration of a Glucoside in Wheat

THE presence of 2-O-glucosyl-2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one in wheat was demonstrated by Virtanen[1] and by ElNaghy and Linko[2]. The latter reported higher concentrations of this glucoside in Khapli and Justin wheats, which are resistant to most races of stem rust, than in Little Club and other susceptible varieties. We have measured the concentrations of the glucoside in the primary leaves of five of the so-called differential varieties of wheat with varying degrees of rust resistance (Little Club, Acme, Kubanka, Mindum and Khapli) and have found that there is a significant negative correlation between glucoside content and the number of races of stem rust to which each variety is susceptible. We have also found that the glucoside content of Kenya 58-Marquis[10] (produced by back-crossing a Kenya 58-Marquis hybrid to Marquis nine times[3]) is correlated with its resistance to race 15*B* of *Puccinia graminis tritici* Erikss. and Henn. This line of wheat carries the temperature sensitive gene *Sr*6 and is resistant to race 15*B* at 62° F and susceptible at 79° F (ref. 4).

Wheat seedlings were grown in the greenhouse or in growth chambers at 62° ± 1° F or at 79° ± 1° F. The glucoside was extracted as described by ElNaghy and Linko[2], chromatographed in two dimensions on paper, using *n*-butanol–methanol–benzene–water (3 : 1 : 1 : 1) as the first solvent and 10 per cent formic acid as the second. It was identified by comparison of its R_F value, ultra-violet spectrum and the spectrum of its colour complex with ferric chloride with those of an authentic sample obtained by one of us (M. A. E.) from Dr. Virtanen. Relative concentrations of the glucoside in the extracts were determined by spraying chromatograms with ferric chloride (2 per cent w/v in acetone containing a few drops of 10 per cent hydrochloric acid) followed by elution of the coloured spots with 80 per cent methanol and measurement of their optical densities at 560 mμ in a Beckman (*DU*) spectrophotometer.

The percentage of rust races to which the varieties used are susceptible was computed from the data in Table 4 of Stakman *et al.*[5]. Reaction types 3 and 4 were scored as susceptible and types 0 to 2 as resistant.

Table 1. RELATIVE CONCENTRATIONS OF GLUCOSIDE IN WHEAT VARIETIES

Variety	Percentage of rust races infecting (*I*)*	Glucoside (*G*)†
Little Club	91	0·030
Acme	65	0 105
Kubanka	48	0·150
Mindum	42	0 230
Khapli	4	0·275
Kenya 58-Marquis[10]		
At 62° F	—	0·250
At 79° F	—	0·155

* Calculated from data in Table 4 of Stakman *et al.* (ref. 5).
† Optical density at 560 mμ of glucoside–$FeCl_3$ complex from 10 g (fresh weight) primary leaves in 4 ml. 80 per cent methanol. $G = 0\ 3045 - 0\ 00293\ I$.

The results, given in Table 1, show that there is a significant negative correlation ($r = -0{\cdot}960$, $P = 0{\cdot}01$) between the percentage of the known races of stem rust that infect a variety and its glucoside content. In addition, the glucoside content of Kenya 58-Marquis[10] was 61 per cent higher when plants were grown at 62° F (resistant) than when grown at 79° F (susceptible). The effect of temperature on glucoside content may be merely fortuitous; it has not been demonstrated whether or not high temperature lowers the glucoside content of varieties in which resistance is unaffected by temperature. We also found, as did ElNaghy and Linko[2], that the aglucone, 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one, isolated from crushed primary leaves of Khapli as described by Virtanen and Hietala[6] inhibited the germination of uredospores.

The results do not, of course, prove that enzymatic release of the aglucone from the glucoside plays a part in

resistance. This was postulated by ElNaghy and Linko[2] and from this point of view the aglucone appears to meet several of the criteria which would be required for its classification as a phytoalexin[7]. It is, however, difficult to imagine that variations in the rate and degree of hydrolysis of the glucoside combined with the possible differential sensitivity of different races of the rust fungus to the aglucone do, in fact, account for the pattern of resistance of a single variety of wheat to a number of different races of rust. There are, undoubtedly, many other chemical factors involved. Nevertheless, so far as we are aware, this is the only instance in which it has been possible to demonstrate a correlation between the general level of resistance to rust and the concentration of a single metabolite. The problem therefore deserves a more detailed investigation.

We are grateful to Dr. D. R. Knott for a supply of seed of Kenya 58-Marquis[10]. One of us (M. A. E.) wishes to thank the Government of the United Arab Republic for financial support. The other (M. S.) is grateful to the National Research Council of Canada for a grant.

Effect of Human Growth Hormone on 'Insulin Basic Protein Complex'

Young and George[1] report that, in their immunoassay system utilizing resin separation, the addition of human growth hormone (HGH) to fasting human serum causes a decrease in 'percentage antibody-bound' of iodine-131 labelled insulin, and they infer that HGH releases free insulin from a serum protein-bound form. We have been unable to confirm this phenomenon in a double-antibody immunoassay system[2,3].

(1) The addition of HGH to fasting human sera incubated with anti-insulin serum and ^{131}I-insulin causes no alteration in the percentage of antibody-bound ^{131}I-insulin (Table 1).

Table 1. ADDITION OF HGH TO FASTING HUMAN SERA CAUSES NO CHANGE IN THE PERCENTAGE OF ^{131}I-INSULIN BOUND BY ANTIBODY
(In double antibody assay system; corresponding standard curve is shown for reference)

Amount HGH added	Bound ^{131}I-insulin (%) (final volume 1·0 ml) Fasting human sera		Buffer solution ± human insulin				
	Serum *A* 0·1 ml.	Serum *B* 0·5 ml.	0 μU	0·6 μU	1·25 μU	2·5 μU	5·0 μU
0	61·0	50·5	66·0	61·4	60·2	55·8	48·1
10 mμg	61·7	—	—	—	—	—	—
33 mμg	—	50·7	66·7	—	—	—	—
100 mμg	61·4	—	—	—	—	—	—
5 μg	61·2	—	—	—	—	—	—

Table 2. ADDITION OF INSULIN TO FASTING HUMAN SERUM CAUSES NO CHANGE IN THE PERCENTAGE OF ^{131}I-HGH BOUND BY ANTIBODY
(Corresponding standard curve shown for reference)

Amount insulin added	Bound ^{131}I-HGH (%) (final volume 0·7 ml.) Fasting human serum 0·1 ml.	Buffer solution ± HGH 0 mμg	0·1 mμg	0·2 mμg	0·4 mμg
0	—*	56	54	51	39
100 μU (human)	56	58	—	—	—
1,000 μU (bovine)	56	59	—	—	—

* No measurable growth hormone in this serum sample in previous assay (percentage bound ^{131}I-HGH in 0 mμg buffer tube = 48 per cent; and in 0·1 ml. serum tube 47 per cent).

(2) The addition of human insulin to human serum, incubated with anti-HGH serum and ^{131}I-HGH, similarly does not impair percentage antibody-bound ^{131}I-HGH (Table 2).

Hence the hypothesis that HGH and insulin can interact at a basic protein binding site cannot be supported. We suggest that Young and George's findings represent an artefact of their anion-exchange resin method. It seems likely that factors in human serum plus the HGH solution alter the binding reaction of the resin, causing a false decrease in 'antibody-bound ^{131}I-insulin'. Such methods require a monitoring device to ensure that complete separation of the antibody-globulin is attained, such as the use of ^{131}I-γ-globulin in control samples[4].

While both hormones are probably bound in serum–insulin to α-1-globulin[5] and HGH to α-2-macroglobulin[6], not only are these different binding proteins, but our data indicate that it is unlikely that either displaces the other from a binding site.

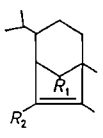
Gibberellin-like Activity of Helminthosporol and Helminthosporic Acid

HELMINTHOSPOROL (I) was isolated from a culture of *Helminthosporium sativum* by Tamura *et al.*[1], and was shown in this and subsequent studies[2] to stimulate the growth of the second leaf sheath of rice seedlings. However, (I) did not promote the growth of dwarf maize, nor did it give positive results in some other biological tests. Subsequently, Tamura and Sakurai[3] prepared a variety of related compounds and showed that (I) and helminthosporic acid, (II), promoted the elongation of rice seedlings and of lettuce seedling hypocotyls grown in light[4]. Thus, at high dose levels, these substances sometimes showed gibberellin-like activity. Various substances related to (−)-kaurene are probably on the biosynthetic pathway to gibberellic acid, (III), in *Gibberella fujikuroi*[5,6], and probably in higher plants also[7]. Some of these substances give positive results in a number of biological tests for gibberellins[8,9], as does steviol[10]. *Gibberella* converts steviol to an unidentified substance having activity in a wider range of test systems[11].



In view of the importance of gibberellic acid to the malting industry[12], and the interest attached to its mode of action, it seemed worthwhile to investigate the ability of (I) and (II) to trigger the release of sugars from deembryonated barley *in vitro*, a release that is catalysed by hydrolytic enzymes synthesized *de novo* in the aleurone layer[13], since this response has always seemed specific for gibberellins. The evident similarity of (I) and (II) to the fused rings *C* and *D* of the kaurene derivatives, the gibberellins and steviol, and the fact that, unlike the other substances mentioned, (I) and (II) have only two rings rather than four, suggest that they may approximate to the minimal chemical structure needed to elicit a gibberellin-like response. In addition, (I) and (II) were tested for their ability to counteract the dwarfing effect of 2-chloroethyl-trimethylammonium chloride (CCC) on the hypocotyls of lettuce seedlings[14]. This compound prevents the synthesis of gibberellic acid by *Gibberella*[15], and so may stop gibberellin synthesis in higher plants. The results, Table 1, show that (I) and (II) are indeed able to reverse dwarfing due to CCC but less well than gibberellic acid itself, a result very similar to that obtained by Tamura and Sakurai[3], using light as the dwarfing agency.

Table 1. LENGTH OF HYPOCOTYLS OF 'ARCTIC KING' LETTUCE SEEDLINGS PREGERMINATED IN DARK, AND SUBSEQUENTLY GROWN FOR 3 DAYS, AT 25° C, IN CONTACT WITH THE TEST SUBSTANCES

	Length of hypocotyls, cm (each value is the mean of 12–15 measurements)

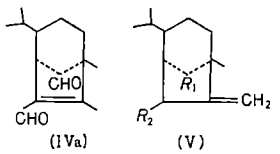
Helminthosporol	—	1·08	1·18	1·10	1·09	1·20	1·24
Helminthosporic acid	—	1·09	1·05	1·14	1·12	1·22	1·51



Controls 1·01, 1·03.

Table 2 shows that sugar release from de-embryonated barley is stimulated by (I) and (II), though less well than by gibberellic acid. Several trials show that in six-day incubations the half-maximum sugar release was attained with about 0·002 μg of (III) per flask and 40–55 μg of (I) or (II) per flask. It seemed that neither (I) nor (II) was capable of stimulating such a large sugar release as gibberellic acid, and in several trials neither consistently showed to advantage over the other. At the doses tested, the greater part of sugar release was achieved by (I), (II) and (III) in 4 days. The results were variable, and this may possibly be explained in part by spontaneous oxidation at (I) and (II) by air[3] as also occurs with the related substance helminthosporal (IV)[16]. Paper chromatography of the sugars released by the grain indicated that the pattern of release caused by (I) and (II) was qualitatively the same as that previously reported as being caused by (III)[13]. Briefly, during the initial incubation period maltodextrins and fructosans, accompanied by some sugars with lower molecular weights, appeared in solution and then progressive further release and hydrolysis occurred, until at the end of 7 days' incubation the only carbohydrates readily detected were *iso*-maltose, glucose, fructose and a pentose (probably arabinose). If the stereochemistry of (I) and (II) is similar to that of helminthosporal, (IV), (IV*a*)[17], a toxic substance isolated by de Mayo *et al.*[16], also from a strain of *Helminthosporium*, then the similarity between the ring systems of (I) and (II) and rings *C* and *D* of gibberellic acid (III) is even more marked. The most notable difference is that, on the *D* ring of gibberellins, kaurene and steviol, there is an exomethylene group (or a methyl and hydroxyl attached to the same carbon that should readily yield an exomethylene group by the elimination of water), whereas in (I) and (II) there is a methyl group adjacent to an endocyclic double bond. By analogy with kaurene and *iso*-kaurene[18] (I) and (II) might equilibrate with substances having the skeleton (V) in which case these might be the true effective structures rather than (I) or (II). However, a single attempt to equilibrate helminthosporol with this hypothetical isomer by the use of iodine in benzene[18] destroyed all activity. Interestingly, de Mayo *et al.*[6] have prepared a derivative of helminthosporal (IV) that contains a lactone ring and an exomethylene group derived from one of the aldehyde groups. The marked variations between various gibberellins[19,20] and (I) and (II) in their ability to trigger sugar release must be due to other features of their structure, presumably of rings *A* and *B*. Possibly the gibberellin molecule may be regarded as consisting of the 'effector part'—the *CD* part of the system, and the 'affinity part' that accounts for the binding of the molecule to an active site.

		R_1	R_2
I	Helminthosporol	CH_2OH	CHO
II	Helminthosporic acid	CH_2OH	COOH
IV	Helminthosporal	CHO	CHO

I thank Prof. Saburo Tamura for generous gifts of helminthosporol and helminthosporic acid, and Miss J. Rostance for careful technical assistance.

Residues from Organic Solvents showing Gibberellin-like Biological Activity

Two years ago, while attempting to measure the gibberellin content of various antibiotic preparations, I was using a purification procedure that had, as its first step, the extraction with ethyl acetate of an acidified solution of the material under test. In control experiments, in which acidified, distilled water was extracted rather than a solution of the biological material under test, evaporation of the final solvent left a residue that had the

Table 2. REDUCING SUGARS RELEASED BY SIX DE-EMBRYONATED BARLEY GRAINS INCUBATED IN 2·5 ML. ACETATE BUFFER (0·5 mM, *p*H 5·3) FOR 6 DAYS AT 25° C, IN A ROTARY SHAKER
Reducing sugars expressed as mg maltose monohydrate

properties of an unstable 'gibberellin' in that it promoted the synthesis of hydrolytic enzymes in de-embryonated barley, resulting in a large increase in the quantities of reducing sugars released into the culture medium[1].

These observations have now been confirmed and extended. Ethyl acetate and, to lesser extents, methyl and *n*-butyl, but not isobutyl acetates, left residues with highly variable biological activity when evaporated using rotation at 20° C, whereas various esters of propionic acid did not. The use of higher temperatures for rotary evaporation leads to even more irregular recoveries of active material. Sodium acetate is not active in this test for gibberellins; indeed, incubations are carried out in dilute acetate buffer (0·5 mM), and at higher concentrations acetate inhibits the response of the test system to gibberellic acid[2]; thus the recent observations on the stimulating effects of low concentrations of acetates on the germination of dormant malting barley cannot be attributed to a 'gibberellin-like' action but rather to some less specific effect as shown by many other substances[3,4]. Thin-layer chromatography shows that there are at least twelve substances in the residue from ethyl acetate, but it has not proved possible to recover active material from these chromatograms, and only traces of active material have been recovered from paper chromatograms. Where detectable, activity occurred between R_F values of 0·2 and 0·5, and most frequently at R_F 0·3 on chromatograms run with *n*-butanol/1·5 N ammonia (3 : 1 by volume, top phase) on Whatman No. 4 paper. Activity was also occasionally detected on the base line, and at R_F 0·9 on these chromatograms. Ethyl acetoacetate is a relatively non-volatile contaminant of ethyl acetate, but neither this nor the pure lithium or sodium salts nor free acetoacetic acid showed biological activity. However, sodium acetoacetate that had been contaminated by precipitation with ethanol did show activity, and so did residues from the rotary evaporation of ethanol ('rectified spirit') and of acetone. At least some samples of rectified spirit yielded more activity per l. evaporated than did any of the ethyl acetate samples tried, but with all solvents there were large variations between batches. Again, thin-layer chromatography showed that the residue from ethanol was an extremely complex mixture. The direct addition of small amounts (up to 50 μl.) of ethanol to the incubation mixture caused sugar release, but the intensity of the response varied with different samples of ethanol and was less than could be obtained with traces of ethanol residues, indicating that a contaminant, rather than ethanol itself, was the active substance. Marginal activity was also detected with *n*-propanol and old (but not freshly distilled) ethyl acetate. 'Tails' from the commercial distillation of rectified spirit were inactive. A commercial preparation of D,L-α-tocopheryl acetate, which was shown to be heterogenous by thin-layer chromatography, showed very marked activity. Many of these results are shown in Table 1.

Attempts to isolate the active material have not been successful, but some observations on their characteristics may be recorded. Shaking ethyl acetate with large volumes (3 × 1/3 volume) but not with small volumes (3 × 1/12 volume) of water apparently reduced the final yield of 'active material', indicating that the active material is at least slightly soluble in water saturated with ethyl acetate. The active material from the residual solid does not sublime under high vacuum from a flask at 60° C to a receiver at −70° C. This result is hard to reconcile with the fact that active residues were obtained by rotary evaporating ethyl acetate that had been washed, dried and distilled through a fractionating column, unless it is assumed that the material appeared in the distilled solvent on standing or changed in the absence of ethyl acetate. 'Spectrosol' ethyl acetate also left active residues after rotary evaporation. However, there were indications that the 'purification' of ethyl acetate reduced the subsequent yield of active material, but that after storage the yield returned to about its previous level. Exposing ethyl acetate to sunlight for a week before rotary evaporation reduced the yield of active material. The active material was soluble in diethyl ether and chloroform, but not petroleum ether. None of these solvents left an active residue after rotary evaporation. Similarly, residues were obtained from freshly purified and redistilled acetone, and from ethanol, and these also showed biological activity.

In view of the repeated failures to isolate the active substance(s), a wide range of compounds that could conceivably be derived from ethanol or ethyl acetate were tested for biological activity (Table 2). At the same time many other substances were tested, some of which show plant growth regulating activities of various kinds. The fact that these tests gave negative results shows clearly that the test using as an index the release of sugar from de-embryonated barley is highly specific for gibberellin-like molecules and substances such as helminthosporol[1,5–7]. It is notable that (−)-kaurene and (−)-kauranol gave negative results in these trials.

Table 1. SUGAR RELEASE FROM DE-EMBRYONATED BARLEY INCUBATED FOR 6 DAYS AT 25° C WITH THE TEST SUBSTANCES

Substance under test (quantity/flask)	Reducing sugars in solution* (as mg maltose monohydrate)
D,L-α-Tocopheryl acetate (25 μl.)	46, 78, 110
Residue methyl acetate (from 350 ml.)	14, 16, 17
Residue ethyl acetate (from 150 ml.)	59, 76
Residue ethyl acetate (from 200 ml.)	120, 130
Residue ethyl acetate (spectrosol, from 350 ml.)	11, 57
Residue *n*-butyl acetate (from 250 ml.)	128, 156
Ethanol, specially purified (25 μl.)	42, 56, 60
Ethanol, commercial sample (50 μl.)	34, 61
Ethanol, redistilled (50 μl.)	22, 44
n-Propanol (50 μl.)	8·7 9·3
Residue ethanol (from 500 ml.)	85, 107
Residue acetone (from 350 ml.)	35, 36
Residue same acetone, redistilled (from 350 ml.)	35, 42

* In the absence of stimulating substances reducing sugars equivalent to 0·3–2·0 mg maltose monohydrate were released, while in the presence of gibberellic acid (about 100 μg) the range was equivalent to 150–180 mg.

Table 2. SUBSTANCES TESTED WHICH GAVE NEGATIVE OR MARGINAL VALUES IN THE DE-EMBRYONATED BARLEY TEST FOR GIBBERELLINS

(a) Substances reported to regulate plant growth or metabolism

Indole acetic acid; benzylaminopurine; 6-furfurylaminopurine (kinetin); 2,4-dichlorophenoxyacetic acid; α-naphthalene acetic acid; 2,3,5-triiodobenzoic acid; 2,4-dichloroanisole; 3-amino-1,2,4-triazole; maltol; kojic acid; digitonin; tigogenin; tomatine; phenyldisodium orthophosphate; *sym*-diphenylurea; thiourea; penicillin *G*; penicillin *V*; 6-amino-penicillanic acid; streptomycin sulphate; aureomycin sulphate; sugar-cane wax, *n*-heptaldehyde; methyl oleate; *n*-octadecanol; phenyl acetic acid; *cis-o*-methylcinnamic acid; coumarin; *o*-coumaric acid; 3-methylcoumarin; 6-methylcoumarin; caffeic acid; ferulic acid; 2(3)-benzoxazolone; ethylene; sebacic acid; 2-chloropyridine; 2-bromopyridine; pyridine-N-oxide, pyridine-2-carbinol; 2-chloro-ethanol.

(b) Vitamins, vitamin concentrates, and related compounds

Yeast extract; ascorbic acid; menaphthone, cholesterol; ergosterol; β-sitosterol; vitamin A acetate; carotene (commercial prep.); linolenic acid; linoleic acid; glucose-*cyclo*-acetoacetate (acid and ethyl ester)

(c) Substances relating to terpenes, or their metabolism

D,L-Mevalonolactone; β-hydroxy-β-methylglutaric acid; *cis*-β-methyl glutaconate; *trans*-β-methyl glutaconate; acetoacetic acid (sodium and lithium salts, ethyl ester); β-hydroxybutyric acid (and ethyl ester); ββ′-dimethylacrylic acid; crotonic acid; squalene; farnesol; citronellol; myrcine; linalool; citral; β-pinene; camphene, santalol; β-ionone; (−)-kaurene; (−)-kauranol.

(d) Substances conceivably derived from ethyl acetate

Diacetyl; acetoin; triacetic lactone; dehydracetic acid; 2,6-dimethylpyrone-3-carboxylic acid; 2,6-dimethylpyrone; acetyl acetone; diacetyl acetone; diacetone alcohol; mesityl oxide; mesitylene; phloroglucinol; acetal; aldol; pinacol; iso-phorone; acetaldehyde; methanol; diethyl acetonedicarboxylate.

(e) Other substances

Cadaverine; D,L-penicillamine; citric acid; abietic acid; morin; phytol; iso-phytol; β-propiolactone; γ-butyrolactone; *cyclo*hexanone; 2-methyl- and 3-methyl-*cyclo*hexanones; iso-propanol; *n*-butanol; iso-butanol; allyl alcohol; propargyl alcohol; 2-methylbutene-3-ol; hept-1-ene-4-ol; 3-methylpent-1-ene-3-ol; *n*-butyl propionate; iso-butyl propionate; ethyl crotonate; sodium vinyl acetate; crotonaldehyde; octene-1; 2,2,4-trimethylpent-1-ene; 2,2,4-trimethylpent-2-ene. Residues from rotary evaporation of diethyl ether, petroleum ether, and chloroform; 3-hydroxypropionic acid; glyoxylic acid; glycollic acid; glycollic aldehyde; ethylene glycol; propane-1 : 2-diol; propane-1 : 3-diol; butane-1 : 3-diol; butane-1 : 4-diol; butane-2 : 3-diol; pentane-1 : 5-diol; hexane-1 : 6-diol.

The discovery that the evaporation of ethanol, ethyl acetate and acetone and some other solvents leaves residues with gibberellin-like activity emphasizes the need for caution in the use of these and other solvents in investigations on gibberellins and the need for adequate 'blank' test procedures. The ethyl acetate used was

manufactured from ethylene via ethanol, and so the active residues must be among the first materials with 'gibberellin-like' activity to be derived from a chemical, rather than a biological, source. It may be remarked that positive results were checked by submitting the 'sugars' released in the test to paper chromatography. This precaution was necessary to exclude the possibility that the substances under test or their breakdown products, rather than sugars from the endosperm, were responsible for the observed reducing power.

I thank the Distillers Company for a gift of ethyl acetate 'tails' and for helpful discussions, Dr. R. H. B. Galt for a gift of (−)-kaurene and (−)-kauranol, and Miss J. Rostance for careful technical assistance. I also thank Dr. A. Whitear for help with many chemical problems.

pH Dependence of Lactate Dehydrogenase Isozyme Inhibition by Substrate

THE isolated, purified isozymes of lactate dehydrogenase (LDH) differ from one another in a variety of ways. In addition to electrophoretic mobility and immunological reactivity[1], they differ in kinetic behaviour[2], thermal stability[3,4], sub-unit composition[5], and inhibition by lactate[6], pyruvate[7], urea[8], oxalate[9], and α-hydroxybutyrate[10]. This communication describes the finding that the dissimilarity between LDH 1 and LDH 5 in degree of inhibition by lactate can appreciably be reduced by small alterations in *p*H. This dependence of substrate inhibition on *p*H illustrates the need to explore other variables before generalizing from limited *in vitro* to complex *in vivo* conditions.

Human heart and psoas muscle obtained at autopsy were homogenized in barbital buffer, *p*H 8·6. The homogenates were separated by starch-block electrophoresis, as previously described[11]. LDH 1 and LDH 5, recovered by elution from the block, were assayed spectrophotometrically for activity at 340 mμ with NAD (10^{-3} M) as coenzyme and increasing concentrations of the substrate sodium lactate (1×10^{-4}–$3{\cdot}6 \times 10^{-1}$ M). These reactions were measured at *p*H 8·5, 8·3, 8·0, 7·4, 7·0 and 6·6 at 25° C. The coenzyme and phosphate buffer (0·4 M), used to keep a constant cuvette volume of 3·0 ml., were each prepared at the *p*H being investigated. The *p*H of the reaction mixture was measured after the reaction had taken place and it was found that it did not vary from the initial *p*H by more than ± 0·2.

Fig. 1 (bottom) shows that at *p*H 8·3 LDH 5 resists inhibition by increasing lactate concentrations. However, at *p*H 6·6 and *p*H 7·0, after reaching a maximum at low concentrations, LDH 5 activity progressively declines. Variations between the curves at *p*H 6·6 and *p*H 7·0 are probably not significant, and can be attributed in part to differences in the source and preparation of the enzyme. Such small variations occurred in three similar experiments run at identical *p*H's on different enzyme preparations. The curve for LDH 5 at *p*H 8·5 is not shown in Fig. 1; it resembles the curve obtained at *p*H 8·3. Fig. 1 (top) reveals that inhibition of LDH 1 by lactate is appreciable at all *p*H's used. Slight increases in inhibition are observed at lower *p*H. However, even at *p*H 6·6 LDH 5 is inhibited less by lactate than is LDH 1 at *p*H 8·3; the differences are consistently more than 20 per cent. The dependence of LDH inhibition by lactate on *p*H was also observed in LDH 5 obtained from rat liver, as well as in commercial preparations of LDH 1 (pig heart, Boehringer) and LDH 5 (rabbit muscle, Boehringer).

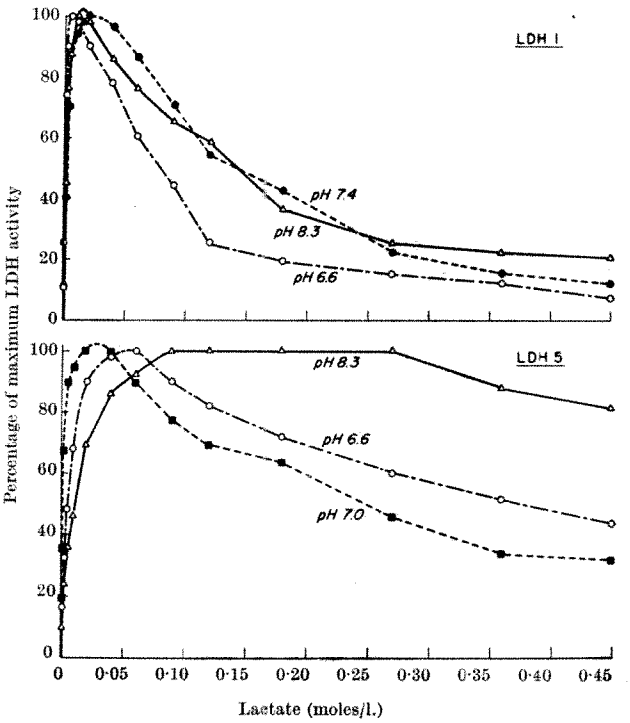

Fig. 1. Reactivities of LDH 1 (top) and LDH 5 (bottom) to increasing concentrations of sodium lactate as modified by alterations in *p*H

At *p*H 8·3, LDH 1 and LDH 5 react with lactate in a manner similar to that with pyruvate; at *p*H 8·3, LDH 5 resists the high lactate concentrations which inhibit LDH 1. Winer and Schwert[12] reported that pyruvate inhibition of a crystalline beef heart preparation containing two LDH isozymes is dependent on *p*H; their results agree with the data presented here for lactate in that pyruvate inhibition of LDH activity increased as the *p*H was lowered[12].

In addition to variations in *p*H, alterations of temperature drastically affect inhibition of the LDH isozymes; thus at 40° C, which more closely resembles physiological conditions than 6° C or 25° C, LDH 1 is more similar to LDH 5 in reactivity to pyruvate[13] than it is at 6° C or 25° C.

Different *in vitro* reactivities of isolated, purified LDH 1 and LDH 5 to pyruvate[7] at temperatures which are not physiological form the basis of a theory which states that LDH 5, because of its resistance to pyruvate, occurs as the predominant isozyme in anaerobically metabolizing tissues where, it is claimed, high levels of pyruvate develop[14]. In comparison, LDH 1, because of its inhibition by pyruvate, occurs as the principal isozyme in aerobically metabolizing tissues where low pyruvate concentrations are found[14]. Evidence for this theory, largely circumstantial, has been drawn from reports of shifts in isozyme pattern toward increased prominence of LDH 5 in such diverse environments as exist in neoplasia[15], growth of cells in tissue culture[16], hormonal stimulation of uterus[17], and phylogenetic evolution of various muscles[18]. Several exceptions to the theory have already been reported, most notably the examples of mature human erythrocytes[11], platelets and bovine lens fibre cells[15], all anaerobic cells which have little LDH 5, but large amounts of LDH 1 (ref. 20). Furthermore, pyruvate and lactate levels of cells shifting toward LDH 5 predominance under the anaerobic environments already mentioned reach the

peak but not the inhibitory regions of the curve (Fig. 1) relating enzyme activity to substrate concentration[21]. Thus, substrate concentrations high enough to inhibit LDH isozymes may be unattainable *in vivo*[21].

Regarding this theory of LDH isozyme distribution among tissues, the present experiments on *p*H dependence of LDH isozyme inhibition by lactate as well as others involving the effect of temperature on the reactivity of LDH 1 and LDH 5 toward pyruvate[21] demonstrate that even the *in vitro* differences between isolated, purified LDH 1 and LDH 5 in reactivity toward substrate may be modified and appreciably diminished by altering certain simple conditions. This investigation, therefore, suggests the dangers of extrapolating from limited *in vitro* to complex *in vivo* conditions when attempting to elucidate different tissue distributions of LDH isozymes.

Respiratory Activity of Rat Intestinal Mitochondria

THE difficulty of measuring the respiratory activity of intestinal homogenates and of mitochondria isolated from the small-intestinal mucosa of the rat has been recorded by others[1–3]. The inhibition of succinoxidase activity reported by Nakamura *et al.*[1] was later shown by Stanbury[2] to be associated with the release of the unsaturated oleic and linoleic fatty acids. This inhibition was partly overcome by the addition of rat serum[1]. The present study was undertaken to examine more fully the protective effect of serum, as a preliminary to the study of the respiratory activity of the jejunal mitochondria of the rat infected with the nematode *Nippostrongylus brasiliensis*.

In all experiments the mitochondria were isolated by the following procedure. White rats were killed by a blow on the head and two-thirds of the small intestine was then removed, everted, washed in saline, and blotted to remove excess mucus. The mucosa was scraped off with the edge of a glass slide. The mucosae from two rats were pooled and the mitochondria were isolated from a fresh weight of 2–3 g by the method of Schneider[4]. The standard medium for isolation and resuspension of the mitochondria was 0·25 M sucrose + 0·003 M ethylenediamine tetraacetic acid (EDTA). The latter was added to chelate with the calcium expected to be released from parasites homogenized with the intestinal mucosa in subsequent experiments with infected rats[5]. A second medium contained the same concentrations of sucrose and EDTA, but 30 per cent bovine serum albumin (BSA) solution (Armour Pharmaceutical Co.) was added to give a final concentration of 1·5 per cent. The mitochondria were resuspended in the same medium in which they were isolated, so that from 0·3 to 0·6 mg of nitrogen was contained in the 0·5 ml. which was added to each Warburg flask.

The reaction mixture of 3 ml. and the procedure used for manometry were those described earlier[5], except that 1 mg nicotinamide-adenine dinucleotide (NAD) in 0·04 M nicotinamide (final concentration) was added to each flask. It was found that NAD in the presence of all substrates except succinate did not appear materially to affect the activity over the initial 10–20 min, but was better able to sustain the respiratory activity for 50 min. All activities were calculated from the uptake of oxygen over the first 20 min after an equilibration period of 10 min. The results of typical experiments when mitochondria were isolated in the standard medium with and without BSA are shown in Table 1.

Table 1. $QO_2^{(N)}$ OF MITOCHONDRIA OF THE SMALL-INTESTINAL MUCOSA OF THE RAT ISOLATED IN 0·25 M SUCROSE + 0·003 M EDTA WITH AND WITHOUT 1·5 PER CENT BSA

Substrate (10^{-2} M)	Standard medium	
	Without BSA	With 1·5 per cent BSA
Glutamate	≏ Endogenous rate	331
Malate	,, ,,	438
α-Oxogluturate	,, ,,	265
Succinate	211	532

When mitochondria were isolated without BSA, the $QO_2^{(N)}$ for glutamate, malate and α-oxogluturate was no better than the endogenous rates recorded with mitochondria isolated with or without BSA. The initial activity with succinate was relatively high but fell rapidly and was very low 40 min after equilibration. Isolation with 1·5 per cent BSA substantially increased the rate of $QO_2^{(N)}$ for succinate, which was then sustained for a longer period and resulted in a high rate of activity for the other substrates.

When 0·5 per cent BSA was used in the medium, the activities were consistently one-third to one-half those in 1·5 per cent BSA. If the concentration of BSA was increased to 2·5–3·0 per cent, frothing during homogenization interfered with the isolation and no further increase in activity was observed.

Electron micrographs were prepared from mitochondrial pellets fixed in buffered 1 per cent osmium tetroxide and sucrose (45 mg/ml.), embedded in methacrylate and examined in a Siemens Elmiskop I microscope. Mitochondria isolated as described here are shown in Figs. 1 and 2. Without BSA the mitochondria were swollen, vacuolated and the cristae were ill defined. When 1·5 per cent BSA was added, the mitochondria were smaller, non-vacuolated and the cristae were well defined.

Peroxidation may be associated with swelling of mitochondria[6], but there was no evidence of peroxidation when mucosal homogenates or isolated mitochondria were examined by the thiobarbituric acid method of

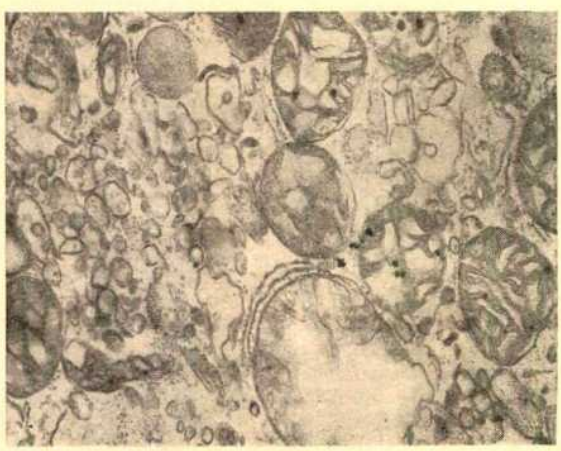

Fig. 1. (×20,000)

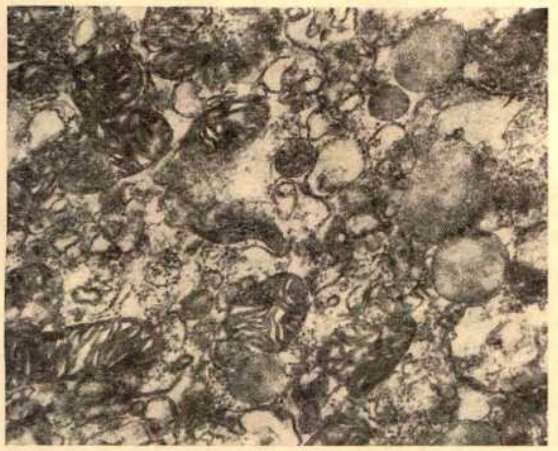

Fig. 2. (×20,000)

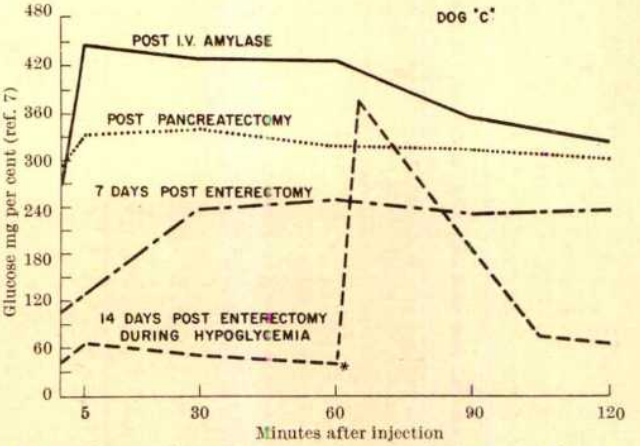

Fig. 1. Glucose tolerance tests. Test dose; 0·3 ml. 50 per cent glucose per kg, intravenous. * 3·0 ml. 50 per cent glucose per kg, intravenous

Tappel and Zalkin[7]. Nakamura *et al.*[1] reported that rat serum added to rat intestinal homogenates increased succinoxidase activity and suggested that the albumin of the serum bound free fatty acids liberated by homogenization. They did not state the concentration of serum used or the stage of isolation at which it was added; nor did they examine the effect of serum on respiratory activity in the presence of the other substrates used in the present experiments. The protective effect of albumin in the presence of fatty acids has been examined recently in more detail by Björntrop *et al.*[8], who confirmed that it bound the fatty acids. It was concluded therefore that 1·5 per cent BSA added to the medium of 0·25 M sucrose and 0·003 M EDTA was sufficient to protect the mitochondria isolated from the small-intestinal mucosa of the rat from the effect of unsaturated fatty acids.

I thank Mr. John Gibbins of the Department of Pathology, Faculty of Medicine, University of Sydney, for the electron micrographs

PHYSIOLOGY

Hypoglycaemia, Elevated Liver Glycogen and Diminished Liver Amylase in Pancreatectomized–Enterectomized Dogs

DURING the course of investigations into the source and role of serum amylase, we made the surprising observation that when depancreatomized diabetic dogs are enterectomized, the typical hyperglycaemia was changed into pronounced hypoglycaemia, associated with high levels of liver and tissue glycogen.

Three dogs were pancreatectomized by the avulsion technique[1]. Biopsies of muscle and liver for glycogen and amylase determination were taken. The dogs were maintained on kennel ration to which was added 5 g of commercial lipase and 1 g of choline per day. Insulin (about 10 U of N.P.H.) was given subcutaneously once a day; a daily urinary glucose excretion of 0·5–1·0 per cent as measured by 'Clinitest' tablets was maintained. In two dogs, several determinations of intravenous glucose tolerance, using 0·3 ml. of 50 per cent glucose per kg body-weight, yielded typical diabetic curves. After 1–2 months, the three pancreatectomized dogs were again operated on. Specimens similar to those obtained at the first operation were again taken, and the entire small intestine was then removed leaving only about 2 cm of ileum. Vagotomy was performed at the same time to protect the remaining ileum and colon from the gastric acid.

Following the second operation, the animals were maintained by the intravenous infusion of 5 per cent glucose in 0·45 per cent sodium chloride to which were added 15 U. of regular insulin and 20 mequiv. of potassium chloride per l., and appropriate amounts of vitamins and antibiotics. On this regimen, the daily urine contained about 1 per cent glucose. The intravenous glucose tolerance test yielded typical diabetic curves. At the second operation, no pancreatic tissue was found in any dog.

Within 7–15 days after the second operation, each of the previously hyperglycaemic animals became hypoglycaemic and remained hypoglycaemic despite the intravenous infusion of large amounts of glucose without insulin. Intravenous glucose tolerance tests carried out during the period of hypoglycaemia yielded flat curves (Fig. 1). Biopsies of the liver obtained at this time from each of the animals showed abnormally high levels of glycogen (about twice the pre-enterectomy values), and low levels of amylase (about a third of the pre-enterectomy levels).

After the hypoglycaemia and negative glucose tolerance tests were demonstrated in one dog, the animal was anaesthetized, and biopsies of the liver, muscle and kidney were taken for glycogen and amylase determination. 2,000 U. per kg body-weight of crystalline hcg amylase were then infused intravenously, and specimens of venous blood for serum amylase and blood glucose were taken at 30 min, and then at hourly intervals for 6 h. At the sixth hour, biopsies of the liver, muscle, and kidney were again obtained, the animal closed, and the intravenous glucose tolerance test repeated.

The infusion of amylase caused a striking increase in the level of blood glucose (Fig. 1), and a fall of the liver glycogen. The glycogen content of the kidney changed little, and that of the muscle rose (Table 1). The amylase levels of the liver, kidney and skeletal muscle rose (Table 1); that of the liver most markedly. With the blood glucose stabilized at the end of 6 h at about three times the pre-infusion level, the repeat glucose tolerance test was typically diabetic (Fig. 1).

Although the series is small, the hypoglycaemia and obliteration of the glucose tolerance curve occurred in three of three animals subjected to delayed enterectomy following pancreatectomy. In all dogs, the liver glycogen

was abnormally high during the period of hypoglycaemia. The basic physiological effect seemed to involve difficulty in mobilizing liver glycogen. The intravenous infusion of crystalline hog amylase restored the hyperglycaemia and diabetic glucose tolerance curve. The simultaneous removal of the pancreas and small intestine causes no such effect[2].

Release of Acetylcholine from the Cerebral Cortex during Stimulation of the Optic Pathway

ELECTRICAL stimulation of a peripheral sensory nerve produces an increase in the rate at which acetylcholine (ACh) is liberated from the surface of the exposed contralateral somatosensory cortex[1]. Under light anaesthesia this procedure also evokes a smaller but more widespread release of ACh from the brain, probably by activating non-specific ascending pathways from the reticular formation[2].

It is not known whether these effects are confined to somatic sensory pathways, and the present experiments examine the release of ACh from the surface of the brain during stimulation of the optic pathway.

Rabbits were anaesthetized with 'Dial Compound' (allobarbitone and urethane, Ciba, Ltd., 0·7–0·9 ml./kg) and ACh was collected from the exposed surface of the cortex using the 'Perspex' cylinder technique introduced by MacIntosh and Oborin[3]. Details of the method and of the biological assay procedure for ACh have been described previously[1]. In the present experiments the fluid in the cylinders contained eserine sulphate ($1·0 \times 10^{-4}$ g/ml.) and the release of ACh was raised by the addition of atropine sulphate ($4·0 \times 10^{-7}$ g/ml.).

The eyes of the rabbits were shielded from light and the resting release of ACh from the primary visual receiving area of the cortex was determined bilaterally for 4–15 collection periods each of 15 min duration. These resting outputs varied considerably from animal to animal and with the depth of anaesthesia, but were relatively constant in any one animal, not varying by more than ± 15 per cent over 2–4 h. The output from lightly anaesthetized animals was 2·2–34·7 ng ACh/15 min/cm² cortex.

In eight lightly anaesthetized rabbits, exposure of the eyes to bright light for 30–60 min was associated with a bilateral increase in the rate of ACh release from the visual cortex (2·2–7·3 times the resting output, Fig. 1*A*). This evoked release from the visual cortex was accompanied by a smaller rise from the motor and somatosensory cortex (1·2–2·5 times the resting output, Fig. 1*B*.)

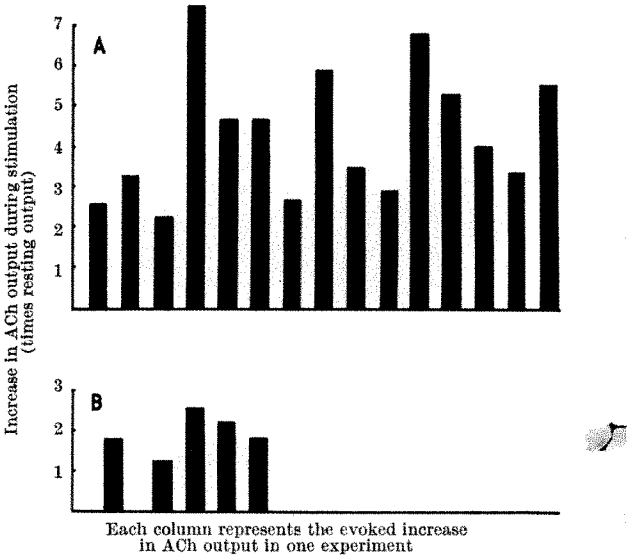

Fig. 1. Summary of individual experiments. The increase in ACh output during bilateral stimulation of the retina by light. *A*, Primary visual receiving areas; *B*, motor and somatosensory areas

In five lightly anaesthetized rabbits direct electrical stimulation (20–60 stimuli/sec, 1·0 msec pulses) of the dorsal nucleus of the lateral geniculate body, using a stereotactically placed coaxial electrode, produced an immediate increase in the rate of ACh release from the ipsilateral primary visual cortex (2·0–4·9 times the resting output, Fig. 2*A*). There was a simultaneous but smaller rise in ACh output from the contralateral primary visual area and from the motor and somatosensory regions of the cortex (1·1–1·9 times the resting output, Fig. 2*B*).

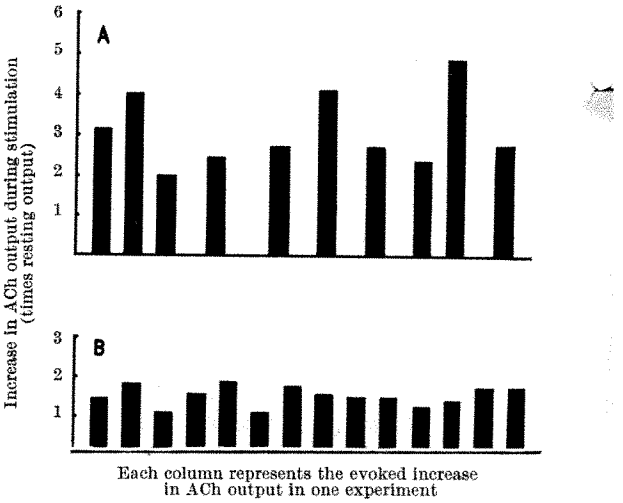

Fig. 2. Summary of individual experiments. The increase in ACh output during stimulation of the lateral geniculate body. *A*, Primary visual receiving area; *B*, motor, somatosensory and contralateral visual cortex

These experiments suggested that stimulation of the optic and of the somatosensory pathways evoked a similar pattern of ACh release from the surface of the brain; a large increase from the primary receiving areas and a widespread but smaller release from other regions of the cortex.

It is likely that the widespread evoked release of ACh is a consequence of the indirect activation of ascending path-

ways from the reticular formation, since Kanai and Szerb[2] have reported that direct stimulation of the mesencephalic tegmentum will produce this effect.

It is not yet clear whether the larger increases in ACh release obtained from the primary receiving areas are due entirely to a more effective activation of reticular pathways to these regions. They may be attributable in part to the liberation of ACh from intracortical nerve endings associated with the fourth order neurone in the direct sensory pathway.

Inability of the Electroretinogram to recover after a Brief, High-intensity Light Stimulus

Buckser and Potts[1] observed the recovery of the rat electroretinogram (ERG) after weak light adaptation, and related this to the visual threshold. Buckser[2] proposed a model to relate the recovery of the ERG *a*-wave after partial light adaptation to the level of the light adaptation. This communication reports the failure of the ERG to recover to the dark adapted ERG after exposure to a brief, high-intensity light flash.

Dark adapted albino rats were curarized, artificially respirated, and positioned under a commercial photographic electronic flash unit (Hershey Manufacturing Co.). The light was focused on the cornea by means of appropriate lenses. The preparation of the rat, the recording technique, and the reproducibility of the results are described elsewhere[3]. An a.c. amplification system with low- and high-frequency cut-offs at 0·06 and 1,000 c/s, respectively, was used.

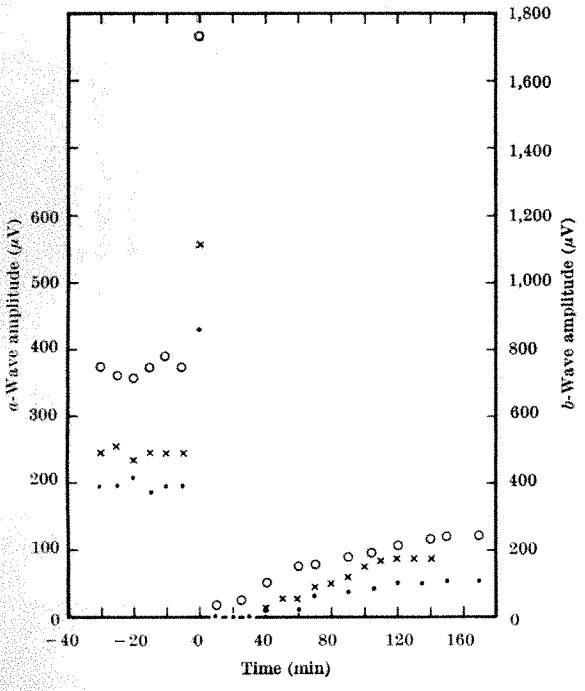

Fig. 1. Recovery of the *a*-wave and *b*-wave amplitudes after a brief high-intensity stimulus. '0' time represents the time the high-intensity stimulus is given. Negative time represents the time before the high-intensity stimulus was given. ● and ×, The *a*-wave amplitudes obtained from two different experiments. ○, The *b*-wave amplitudes obtained from one experiment

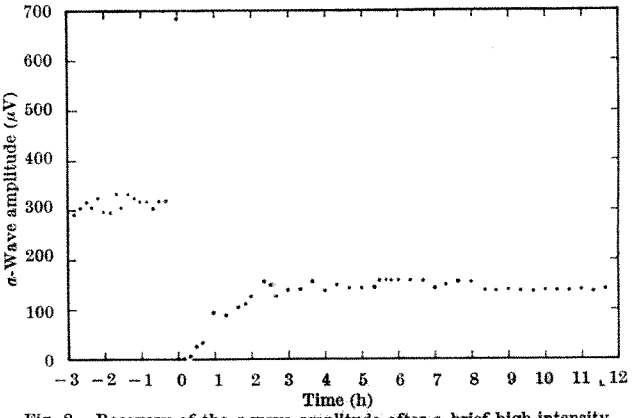

Fig. 2. Recovery of the *a*-wave amplitude after a brief high-intensity stimulus. '0' time represents the time the high-intensity stimulus is given. Negative time represents the time before the high-intensity stimulus was given

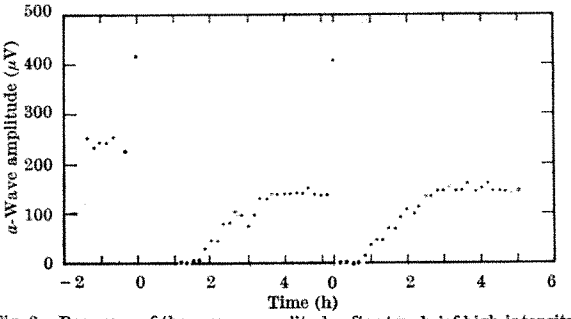

Fig. 3. Recovery of the *a*-wave amplitude after two brief high-intensity flashes. '0' time represents the time the high-intensity stimulus is given. An equilibrium recovery response was attained before the second flash was given. Negative time represents the time before the high-intensity stimulus was given

A series of ERG's were obtained from the dark adapted rat with neutral density filters equal to 5·0 positioned between the flash unit and the eye with an interval between flashes never less than 10 min. The neutral density filters were removed and a single ERG was recorded in response to the entire energy of the flash unit. The filters were replaced, and the ERG's again recorded with the interval between flashes being 10 min or greater.

The *a*-wave amplitude, $E(a)$, obtained from two experiments is shown plotted against time in Fig. 1. In the experiments reported here the $E(a)$'s were approximately constant at 195 and 245 μV when the 5·0 neutral density filters were used prior to the high-intensity flash, and 430 and 555 μV in response to the high-intensity stimulus. Approximately 40 min were required after the high-intensity light before an *a*-wave was detected. The *a*-wave amplitude recovered to approximately 50 and 80 μV 2 h after the light flash and remained constant. The recovery *a*-wave amplitudes after the high-intensity light flash are much lower than the pre-high-intensity amplitudes. The failure of the *b*-wave amplitude to recover to the pre-high-intensity flash amplitude is also shown in Fig. 1.

In Fig. 2, $E(a)$ is shown before, in response to, and after the high-intensity light flash. The *a*-wave amplitude does not recover to the pre-high-intensity flash, even after almost 12 h of dark adaptation.

The eye was exposed to a second high-intensity light flash after an equilibrium response was obtained following the initial bright lights. The ERG recovery was again recorded in response to the 5·0 neutral density filtered light flash. The results are shown in Fig. 3. The *a*-wave amplitudes, after recovery from both high-intensity light stimuli, are considerably lower than the pre-high-intensity stimuli. $E(a)$ was constant at approximately 245 μV prior to the initial high-intensity stimulus, and recovered to 140 and 150 μV following the first and second high-intensity stimuli, respectively. $E(a)$ in response to the two high-intensity stimuli was 415 and 407 μV.

Additional work is being done to determine whether the decrease in the ERG amplitude is related to the pigment concentration, or changes in the structure of the retina and the receptor cells.

I thank Mr. David Buffin for performing many of these experiments.

PHARMACOLOGY

Adrenergic β-Receptors and Non-shivering Thermogenesis

Sellers, Scott and Thomas[1] demonstrated that after prolonged cold exposure (cold acclimatization) heat production through shivering is gradually replaced by an increase in non-shivering thermogenesis. It is often assumed that muscle tissue is an important site of non-shivering thermogenesis. Recently, Himms-Hagen[2] has suggested that acceleration of the triglyceride cycle of brown adipose tissue is a major mechanism of non-shivering thermogenesis in cold-acclimatized rats. As lipid metabolism of adipose tissue is under β-adrenergic control, a study of the effect of β-adrenergic blockade on electrical muscle activity in rats exposed to about 4° C after acclimatization to 23° C or 4° C would be expected to yield valuable information. This communication presents preliminary data of such an investigation. Cold-acclimatized rats were removed from the cold room, anaesthetized with urethane (1 to 1·25 g/kg)—a drug known to alter only the degree, not the type, of the electrical response of muscle activity[1]—and exposed to a temperature of 4° C. Needle electrodes were inserted into a leg muscle and electrical activity was measured with a Grass model 5 polygraph[3]. Rectal temperature was monitored throughout the experiment. Each rat was tested at least twice, once when given drug treatment, and once when given saline or nothing. The β-adrenergic blocking agent, propranolol (*AY* 64043) (kindly donated by Ayerst, McKenna and Harrison, Ltd., Montreal), was used at doses of 0·3 or 0·9 mg/kg intraperitoneally every 30 min. Fig. 1 shows rectal temperature, duration of exposure to 4° C and the effect of the drug on electrical muscle activity in six cold-acclimatized rats. None of the animals shivered during an experimental period of 2·5 h when treated with saline. A seventh rat showed signs of shivering and was therefore excluded from this series. After treatment with propranolol, all six rats showed a marked increase of electrical muscle activity. Representative tracings of the muscle activity before and after propranolol are shown in Fig. 1: no effort was made to quantitate accurately the observed increase.

It is concluded that β-adrenergic blockade interferes with non-shivering thermogenesis so that heat production, mediated by electrical muscle activity, increased.

In order to determine whether the response was dose-dependent, two dose levels of propranolol were used. As can be seen from Fig. 1, the differences between the effects of the two doses are not obvious, and so this question remains to be settled.

It is not possible to draw any conclusions from these experiments regarding the site of non-shivering thermogenesis (muscle, adipose or other tissues); however, they confirm the importance of β-adrenergic receptors in cold-acclimatization. In other experiments it was found that rats acclimatized to 23° C and exposed to 4° C all shivered and propranolol did not interfere with the shivering.

Further investigations of the mechanisms underlying these observations are in progress. This work was supported by grants from the Defence Research Board and the Medical Research Council of Canada.

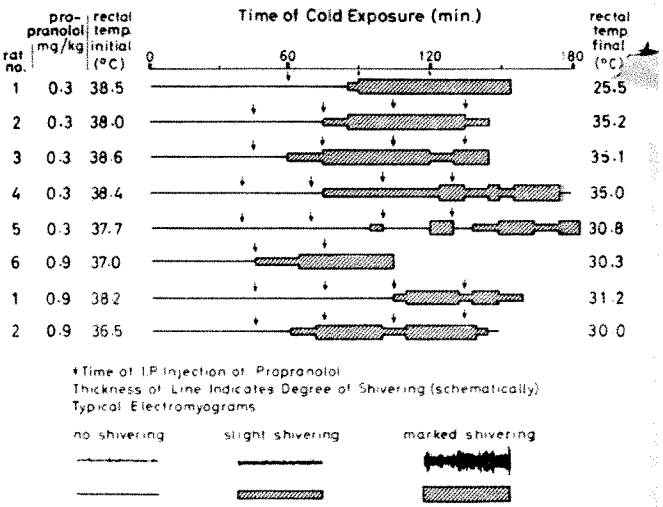

Fig. 1. Effect of propranolol on shivering of cold-acclimatized rats anaesthetized with urethane and re-exposed to 4° C. Note absence of shivering during control period

Destruction of Cephalosporin C by Ultra-violet Light

WITH the recent development of potent penicillinase-resistant semi-synthetic cephalosporins[1], there is considerable interest in the parent antibiotic, cephalosporin *C* (ref. 2). This antibiotic, which displays a peak of ultra-violet absorption at 260 mμ, is often detected on paper chromatograms by exposure to a source of ultra-violet light. Using this technique during some investigations on the biosynthesis of the antibiotic[3], I noted an extreme lability of cephalosporin *C* to ultra-violet light.

It had been common practice in this laboratory to locate the antibiotic on paper chromatographic strips by placing the strips on the glass filter surface above the ultra-violet light source. After the dark area was circled in pencil, the strip was placed on the surface of an agar medium seeded with either *Escherichia coli* or *Bacillus subtilis*; the plate was incubated at 37° C for 16 h. It was noted that the intensity of the antibiotic activity of the cephalosporin *C* spot varied from experiment to experiment and depended on the type of ultra-violet filter used. (These original observations were made by Robert B. Walton and Richard Burg.) When a red-purple 'Corex *A*' polished filter (No. 9863, Corning Glass Works, Corning, New York) was used, the resulting antibiotic activity was good. On the other hand, use of a clear 'Vycor' glass filter (No. 7910, Corning) resulted in poor antibiotic activity. It was suggested that, because the 'Vycor' filter allows more 260 mμ light to pass, ultra-violet light was being absorbed by the compound on the paper and inactivating it. To investigate this, paper disks (Schleicher and Schuell Co., Keene, New Hampshire) were dipped into a solution containing approximately 100 μg of the sodium salt of cephalosporin *C* per ml. of 0·02 M phosphate buffer (*p*H 7·0). After drying, the

Table 1. INACTIVATION OF CEPHALOSPORIN *C* ON PAPER BY ULTRA-VIOLET LIGHT

0·50	86
1·0	49
2·0	35
4·0	< 35

* Assayed by size of zone of inhibition against *E. coli MB*-208.

disks were exposed for various lengths of time to the ultra-violet light source covered by the 'Vycor' plate. As shown in Table 1, rapid inactivation occurred. When a 'Corex' plate was used, no destruction of cephalosporin *C* occurred in this same time interval although prolonged exposure did cause inactivation. Visible light from a fluorescent lamp did not inactivate the antibiotic. Inactivation by ultra-violet light also occurred when the antibiotic was applied to Whatman No. 1 chromatography paper instead of antibiotic disks.

To determine whether inactivation also occurred in solution, cephalosporin *C* at 400 μg per ml. of buffer was irradiated in a manner usually used for mutation of bacteria. 20 ml. were placed into a dish and the solution was agitated by a magnetic stirrer. Irradiation was from an ultra-violet lamp placed 10 in. above the bottom surface of the dish in a dark room ; no filter separated the light source from the solution. At various times, paper disks were dipped into the solution and were assayed by an agar diffusion assay against *B. subtilis*. As shown in Fig. 1, rapid inactivation occurred in solution. There was no photoreactivation of cephalosporin *C* as determined by exposing the solution to visible light after irradiation. A similar experiment in which the absorbance at 260 mμ was measured in a Beckman spectrophotometer (model *DB*) at various times showed that ultra-violet light also decreased the 260 mμ absorbance of cephalosporin *C* (Fig. 2). It is of interest that in each of the experiments (Table 1 and Figs. 1 and 2), there was an initial increase in activity or absorption before degradation occurred. The significance of this observation has not as yet been ascertained.

The site of action of ultra-violet light on cephalosporin *C* is probably the β-lactam-dihydrothiazine nucleus. No cleavage of the aminodipyl side-chain was detected by a phenylacetylation technique[4]. Removal of the *o*-acetyl group could result in a decrease in antibiotic activity but not in loss of absorption at 260 mμ[5]. The loss of only 17 per cent of the 260 mμ absorption which occurred at the same time as destruction of almost 90 per cent of the antibiotic activity is consistent with the fact that many of the degradation products of the cephalosporin nucleus retain the ability to absorb light of 260 mμ wave-length[6].

HAEMATOLOGY

Absorption-spectrum of Haemoglobin of Leeches

ALTHOUGH it has been known for nearly a hundred years[1] that the red pigment of the circulatory fluid of non-rhynchobdellid leeches is haemoglobin, there appear to be no records of the absorption-spectrum or of its main features. While removing the blood from the tissue-pigments of leeches I have had occasion to record the absorption-spectra in neutral aqueous solutions of the oxyhaemoglobin of *Hirudo medicinalis* L, *Haemopis sanguisuga* (L) and *Erpobdella testacea* (Savigny). The spectrum for *Hirudo* is shown in Fig. 1, and the positions of the main features in the spectra of all three genera are given in Table 1.

From these records there seems little doubt about Lankester's original identification of the pigment. They show one further point of interest, namely, that the main α- and β-peaks are situated at a longer wave-length than those of most other haemoglobins which have been recorded[2], including those of other annelids. The difference is most marked for the α-peak at 582–4 mμ. This wave-length is even longer than that of the myoglobins which, in general, is longer than that of the recorded haemoglobins—with the exception of *Simocephalus* haemoglobin[2]. Taking into account both the α- and the β-peaks, the haemoglobin of the larva of *Gastrophilus*[3] shows rather a close resemblance to that of the leeches.

The myoglobins have a higher oxygen-affinity than the haemoglobins, and both the *Gastrophilus* larva and Cladocera such as *Simocephalus* are known to develop and use haemoglobin only under anoxic conditions[3,4]. It is there-

Table 1. WAVE-LENGTHS (mμ) OF THE PEAKS (UPPER LINE) AND TROUGHS (LOWER LINE) IN THE ABSORPTION-SPECTRA OF THE OXYHAEMOGLOBINS OF (1) *Hirudo*, (2) *Haemopis* AND (3) *Erpobdella*

(2)	274	347	417	544	582
		314	382	514	567
(3)	273	342	418	546	584
		318	372	515	567

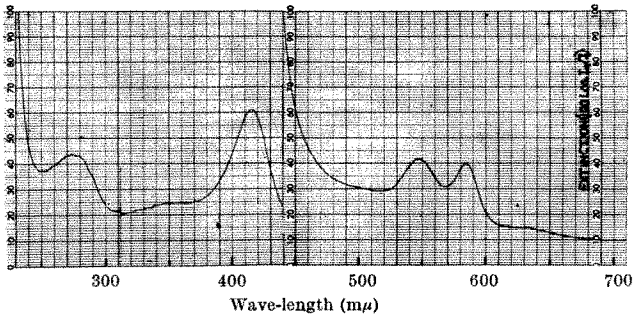

Fig. 1. Absorption-spectrum of aqueous solution of oxyhaemoglobin of *Hirudo*: extinction of light (100 log (I_0/I) as a function of wave-length, in mμ. Scanned from right to left. Solution diluted 4 × for wave-band below 440 mμ. Artefact at 312 mμ marks switch-over from tungsten to hydrogen lamp

fore possible that the haemoglobin of leeches also has an unusually high oxygen-affinity and that this has adaptive value. At the same time there is at present no reason to think that leeches live under conditions as extremely anoxic as the outstanding values of the α-peak of their haemoglobin would imply, and the problem is one of some interest. Internal parasites usually have haemoglobins with a higher oxygen-affinity, and with an α-peak at a longer wave-length, than those of their host[2], but carnivores such as *Haemopis* and *Erpobdella* are not even external parasites. Many leeches tolerate stagnant conditions, but these three genera swim well and are presumably not at the mercy of their surroundings. Conceivably a high oxygen-affinity compensates for shortcomings elsewhere in the oxygenation-system.

Blood Platelets as a Source of Enzyme Activity in Washed Trypanosome Suspensions

THE standard method used for separating trypanosomes from infected blood involves repeated differential centrifugation of a suspension of trypanosomes and blood elements in a phosphate-buffered saline solution containing glucose. The success of this procedure varies not only from one species to another but also with the degree of parasitaemia. Suspensions of the Liverpool strain of *Trypanosoma rhodesiense* may be obtained free of red blood cells and leucocytes in this way, but with *T. vivax*, *T. congolense*, *T. lewisi* and the '*M*' and '*J*' strains of *T. rhodesiense* other techniques have to be used for complete removal of blood cells and platelets[1,2].

In this laboratory, critical microscopic examination of suspensions of the Liverpool strain of *T. rhodesiense* prepared in the foregoing manner showed that, although red blood cells and leucocytes were absent, a quantity of platelets, varying between 12 and 20 per cent of the trypanosome count, was regularly present. Counts were made with a haemocytometer using an untreated glass pipette and the diluting fluid of Cramer and Bannerman[3]. Several techniques, dependent on the size, adhesive or agglutinating properties of platelets[2,4–8], were tried in order to reduce this contamination. The most successful of these for routine separation was the defibrination technique used by Fulton and Spooner[2]; this reduces the contamination to less than 3 per cent and gives a 95 per cent recovery of trypanosomes.

A knowledge of the extent of contamination from blood platelets is essential for any quantitative enzymatic investigations, since platelets exhibit significant metabolic activity[9,10]. Fig. 1 shows the relative contribution of

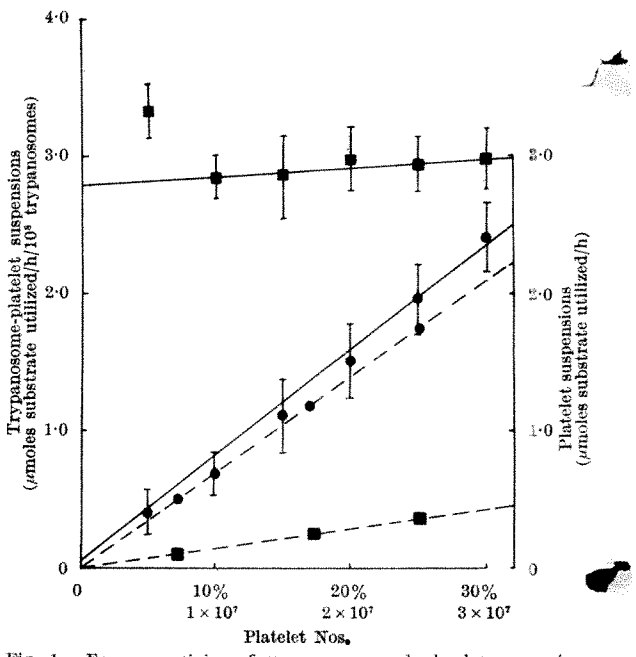

Fig. 1. Enzyme activity of trypanosome and platelet suspensions. ●, Lactic dehydrogenase activity; ■, L-α-glycerophosphate dehydrogenase activity. Each experimental sample (3·0 ml.) contained phosphate buffer, *p*H 7·4 (300 μmoles), NADH (0·5 μmole), and 0·1 ml. of a water lysed trypanosome-platelet (—) or platelet (– – –) suspension. The mixed suspensions contained about 10^9 trypanosomes/ml. (10^8 trypanosomes *c.* 0·5 mg protein by the biuret method). The platelet suspensions contained between 0·5 and 5×10^8 platelets/ml. (1 mg protein *c.* $9{\cdot}3 \times 10^8$ platelets). Sodium pyruvate (10 μmoles) or a solution of mixed triose phosphate esters (3·5 μmoles) was added at the start of the experiment

platelets in mixed trypanosome-platelet preparations to L-α-glycerophosphate dehydrogenase (GPDH) (L-glycerol-3-phosphate : NAD^+ oxidoreductase, *EC* 1.1.1.8) and lactate dehydrogenase (LDH) (L-lactate : NAD^+ oxidoreductase *EC* 1.1.1.27) activity. This activity was determined from the decrease in optical density at 340 mμ as reduced nicotinamide-adenine dinucleotide (NADH) was oxidized. The first of these enzymes is part of the coupled dehydrogenase–oxidase system which accounts for the major part of the respiratory metabolism of the blood forms of *T. rhodesiense*[12,13]. Lactate dehydrogenase activity has been reported or implied in the same species[13–16]. The present results show that whereas platelets contribute little to the GPDH activity of a *T. rhodesiense* suspension, they are almost entirely responsible for the observed LDH activity. In quantitative enzymatic investigations, therefore, whether of blood parasites or of other blood cells, the possibility of error due to contamination by platelets cannot be disregarded.

IMMUNOLOGY

Effect of Immunosuppression on First-generation Isotransplantation of Chemically Induced Tumours in Mice

THE existence of host defence mechanisms which operate against autochthonous cancer has been suspected for many years, and the possibility has been suggested that such resistance might depend on mechanisms similar to those which bring about homograft and heterograft rejection[1,2]. This presupposes that the host is able to recognize its own tumour cells as foreign and to react so as to inhibit them, perhaps by way of specific immunological mechanisms. Several authors have presented evidence from transplantation and serological studies which suggests that tumour cells are antigenically different from normal cells of the tumour-bearing host in which they arise[3].

Suppression of the immunological reactivity of a graft recipient by various forms of chemotherapy or total-body radiotherapy has been shown to delay rejection of homologous (allogeneic) transplants of normal tissues in animals and man, and homologous or heterologous (xenogeneic) transplants of tumour in experimental animals[4–8]. If such immunosuppression were shown similarly to influence growth of syngeneic tumours (auto- or iso-transplants), it would provide yet another kind of evidence that tumour tissue contains antigens foreign to the normal host tissues and that the immunological mechanisms of the host react against these antigens to inhibit tumour growth. It seemed reasonable to test this possibility by studying quantitatively the transplantability of syngeneic tumours under conditions which suppress or enhance immunological responses. Such an investigation has been undertaken in this laboratory and the results obtained with *cyclo*phosphamide ('Cytoxan') are sufficiently interesting and reliable to merit this preliminary report. Experiments with other immunosuppressive agents are in progress.

*Cyclo*phosphamide ('Cytoxan') was chosen for this study because its immunosuppressive effect had previously been demonstrated in a variety of experimental systems[4–6] and because its pharmacological characteristics seem well suited to the objective. This drug, like other polyfunctional alkylating agents of the nitrogen mustard type, acts very rapidly after systemic administration to initiate cytotoxic changes, including destruction of those cells responsible for immunological reactions. These effects progress over a period of several days and persist for two or more weeks, but although cytopathological evidence of this effect is progressive over this considerable period of time, the drug itself is very rapidly hydrolysed to a non-cytotoxic form within a few minutes or hours of injection. Thus, if administration of the drug is stopped 24 h or more before a transplant is injected, it results in a host in which immunosuppression will continue for a considerable time but in which there is no persistence of a cytotoxic drug which might inhibit the tumour transplant.

Tumours were induced in *C57BL*/6 mice by single intramuscular injections in the thigh of 1·0 or 0·5 mg of 20-methylcholanthrene (MC) suspended in 0·1 ml. of olive oil. Fibrosarcomata usually developed at the injection site 4–6 months later.

For a transplantation study one tumour donor was killed and the tumour was promptly removed, minced as finely as possible with scalpels, suspended in an isotonic solution (Puck's saline *A*)[9] containing 0·01 per cent trypsin and 0·02 per cent collagenase and agitated for about 1 h on a magnetic stirrer. The cell suspensions were then washed three times with 10 ml. of saline *A*, counted in haemocytometers, and resuspended in saline *A* at the desired concentration.

Recipients were *C57BL*/6 mice of the same sex as the tumour donor, 7–10 weeks of age (Millerton Research Farms, Millerton, New York). Isogeneity of the *C57BL*/6 line has been demonstrated by acceptance of reciprocal skin grafts.

The cell doses chosen for tumour transplantation were those expected to produce about 50 per cent tumour takes in the control group, as judged by results of preliminary experiments with the same type of tumour. Tumour cell suspensions were injected subcutaneously into the inguinal region of the recipients in a volume of 0·1 ml. Care was taken to mix the suspension thoroughly at frequent intervals before injections in order to assure even cell distribution.

The recipients were palpated at regular intervals to follow tumour development and growth. Tumours were measured by callipers in the longest diameter and were recorded in categories of tumour size in increments of 5 mm of tumour diameter.

Prior to the implantation of the tumour cells, experimental groups of mice were treated by intraperitoneal injections of 'Cytoxan'. Animals in the control group were given intraperitoneal injections of 0·1 ml. of isotonic saline on each day that the experimental group received treatment. In one experiment, treatment consisted of five daily injections of 0·30 mg of 'Cytoxan' per mouse (about 15 mg/kg of body-weight) dissolved in 0·1 ml. of isotonic saline commencing 7 days prior to tumour transplantation. Thus tumour cell inoculation was 72 h after the last *cyclo*phosphamide injection. In all other experiments the treated mice received a single injection of 0·6 mg 'Cytoxan' in 0·1 ml. of isotonic saline (about 30 mg/kg) 4 days prior to challenge followed by three daily injections of 0·30 mg. This gave an interval of 24 h between the last injection of the drug and the inoculation of tumour cell suspension. A fresh solution of 'Cytoxan' was prepared daily. There was no lethality due to the drug at this dosage level.

Several attempted homotransplants of the MC-induced tumours from *C57BL*/6 mice were not accepted by random-bred Swiss mice.

Three experiments were carried out with numbers of mice sufficient for statistical evaluation. Data from preliminary experiments have been omitted. The incidence of tumour takes ranged from 31 to 88 per cent in the control groups of the three experiments presented, while the number of cells inoculated was of the same magnitude in all the tests (Table 1). Other experiments with the same type of tumour indicate that there is an almost 100 per cent acceptance of tumour isotransplants with inocula of a million cells whereas inocula in the magnitude of 100,000 cells gave variable results but seldom give 100 per cent takes. Since a different primary tumour was used in each of the experiments presented, whereas the recipients were syngeneic (isologous), these variations in tumour transplantability presumably reflect differences in aggressiveness inherent to the individual tumours. Wide variation in latent period and in rate of growth was also observed during the induction of primary tumours.

Table 1. FREQUENCY OF TAKES* OF FIRST PASSAGE METHYLCHOLANTHRENE-INDUCED SARCOMATA IN ISOLOGOUS RECIPIENTS (*C57BL*/6 MICE)

	Inoculum of cells per mouse × 10^5	Controls	(%)	Pre-treated	(%)	Duration of exp. days	*P*
Exp. No. 43	2·5	70/99	71	82/98	84	60	< 0·05
Exp. No. 49	1·5	22/74	31	39/72	54	60	≪ 0·01
Exp. No. 53	2·0	85/97	88	77/85	91	40	> 0·60
Total	—	177/270	65	198/255	78		< 0·01

* Fraction indicates the number of tumours over the total number of mice in the group. Tumours that regressed are registered as no-takes.

The data presented in Table 1 show that there was a significantly higher number of acceptances of tumour isotransplants in mice which were pre-treated with 'Cytoxan', as compared with control groups, in two of the three experiments. The probability values (*P*) by χ^2 analysis were $P < 0{\cdot}05$ in experiment number 43 and $P < 0{\cdot}01$ in experiment number 49. This difference was not observed in experiment number 53, but since the

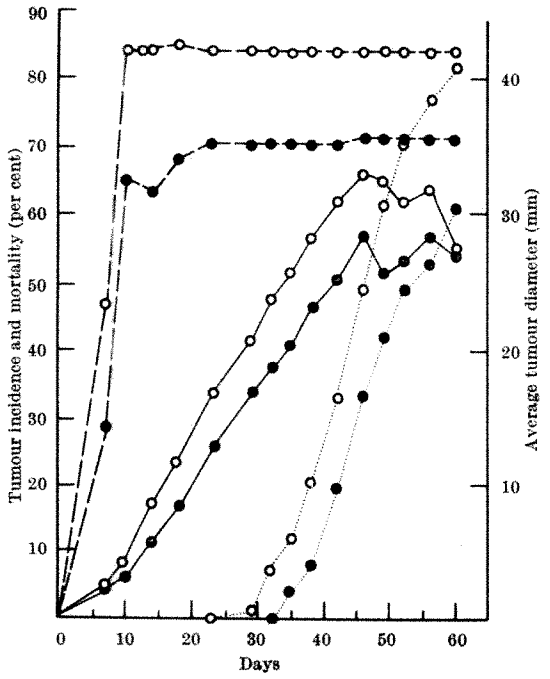

Fig. 1. Experiment No. 43. Comparison of tumour takes and mean tumour diameters in isogeneic recipients pre-treated with 'Cytoxan' and in untreated controls. ○, Controls; ●, experimental animals. – – – –, Incidence as a percentage of the total number of mice per group; ——, average tumour diameters (tumour-bearing mice only) in mm; ·····, mortality due to tumour as a percentage of the total number of mice per group

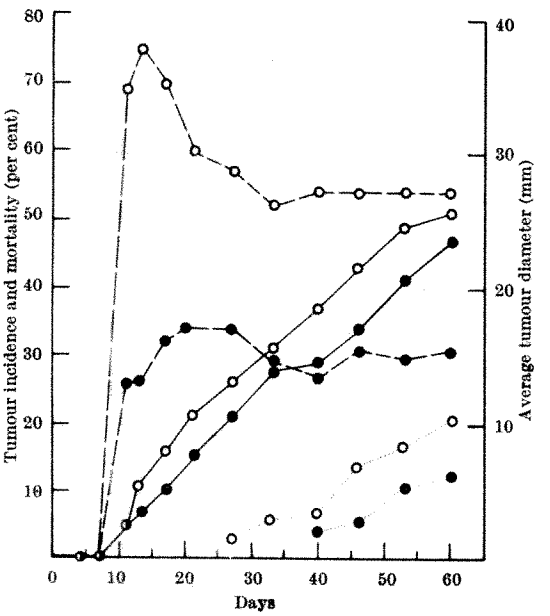

Fig. 2. Experiment No. 49. Same conditions as Fig. 1

incidence of tumour takes was about 90 per cent in the control group of that experiment, a significant increase in the number of takes in the experimental group could not be expected.

The total dose of 'Cytoxan' was the same in all these experiments, but the interval between the last injection of the drug and the inoculation of tumour cells was 72 h in experiment 43, and 24 h in experiment 49. The difference between the experimental group and the controls is greater in the experiment with the 24-h interval. Optimal time relationship as well as optimal dosage of the immunosuppressive medication remains to be determined.

In addition to the increased acceptance of tumour transplants in the pre-treated mice, there was also a slightly shorter period from inoculation to the appearance of palpable tumours, a higher rate of growth, and earlier deaths due to tumours.

Figs. 1 and 2 show the course of two experiments. In experiment 49 (Fig. 1) the peak incidence of palpable tumours in the pre-treated group was on the thirteenth day after inoculation. Afterwards there were a number of regressions until day 33. The period during which the regressions occurred probably coincides with the recovery of the experimental animals from the immunosuppressive effect of 'Cytoxan'. The transplants that were rejected were less than 5 mm in diameter. No significant number of regressions occurred in the other experiments.

Funds for this study were supplied in part by a research grant from the National Cancer Institute, U.S. Public Health Service, and by a training grant from the National Cancer Institute (J. R.).

Antibody Inhibition by a Minimal Dose of Antigen and Response to a Sudden Increase of the Dose

WE have already demonstrated[1-3] that continued administration of an optimal level of an antigenic stimulus to an adult animal finally produces a considerable decrease or even a disappearance of circulating antibodies ($\simeq 400$ days). The inhibition applies to complete as well as to incomplete antibodies; it is specific, that is to say, the animal responds normally to another antigenic stimulus, and it is accompanied by a very poor cytological response[3]. As the phenomenon is produced by relatively small doses of antigen, in contrast to 'immunological paralysis', it is appropriate for testing the response of the inhibited animal to a sudden increase in the antigenic dose. Animals inhibited to *Brucella abortus* show a small but significant increase in antibody, after the injection of a large antigenic dose[2,3]. This communication presents the results of our investigations of this phenomenon in the rabbit using human erythrocytes.

We have recently shown that this phenomenon of antibody inhibition by hyperimmunization is produced, not only by an optimal dose of antigen, but also by a minimal dose. Administration of a minimal dose shows a somewhat different evolution, but eventually gives the same considerable decrease in antibody titre[4]. We thought it would be interesting to investigate the response of animals inhibited by this small dose to a dose ten times higher than that which established inhibition.

Eight rabbits (weighing from 2·3 to 2·7 kg) were hyperimmunized by intravenous injection, three times a week, of 1 ml. of 26 per cent suspension of human erythrocytes (group A_1, from the same donor throughout the experiment); the experiment was continued during a period of 480 days. On the last day of this period, 10 ml. of the same erythrocyte suspension was injected. Four animals died within 24 h of this injection, and the remaining four showed a very clear response to this increase of the antigenic stimulus. With this in mind, we have examined only agglutinating titres, determined by the method of two-fold dilutions with two intercalated series, beginning at dilutions of 1/5 and 1/7·5.

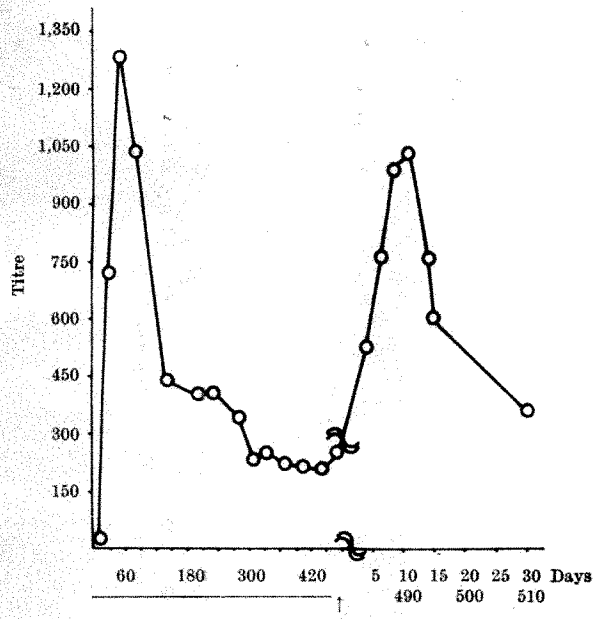

Fig. 1. Response of a batch of four rabbits inhibited by hyperimmunization with human erythrocytes during 480 days, to a single tenfold dose of these erythrocytes

As shown in Fig. 1, these four animals showed a good initial response to hyperimmunization with these doses of antigenic stimulus; the response reached a maximal level at about 60 days (1/1,280), but by the 300th day the titre practically stabilized at about 1/200; this continued for 180 days. They were then injected with a single tenfold dose of antigen and the titre increased rapidly to 1/1,000, which represents a good secondary response, very much greater than that obtained with the same dose injected into a batch of five normal rabbits (Fig. 2).

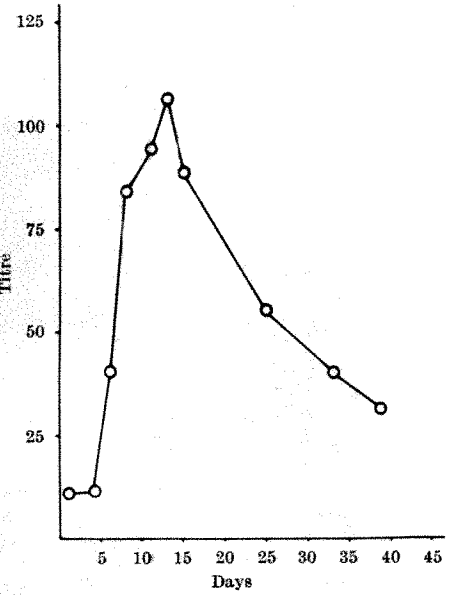

Fig. 2. Response of a batch of five normal rabbits to the same single dose as was received by the rabbits in Fig. 1

This fact confirms our previous observations with *Brucella* that an animal inhibited to an optimal dose of antigen by hyperimmunization responds to a large increase of the antigenic dose with a significant increase in antibody titre. As with the phenomena of 'immunological tolerance' and 'immunological paralysis', this phenomenon of 'inhibition by hyperimmunization' lasts as long as the antigenic stimulation persists. For these reasons we have postulated the existence of an 'immunological equilibrium'[5] between stimulus and response at the intracellular level. This equilibrium can very probably be established at different absolute levels, and, among other possibilities, it can probably be broken by a change in the intensity of the antigenic stimulation, as has been observed in the case of rabbits inhibited by hyperimmunization to small doses of human erythrocytes. This equilibrium must play an important part in the normal non-production of auto-antibodies against the 'self' antigens which are continuously stimulating the immuno-competent system. In some cases this equilibrium with auto-antigens may not be attained at zero level but at a low antibody level, and this is surely the case with normal anti-I cryoagglutinins. We have some experimental data with rabbit cryoagglutinins that seem to favour this explanation. A thorough discussion of this postulated 'immunological equilibrium' between stimulus and response has recently been published[5].

PATHOLOGY

Centron–Cortex and Cortex–Medullary Cord Junctions in the Rat Lymph Node, as seen in 1μ Paraffin Sections

PREVIOUS communications to *Nature* have shown (*a*) that lymph-borne carbon diffusing into rat lymph node cortex from the subcapsular sinus is deflected by a barrier system around the stromal follicle or 'centron'[1]; (*b*) that lymph-borne iron dextran within the medullary cords is prevented from entering the cortex by a similar type of barrier system[2].

The mechanism of these barrier effects is obscure, but their existence has at least directed attention to the much-neglected histology of the junctional zones between centron, cortex and medullary cord, which is the subject of this communication.

The problem is that ordinary technical methods are inadequate for examining these junctions. Routine haemalum-stained 5μ paraffin sections contain too many artefacts. 1μ sections cut in paraffin-beeswax-stearic acid are necessary[3], and double nucleic acid staining[4], with its more precise delineation of lymphoid nuclei and cytoplasm, is also of value.

Experimental conditions should be strictly specified. The left para-aortic lymph node of the 80–100 g rat is examined 4 days after completion of an antigen course delivered into the corresponding hind foot pad (0·1 ml. Commonwealth Serum Laboratories T.A.B. vaccine twice daily for 5 days).

Under such circumstances, the centron shows a high proportion of blast cells, which may lie immediately adjacent to the lymphocytes of the surrounding cortex without any intervening space. However, a narrow cleft is more usual (Fig. 1), bounded on one side by centron blast cells orientated in a smooth semi-circular line, and on the other by a more irregular wall of cortical lymphocytes. Crossing this cleft can be seen fine protoplasmic processes, which serial sections show are derived from stromal macrophages in the vicinity.

In other areas, instead of a cleft, appears a series of irregular sinuses bounded by fragile macrophage extensions of the same type (Fig. 2). The slightest processing

defect causes their disruption, with the production of a wide peri-centron artefact space.

The cortex–medullary cord junctional area has a rather different morphology. Along some of its length the small lymphocytes of the cortex and the plasma cells of the medullary cord are in direct boundary contact, with few plasma cells penetrating the cortex to any depth.

An intermediate zone composed largely of macrophages can sometimes be seen. In such an area the population of lymphoid cells drops considerably, but never disappears. Large, vesicular macrophage nuclei became relatively more numerous and obvious. The background of macrophage cytoplasm forms a continuous pseudosyncytium, with the boundaries of individual cells very poorly defined. There are few visible spaces or cytoplasmic processes. The width of the macrophage zone is irregular; artefact splitting is seldom seen (Fig. 3).

Although the peri-centron and cortex–medullary cord junctions have features that differ in detail, they both show the importance of stromal macrophages. Around the centron this system of cells forms a thin layer of lymphatic sinuses. Between the cortex and the medullary cord the same type of cell is orientated in a broader and more pavemented pattern.

To be correlated with these appearances are the results obtained by treating unfixed lymph node sections with Indian ink[1], which outlines the processes of stromal macrophages, but shows no obvious change in these processes at either the peri-centron or the cortex–medullary cord zones[1,2]. However, this method uses 10–15μ sections, and would not be capable of showing the fine changes in macrophage orientation which are demonstrated by the 1μ sections under examination.

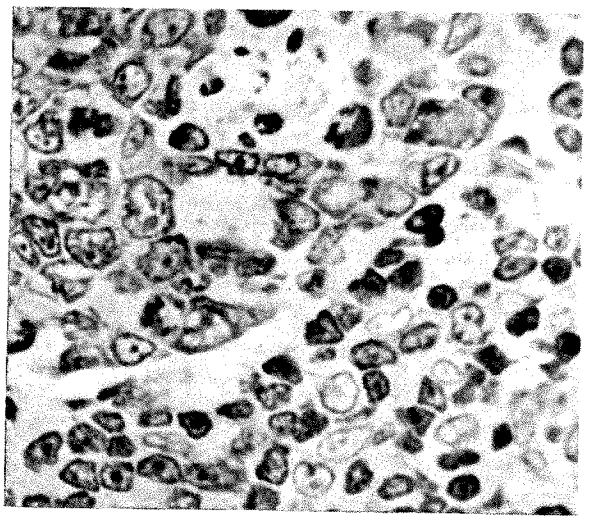

Fig. 1. Portion of lymph node cortex showing, above, the smooth edge of the centron, outlined in blast cells, and, below, cells of the cortex, mainly small lymphocytes. There is a narrow dividing cleft between these areas, running from top right to mid-left. Paraffin-beeswax-stearic acid, cut at 1μ, stained by basic fuchsin-azure *B* (see ref. 4) (× 600)

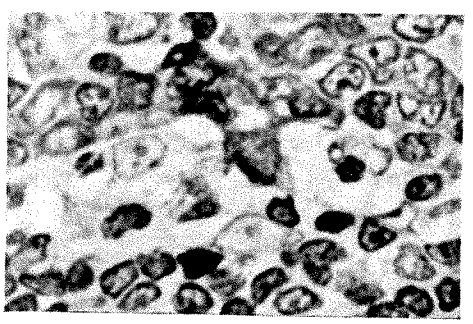

Fig. 2. A view of another portion of the same centron edge as Fig. 1. Note the pale, vesicular macrophage nuclei, with abundant granular cytoplasm throwing out processes, which form the walls of lymphatic sinuses. These processes are specially liable to artefact disruption. Paraffin-beeswax-stearic acid, cut at 1μ, stained by basic fuchsin-azure *B* (× 600)

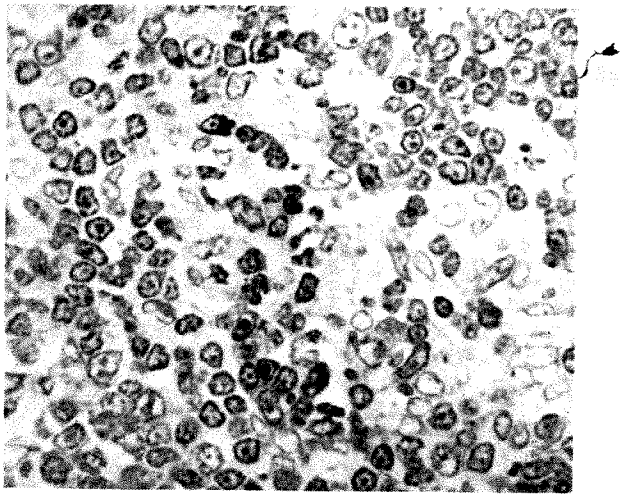

Fig. 3. Junction zone between the cortex and medullary cord of a rat lymph node. Above and right is a group of cortical lymphocytes; below and left are masses of plasma cells in the cord. Note the diagonally placed intermediate area with poorly defined margins, containing a relatively larger number of pale, vesicular macrophage nuclei, and a smaller number of lymphoid cells. Paraffin-beeswax-stearic acid, cut at 2μ, stained by basic fuchsin-azure *B* (× 400)

It is reasonable to assume that peri-centron and corticomedullary particle blockage is in some way a function of the stromal macrophages which are prominent at these sites. How these cells achieve this effect is a matter for further observation and experiment.

Further Evidence of Enhanced Tumour Destruction with Combined Laser Energy and Chemotherapy

A PREVIOUS article[1] has reported on the significant increase in the tumoricidal effect of laser energy when combined with a course of chemotherapy. In the previous study, multiple pulses of ruby laser (6,943 Å) were used on Cloudman *S*-91 melanomata in CDF_1 mice, and *cyclo*phosphamide was used as the chemotherapeutic agent. This communication reports a similar experiment in which neodymium laser energy (10,600 Å) was used, on the same tumour–host system with the same chemotherapeutic agent. It will be seen that the substitution of a neodymium laser for the ruby laser does not significantly effect the increased oncolytic properties of the combination therapy.

For this experiment the Cloudman *S*-91 melanoma was transplanted into 150 CDF_1 mice by injecting 0·05 c.c. of a tumour cell suspension subcutaneously into the shaved dorsal flank. The cell suspension was prepared by mincing 1 g of freshly excised tumour tissue through a Snell cytosieve with 10 c.c. of sterile saline. When the tumours had reached a size of approximately 6 mm in 126 animals they were randomly divided into four groups of approximately 30 mice each.

*Cyclo*phosphamide in a dose of 25 mg/kg/day was administered subcutaneously daily to two groups. Between the fourth and fifth day of chemotherapy the group of mice receiving laser treatment only, and the group

receiving laser plus chemotherapy had their tumours exposed to between 500 and 1,100 J of laser energy. The dose depended on the size of the tumour as follows: 5–6 mm *D* received 500 J; 7–8 mm *D* received 800 J; 9–10 mm *D* received 500 + 600 J. (Tumour size in this experiment was measured in terms of *D*. Two approximately perpendicular measurements of distance across the tumour were taken, *L* and *W*. *D* is defined to be $\sqrt{LW}$.)

The animals were paired prior to laser treatment so that an equal distribution of the various tumour sizes was present in each of the four groups. The laser used in this experiment has previously been described in detail[2]. It consisted of a neodymium glass rod capable of delivering up to 1,000 J of focused energy on the target with a pulse length of 2 msec. The beam was focused through a double convex lens and the treated tumours were placed in the converging part of the beam, 1 cm from the focal point. A spot size of 3 mm was produced on the mouse skin giving an energy density for an 800-J pulse of 11,428 J/cm². Prior to laser exposure, each animal was anaesthetized with an intraperitoneal injection of pentobarbital and immobilized on an operating board under the laser beam.

A gross tabulation of the outcome of the experiment is presented in Table 1. At the time of application of the laser, the average tumour size in the 'laser plus chemotherapy' group was 7·63 mm, while that in the 'laser only' group was 7·75 mm. The difference in size is attributable to the chemotherapy which slows the growth of the tumours used in this experiment. All tumours in a control group of 34 mice grew rapidly and proved fatal. The animals with tumours that were apparently entirely destroyed have been followed for at least 16 weeks after receiving laser treatment and are continuing to be followed.

Table 1. RESULTS OF THE EXPERIMENT

Outcome	Treatment		
	Laser	Chemotherapy	Laser and chemotherapy
Tumour present at all times	1	33	0
Tumour recurred	26	0	6
Tumour apparently cured	2	0	12
Mouse died without tumour	0	0	12
Totals	29	33	30

It is of interest to compare the time interval between laser treatment and the first evidence of tumour recurrence in the two laser groups. The technician error in estimating the presence of measurable recurrent tumour was approximately 2 days; that is, a measurable tumour may have been present at most 2 days before being reported. The minimum recurrence time after laser was only 2 days, the maximum was 22 days, and the average recurrence time was 8·75 days. Although there were fewer recurrences after combination therapy, the minimum recurrence time was 20 days after exposure to the laser, and the maximum was 110 days. If, in our evaluation of the worth of combination therapy as against laser therapy alone, we allow some weight to the amount of time without measurable tumour, the combination therapy is noticeably superior.

Although no detailed comparison of results using the two wave-lengths of laser energy was undertaken, it is apparent from the data of Table 1 that a course of *cyclo*phosphamide in combination with energy from a neodymium laser is more effective than either *cyclo*phosphamide or laser alone. This is in accord with the results obtained in the previous study[1]. The large number of mice which apparently died of toxic effects during the course of combination therapy is an indication that additional experimentation is necessary to determine the optimal method of combining the two treatments. Further experiments along these lines, and on the effects of other drugs as well as other tumour–host systems, are at present in progress.

We thank James R. Dearman and Norman Cook of the Applied Physics Branch, Redstone Arsenal, Huntsville, Alabama, for their generous assistance and for the use of their laser equipment.

RADIOBIOLOGY

Radiation Sterilization of Food

I AM constrained to comment on the article entitled "Direct and Indirect Effects of Radiation on Plant Cells: Their Relation to Growth and Growth Induction" by Holsten, Sugii, and Steward[1]. I am impelled to do this mainly because of what I deem to be an irrelevant statement made in the concluding remarks of the article which states: "The work has other and obvious implications for the radiation sterilization of food, especially in those cases in which the material so radiated is relatively rich in sugar".

I feel that Prof. Steward *et al.* have not only drawn false conclusions from inadequate data but indeed have made wild statements, unsubstantiated by their own evidence and contrary to the immense amount of literature in the field of radiation chemistry.

First, let me comment on the latter statement. Data are presented in Table 8 on the ultra-violet absorption spectra of sucrose irradiated and irradiated plus autoclaved. To me it would have been imperative to run the spectra on autoclaved sucrose as well, and to do this at different intensities of heat and with different quantities of irradiation. Some of these experiments have, in fact, been carried out during investigations concerned with the absorption spectra of sugars and the implication of the spectral changes in respect to the non-enzymatic browning of certain food[2,3]. Among the compounds which absorb in the region cited by the authors and about which some information is available in the literature are 5-(hydroxymethyl) furfuraldehyde and levulinic acid. Perhaps these may have been involved. They have been implicated in the sugar breakdown alluded to above. The absorption maximum at 285 mμ corresponds to 5-(hydroxymethyl) furfuraldehyde and that at 265–268 mμ to levulinic acid. Pigman and Goepp[4] have postulated the formation of levulinic acid from 5-(hydroxymethyl) furfuraldehyde. The ultra-violet absorption spectra of levulinic acid and the role of 5-(hydroxymethyl) furfuraldehyde in the discoloration of sugar solutions were published by Singh *et al.*[5].

The second point relates to the question of correlation between carrot cells, *Vicia faba* seedlings and animal systems. Indeed, there are hundreds or thousands of simple compounds that can cause mutations when relatively simple systems, such as the two cited, are exposed thereto. Such effects cannot, however, be compared with defined whole animal systems, such as rats, cats, dogs, chickens and humans, replete with mechanisms for modification, alteration, and digestion of the foods by the alimentary tract and the detoxification and excretion mechanisms of the liver and kidney.

To me it is difficult to conceive how anyone could imply or speculate that the data that are presented on the irradiation of sucrose solutions, coconut milk, etc., and the response of carrot cells and *Vicia faba* seedlings to these have any pertinence, even remotely, to the radiation preservation of foods of any type. The conclusions drawn by Steward *et al.* are immaterial and unwarranted. It is indeed unfortunate that these conclusions have been given wide publicity by the popular press.

The readers of *Nature* should be aware that the wholesomeness of some twenty-one different foods has been studied in a carefully designed and planned country-wide programme, which has extended over some 10 years. This work was planned in concert with the Office of the Surgeon General of the U.S. Army and the U.S. Food and Drug Administration. It has been periodically and carefully reviewed and scrutinized, in depth, by a committee of the National Academy of Sciences–National Research Council. Extensive laboratory data have demonstrated the safety of the process and shown that the foods studied can be consumed with impunity.

Included among the twenty-one different foods which have been studied with respect to their wholesomeness when they are treated with sterilizing doses of ionizing energy are three which are high in sugar, namely: pineapple jam; sweet potatoes immersed in sugar syrup; fruit compote. These have been fed to multiple generations of two species of animals, one being a non-rodent, over a 2-year period. Complete histopathological data and physiological responses on the animals have been obtained. The feeding studies of the animals have been carried out on a 35 per cent food intake level. All this information is available in the open literature, and these data have been, or are being, submitted to the U.S. Food and Drug Administration in order to obtain clearance for their sale.

In addition to the animal studies, investigations of the chemical effects of ionizing energy on the various components of foods, including carbohydrates, have been carried out as part of the U.S. Quartermaster Program and the Atomic Energy Commission Program and are available in the open literature.

Based on the data obtained in these extensive investigations, which go far beyond the level of due prudence which would normally be required for conventional methods of food processing, the U.S. Food and Drug Administration has started to issue regulations permitting the sale of radiation-treated foods in the United States.

Depletion of Mouse Spermatogonia following Exposure to Polonium-210

LOCALIZATION of polonium-210 (^{210}Po) in the interstitial spaces of the testes of rats has been demonstrated radioautographically[1] and a very slow rate of excretion of ^{210}Po from rat testis has also been shown. ^{210}Po is a naturally occurring alpha-emitting element of the uranium decay chain. A particle energy of 5·3 MeV allows a range for the ^{210}Po alpha particle of about 37μ in tissue. Since this distance is sufficient to penetrate from the interstitial spaces of the testis into the outer cell layers of the seminiferous tubules of the testis where spermatogenesis occurs, it seemed important to ascertain the effect of ^{210}Po on spermatogenesis. The survival of resting primary spermatocytes in stage VII tubules of mouse testis was measured by methods described by Oakberg in studies of the response of the mouse testis to external radiation exposure[3] and later used for the evaluation of tritiated thymidine toxicity[4]. Male Harvard Swiss Wistar mice 2–25 weeks of age were injected peritoneally with 0–2 nc. of ^{210}Po, obtained from the Radiochemical Centre, Amersham, and constituted in 0·05–0·25 ml. of isotonic weakly acid solution prepared by dilution with normal saline. At intervals from 5 days to 10 months after injection, mice were killed by cervical dislocation and their testes removed and fixed in either Bouin's solution or 10 per cent neutral formalin. The tissues were embedded in paraffin and cut into 5μ sections. Prepared slides were stained with periodic acid–Schiff–haematoxylin stains and examined at 1,000 × magnification using an oil immersion objective. Only seminiferous tubules cut in cross-sections so that they appeared round were selected for scoring. Only those tubules in stage VII, as established by maturation of the acrosomes of the spermatids[5], were counted. 15–30 tubules were counted from each slide. Serial adjacent sections were avoided. The results are plotted in Fig. 1.

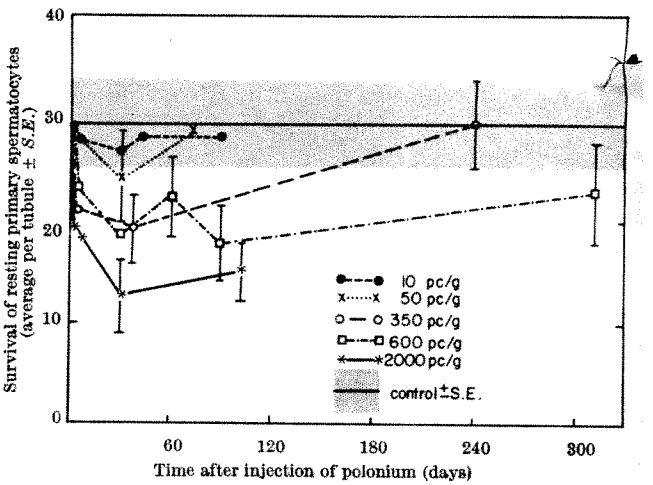

Fig. 1. Survival of resting primary spermatocytes in testes of mice injected with polonium-210 at zero time and killed at varied times thereafter. Amounts injected intraperitoneally indicated by legend. Standard errors indicated by span around points. All points lying outside standard error of control count are significantly different from control value (*t*-test $P < 0{\cdot}01$) except 30-day point on 50 pc./g line (*t*-test $P < 0{\cdot}05$)

These results can be considered in the light of spermatogenesis in the mouse. Resting primary spermatocytes (RPS) in mice are the result of a series of six cell divisions which begin with a dormant type *A* spermatogonium and proceed through mature type *A*, intermediate and type *B* stages to the RPS stage, which is the stage of meiotic prophase, after which mitotic division occurs to form haploid spermatoids[6]. The total time-course of these cell divisions requires about 7 days, so that testes from mice injected with ^{210}Po seven or more days prior to killing have been exposed to the internal radiation from ^{210}Po throughout the total cycle of spermatogonial divisions. Since cell division is known to be highly radiation sensitive, the system just described maximizes radiation exposure during the challenge of a series of cell divisions.

Radiosensitivity of the spermatogonia stages differs considerably from LD_{50} of 20–24 r. for intermediate and type *B* spermatogonia to the LD_{50} of several hundred r. for dormant type *A* cells[7]. The latter cells remain even after large doses of radiation and serve to replenish the cells of the tubule within 60–90 days after an acute radiation exposure. In the present experiments, these cells probably account for the recovery seen after 30 days at almost all doses of ^{210}Po used. At the highest level of exposure, that following administration of 2·0 nc. of ^{210}Po per g body-weight, there was only a slow and slight recovery during the period of observation.

Table 1. RETENTION OF POLONIUM-210 IN MOUSE TESTIS AND KIDNEY FOLLOWING INTRAPERITONEAL INJECTION OF 10 PC. PER G BODY WEIGHT

Days after injection	pc. ^{210}Po per g tissue (corrected for physical decay) Testis	Kidney
30	16·3	55·5
60	11·6	9·8
75	9·2	8·9
90	9·2	15
120	2·5	5·2
140	1·4	4·9

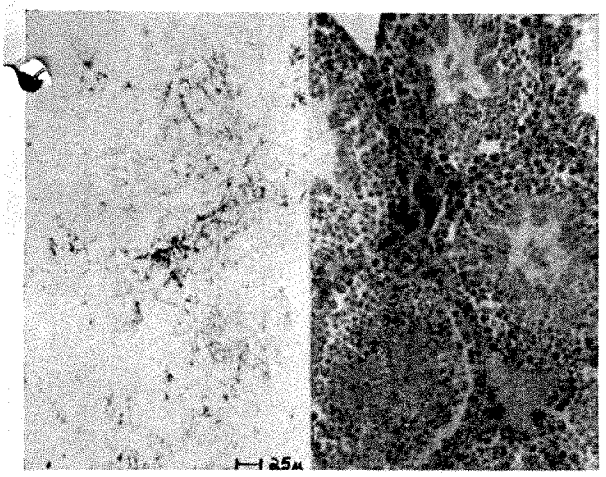

Fig. 2. Autoradiograph of testis from mouse injected intraperitoneally with 2,000 pc./g body weight of polonium-210 and killed 5 days later. Note concentration of radioactivity in interstitial tissue surrounding tubules. Compare the autoradiograph with the stained section of testis (right) taken from a similar animal and photographed at the same magnification. The α tracks, which appear as short streaks, penetrate the basement membranes of the tubules and traverse the spermatogonia in the periphery of the tubules. (Autoradiograph prepared with Kodak '*NTA*' liquid emulsion, exposed four months, developed in Kodak '*D*-19' and photographed unstained)

The most probable reason why regeneration of cellular elements was slow and delayed is that the ^{210}Po remains in the testis and continues to irradiate the spermatogonia. Significant amounts of ^{210}Po persist in the testes even after 90 days, as shown by radiochemical assay of excised testis (Table 1). Autoradiography has confirmed the localization of this ^{210}Po within the intertubular spaces such that the basement membrane of the tubules is exposed to a maintained flux of alpha particles (Fig. 2).

The results of preliminary investigations of the functional effects of this exposure suggest that overall fertility of the mouse is not grossly impaired by ^{210}Po exposure although the systemic effects of larger doses of ^{210}Po impair the general vigour of the animals and appear to depress their reproductive activity. Because of the uncertainties in the effective target and in the regularity of distribution within the tissue, the radiation doses associated with the administration of ^{210}Po cannot be calculated with any accuracy. As an estimate, based on the amounts of ^{210}Po assayed in tissue, the administration of 0·1 nc. of ^{210}Po per g body-weight (the minimum amount effective in producing significant cellular damage to the testis) should deliver at least 300 mrad local radiation dose during the first 10 days after administration. If the relative biological effectiveness of the radiation is 10, this corresponds to a rem dose of 3 r., which is identical to that dose of gamma radiation which produces a similar minimal but significant effect in this system[6].

This work was performed as part of a thesis presented to the faculty of the Harvard School of Public Health in partial fulfilment of the requirements for the degree of doctor of science in hygiene in the field of radiological health, and was supported in part by the Division of Radiological Health, U.S. Public Health Service. I was then on assignment from Training Branch, Division of Radiological Health, when the work described herein was performed.

BIOLOGY

Clutch Size in the *Sulidae*

FACTORS influencing the evolution of clutch size in birds have received notable attention from Kluijver[1], Lack[2], Wynne-Edwards[3] and others. The family *Sulidae* (order Pelecaniformes) provides a good example of adaptive radiation within a group, different clutch sizes having evolved in a balanced ecological/behaviour system. This problem was studied on the Bass Rock, Scotland (1960–63), the Galapagos Islands (1964) and the Peruvian Guano Island of Guañape Norte (1964–5) for *Sula bassana*, *S. sula*, *S. dactylatra*, *S. nebouxii* and *S. variegata* (*S. leucogaster* data from Murphy[4] and Dorward[5]). Data for *S. abbotti* are lacking, but this species probably closely resembles *S. sula*.

These species show a finely graded series of clutch sizes: *S. bassana* and *S. sula* (1), *S. dactylatra* (1–2), *S. leucogaster* (1–3, usually 2 and very rarely 3), *S. nebouxii* (1–3, usually 2 but often 3) and *S. variegata* (1–4, usually 2 or 3).

The single young of *S. sula* grew irregularly, experiencing frequent and extensive weight losses, took around 19 weeks to reach an average fledging weight of 900 g and had a 2-month period of post-fledging feeding by their parents. 30–60 per cent starved before fledging. All experimentally twinned nests failed completely.

S. dactylatra never reared more than one young per season, though the 5–6 day younger chick survived up to 1 month before succumbing to persecution by the sibling. A fledging weight of 2,500–3,000 g was reached in 16–20 weeks and was followed by a post-fledging feeding period of 7–9 weeks.

S. leucogaster also rarely rears more than one chick. This fledges in about 17 weeks at an average weight of 950 g. Post-fledging feeding occurs for at least 8 weeks (Dorward).

S. nebouxii not infrequently rears two young (three have been recorded) even though these hatch, as in *S. dactylatra*, at five-day intervals. A fledging weight of about 1,750 g was reached in 14–15 weeks and post-fledging feeding lasted for 8 or more weeks.

S. variegata often rears two young; sometimes three and four have been recorded. The fledging weight was not recorded, but the fledging period is probably 12–15 weeks. Post-fledging feeding occurs.

Apart from the obvious importance of the Anchoveta-rich Humbolt Current adjacent to its breeding islands, which favours *S. variegata*, I suggest that these facts can be partly explained by differences in the feeding habits of the species concerned. *S. sula* and *S. dactylatra* forage at considerable distances from the nesting colony and often spend 1–5 days away from the nest. *S. nebouxii* and *S. variegata*, on the other hand, regularly fish close inshore and can complete a successful fishing trip in as little as 30 min from leaving to returning. In possible association with this habit they both, but particularly *S. nebouxii*, show a more pronounced sexual dimorphism in size than do other boobies; males weigh on average only 1,280 g (two-thirds of the average female weight) and apparently tend to specialize in inshore fishing in shallow water, sometimes plunging into less than 2 ft. In the later stages of growth the young are fed solely by the female—probably a unique phenomenon in the *Sulidae*. Because the average duration of fishing trips is shorter in *S. nebouxii* and *S. variegata* the young are less subject to starvation periods in the early, more vulnerable stages. In species where starvation periods are more probable, two or three young would endanger the survival chances of all by dividing the available food. The ability of *S. nebouxii* and *S. variegata* to rear more young than *S. sula* or *S. dactylatra* may thus be directly related to the average duration of their fishing journeys. This may itself result from the tendency of each sulid

species to specialize in particular species of fish. Flying fish *Exocoetus* spp. are commoner in the regurgitations of *S. sula* and *S. dactylatra* than of *S. nebouxii*.

Although *S. leucogaster* seems anomalous, rearing only one chick yet apparently showing a tendency to fish closer inshore than *S. dactylatra*, it is clear from Dorward[5] and others that this species suffers frequent and severe food shortage, which in effect favours the rearing of a single chick.

Although at first sight *S. bassana* seems to support the above relationship by invariably laying a single-egg clutch and also typically fishing at considerable distances from the breeding colony (up to 200 miles or even more), an experiment carried out in 1962 and 1965 on the Bass Rock showed that pairs given one extra young under controlled conditions fed both adequately and so gained a large reproductive advantage over their fellows[6]. Evidence gathered for *S. sula* and *S. dactylatra* showed that rearing young had no effect on the weight of the parents, which suggests that the normal clutch size is unlikely to impose such a strain on the parents that an addition would be highly detrimental. By inference this is likely to be true for *S. bassana*. If clutch size is mainly conditioned by the number of young that the parents can feed adequately[3], *S. bassana*, on the above results, may have been expected to evolve at least a balanced polymorphism with respect to clutch size, the advantages of larger clutches perhaps being partly cancelled by their total failure in certain years. However, the British population of *S. bassana* is at present increasing rapidly and is therefore unstable with respect to its food supply. Also, the gannet's long life (annual adult mortality 6 per cent), deferred maturity and low reproductive rate lead to a slow population turnover and may mean that the one-egg clutch, which was presumably derived from the phylogenetically more primitive polyparous condition, has not yet had time to revert as an adaptation to a favourably changed environment.

The foregoing evidence and hypotheses may partly explain the otherwise puzzling variation in clutch size in a closely related, fish-eating family with basically similar plunge-diving feeding mechanisms.

New Polylithophorous Marine Turbellaria

IN 1930–31 Steinböck[3] described *Nemertoderma bathycola*, a peculiar new turbellarian from deep bottoms near Greenland. He considered the species to be rather primitive. A detailed investigation of a closely related if not identical form from the Scandinavian West Coast was published a few years later by Westblad[7]. In 1949 Westblad described *Meara stichopi* which is parasitic in echinoderms[8]. These forms are characterized mainly by a statocyst carrying two statoliths (occasionally one, three or four[1]; Fig. 4), a neuropilem and very primitive genital apparatus.

During recent investigations of the microfauna of some European coasts[4–6], I found all the previously described Nemertodermatidae including (from deep bottoms off Bergen, Norway) Steinböck's original form. In addition, several undescribed species were encountered mainly from littoral sand. One of these (Figs. 1 and 3), an elongated form characterized by an intense salmon-red longitudinal stripe in the anterior part of the body, was found at Kristineberg on the west coast of Sweden. This species

Figs. 1–8. (1) *Nemertoderma* sp. I from the west coast of Sweden; (2) *Nemertoderma* sp. II from the Adriatic; (3) statocyst of *Nemertoderma* sp. I; (4) statocyst of an aberrant specimen of Westblad's *Nemertoderma*; (5) polylithophorous turbellarian from the west coast of Sweden; (6–8) statocysts of three different specimens of the same as (5)

also occurs in the Adriatic in addition to a more compact species. The latter carries a rather strange broom-like organ of unknown function in the anterior region (Fig. 2). Some new forms, also undoubtedly related to *Nemertoderma*, have been recorded among R. Riedl's collections from the Red Sea[2].

A still more interesting discovery, also in littoral sand from Kristineberg and the Adriatic, is the small elongated turbellarian shown in Figs. 5–8. Although it usually carries only a single statolith, specimens with two, three and even six statoliths have been found. The structure of the statocyst is reminiscent of the statocyst of the nemertean *Ototyphlonemertes*. Furthermore, the animal has a pharynx simplex and a ciliated intestine—characters usually associated with the Catenulida.

The strange characters of this polylithic worm and the great variability of form, colour and glands in *Nemertoderma* lead to problems in the systematics of the new forms. Anatomical study of the material should reveal much additional data and a full account will follow.

Carbohydrate and Amino-acid Composition of the Egg Capsule of the Whelk *Buccinum undatum* L.

THE characteristic monosaccharide sugar spectrum for glycoproteins of animal origin has, until comparatively recently, been regarded as being limited to the two hexosamines, glucosamine and galactosamine; the neutral hexoses, galactose, mannose and occasionally glucose; and the methyl pentose, fucose. One or other of the neuraminic acids is frequently present. The occurrence, in nature, of such monosaccharides as xylose, arabinose and rhamnose has hitherto been regarded as being confined to plants and micro-organisms. The presence, however, of xylose as a key constituent of acid-mucopolysaccharides[1], and also accompanied by ribose, arabinose, galactose, mannose, fucose, glucosamine, galactosamine and sialic

acid in a mucoprotein isolated from autoclaved elastin[2], has recently been reported. In the present investigation, xylose and rhamnose have been found to occur in conjunction with protein in a material of invertebrate origin.

The eggs of the whelk *Buccinum undatum* are laid enclosed in protective capsules which, after the hatching of the eggs, are frequently found cast up by the sea along the shore line. These capsules have a horny sclerotized appearance and are semi-transparent and brownish in colour. For the present investigation, the capsules were broken up into smaller fragments and washed thoroughly with water before examination. The capsular material was insoluble in water, 0·5 M sodium chloride and 4 N sodium hydroxide. On treatment with sodium sulphide solution (5 per cent w/v) the material exhibited swelling but did not go into solution. Treatment with performic acid at 4° C again produced swelling, but the material did not dissolve. Prolonged treatment with 45 per cent w/v aqueous phenol at 90° C failed to bring about extraction of material into either the aqueous or phenol phases. Treatment with 4 per cent w/v trichloroacetic acid at 60° C was also without effect and no carbohydrate could be detected in the extract. The capsules also exhibited considerable resistance to proteolytic digestion. Crystalline pepsin, trypsin, chymotrypsin and bacterial proteinase ('Novo') were almost completely without action and the powerful proteolytic enzyme 'Pronase' (Kaken Chemical Co., Japan) brought about only a low degree of degradation after incubation with the material for 5 days.

Paper chromatography of acid hydrolysates of the material and colorimetric estimation of the aniline-hydrogen-phthalate stained spots, after elution[3], revealed the presence of the monosaccharides, galactose, glucose, mannose, xylose, fucose and rhamnose, in the approximate molar ratios of 2 : 1 : 3 : 1 : 2 : 1 respectively. These sugars account for some 5–6 per cent of the total weight of the material, as estimated by an orcinol reaction[4]. Approximately 2 per cent w/w hexosamine (Elson–Morgan reaction[5]) was present, but this sugar has not been positively identified although its position on an automatic amino-acid analyser (Technicon) chromatogram suggested that it was neither glucosamine nor galactosamine. No sialic acid could be detected in the material[6]. The resistance of the carbohydrate to extraction by the various procedures described above suggests that it might be covalently bound to the protein present.

The amino-acid composition of the capsule material, estimated by automatic amino-acid analyser after acid hydrolysis, is shown in Table 1. Tyrosine and histidine are completely absent. The low concentration of sulphur-containing amino-acids suggests that the insolubility of the material cannot be attributed to disulphide cross-linking. Amino-acids account for 77·5 per cent of the total weight of the capsule material.

Table 1. AMINO-ACID COMPOSITION OF THE EGG CAPSULE MATERIAL
(*a*) Amino-acids in g/100 g substance. (*b*) Amino-acids in μmoles/100 μmoles total amino-acids

Amino-acid	(*a*)	(*b*)
$CysSO_3H$	0·76	0·75
Asp	10·73	13·49
Thr	4·43	6·23
Ser	5·21	7·90
Glu	15·47	17·58
Pro	1·02	1·49
Gly	2·09	4·66
Ala	4·03	7·56
Val	4·72	6·74
Met	0·26	0·27
Ileu	4·89	6·24
Leu	7·24	9·24
Phe	5·64	5·72
Lys	6·03	7·32
Arg	3·97	3·81

Examination of the infra-red spectra of finely powdered samples of the material, in Nujol mull, confirmed the chemical data. The characteristic amide bands of protein were present at 1550, 1660 and 3300 cm^{-1} while the presence of carbohydrate was indicated by bands in the region 950–1,100 cm^{-1} and 3,400 cm^{-1}. Ester sulphate bands were not present.

The mode of secretion of the egg capsule in the marine mollusca has been the subject of some controversy (reviewed in detail by Fretter[7]). Cunningham[8] reported that in *B. undatum* the egg capsule was formed by a secretion from the sole gland of the foot whereas Fretter[7] suggested that the capsule in this mollusc was secreted by the lower part of the female genital duct and kneaded into shape by a temporary groove along the base of the foot. On the basis of histochemical evidence Ankel[9] and Fretter[7] have suggested that the egg capsules of several molluscan genera might be composed of mixtures of protein (probably conchiolin) and 'mucin'. Drew[10] noted a distension, by a granular secretion, of the hypobranchial gland of the female of *Nuculla delphinodonta* (lamellibranchiata) during the breeding season and suggested that the egg capsules were derived from this material. A similar conclusion was drawn by Gersch[11] from the observation that the hypobranchial gland in *Gibbula tumida* (gastropoda) secretes most actively during the breeding season. In view of these observations it is interesting to note that the composition of the egg capsule in *B. undatum* does not resemble the composition of the animal's hypobranchial secretion, which is composed of a polyglucose sulphate-peptide complex loosely linked to a glycoprotein which contains mannose, galactose, glucose, fucose, glucosamine and galactosamine and in which the amino-acid composition is different from that of the capsule protein[12].

A Method of preparing Sperm Whale Teeth for Age Determination

PREVIOUS methods of preparing sperm whale teeth for age determination have generally involved the preparation of ground and polished thin sections[1–3], or half teeth[2,4,5], which have been examined under a dissecting microscope[2–7], a surface projector[2], polarized light[2], or after treatment with histological stains, for example carbol fuchsin or haematoxylin[2–4,6].

Since the preparation of thin sections and the use of histological stains are time-consuming, an attempt has been made to develop a quick, less exacting method of acid etching. At the same time a photographic technique has been established to reduce the eye strain involved in using a magnifying glass or dissecting microscope and to eliminate possible errors in counts and measurements caused by examining small fields rather than the tooth as a whole. This technique has been developed in the course of examining large numbers of sperm whale teeth, as part of an investigation into the sperm whale stocks off Western Australia which is now in progress.

Where haematoxylin staining increases the definition of laminations in the dentine by differential absorption of the dye, our method produces a similar effect by differential etching. Light and dark bands in reflected light appear as a sequence of ridges and grooves respectively which photograph extremely well and allow rapid and repeatable counts and measurements to be made. Fig. 1

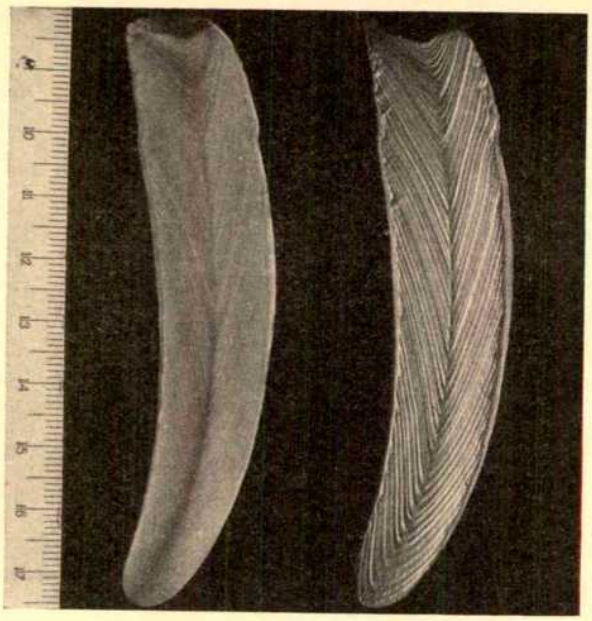

Fig. 1. Longitudinally bisected tooth. Left, before treatment. Right, after treatment. Scale in centimetres

shows a longitudinally bisected tooth from the front of the lower jaw of a female whale 32 ft. in length.

The method of mounting whole teeth for bisection is similar to that described by Sergeant[3]. Using greased 0·25 in. 'Perspex' angle pieces as moulds and laminated five-ply as a base, whole teeth were mounted (with their longitudinal axis horizontal) in Ciba 'Araldite' casting resin (resin *CY*248 and hardeners *HY* 965 and 966). Alternatively Ciba 'Aerosil' can be added to the mixture to obtain a thicker consistency and so reduce the amount of 'Araldite' required. The curing time is about 4 h. Once mounted, teeth were bisected longitudinally with a 12 in. diameter fine-toothed slitting saw. The blade was cooled with a water-soluble oil mixture. When thin sections were required a 'Perspex' plate was glued with 'Araldite' to the cut surface of the mounted half tooth and again cut on the circular saw. With this method, sections about 300-μ thick, which could be ground further with 'Carborundum' abrasive were obtained. Without the 'Perspex' support it was impossible to cut thinner than 500μ as the sections tended to curl and split. The first cut was made slightly short of the centre line to obtain a flat face. The 'Perspex' plate was then glued to the flat face and the next cut made slightly behind the centre line leaving the section attached to the 'Perspex' plate. With teeth which curved in two planes the best cut was sometimes slightly off-centre.

Various concentrations of hydrochloric, nitric and formic acids have been used in an attempt to etch the cut surface of the mounted half tooth. We have found that 5 per cent formic acid in tap water at room temperature (approximately 22° C) for 30 h gives good definition of major zones but little fine detail. The fine dark bands which occur between the major or most prominent dark bands were intensified by an alternative treatment with 20 per cent formic acid at 80° C for 90 min.

It is difficult to determine how etching is proceeding during the process, since the only apparent change is a slight softening and swelling of the dentine due to the effect of acid on collagen, but when the tooth is soaked in water to remove the acid and then allowed to dry at room temperature, the results are quite obvious. The surface instead of being flat is corrugated by a sequence of ridges and grooves. If the corrugation is not sufficiently defined the tooth must be refaced and the whole process repeated.

Because of the monochrome nature of the tooth surface and the reflexion of incident light, difficulty was experienced in counting and measuring the distance between successive ridges. This difficulty was overcome by photographing the etched surface and producing a representation of the almost uniform cream-yellow surface in contrasting tones of grey and black; enlarged prints also facilitated counting and measuring. In order to correct measurements for magnification a scale graduated in millimetres was photographed with each tooth.

A 'Pentax S.L.R.' 35-mm camera body fitted with a 'Takumar' 2·2/55 mm lens and No. 1–9 mm and No. 2–18 mm extension tubes was used together with Ilford 'Pan F' film with a comparatively slow speed (50 A.S.A.) and an extra-fine-grained emulsion.

A satisfactory light source consisted of two 250-W self-reflecting flood lamps (Philips *PF*217*E*/43 S.M.) positioned to give maximum shadow detail and contrast, with two sheets of finely abraded plastic to act as a light-source diffusor.

Models of Living and Fossil Populations of Animals Generated by a Computer

BIOLOGISTS have long been interested in the dynamics of living populations of animals, but for obvious reasons they have been less concerned with the nature of the resulting dead populations. Recently, palaeontologists[1,2] have begun to investigate the dynamics of living populations and their transformation into fossil communities. It is now possible to complement these studies with mathematical models which define the form of a stable living population and its accumulating fossil counterpart. The processes of recruitment, growth, seasonality and mortality have been programmed for an '*IBM* 7094' computer and the output expressed in terms of age-frequency and size-frequency for the living and resulting dead populations.

Although the programme is specifically designed to simulate the population dynamics of certain marine invertebrates, it can be modified for other groups of animals. The number of recruits is specified for each week of a 48-week year, and the kind of recruitment can be varied from the short burst of summer recruitment occurring in Arctic waters to the more even year-round recruitment common in the Tropics. As many as 100,000 animals may be recruited in one year. The recruits are introduced at a size of one unit and are grown in weekly increments to any desired size, up to a maximum of 999 units. The growth increments may be changed at the end of each four-week period and different coefficients of variation in the growth rate may be specified. The maximum life-span of any animal is limited to 10 years. Seasonal cessation of growth, as, for instance, during the winter months or the period of reproduction, may be introduced for any month or any combination of months, reproduction starting at any given age. Mortality rates may be of any kind or degree (we have used constant, increasing and decreasing rates) and are specified in terms of deaths per thousand animals per week. The mortality rate can be increased by a desired factor (maximum × 10) during periods of no growth.

From this programme a series of graphs have been obtained which clarify some of the causes of the different

forms of size-frequency distributions seen in fossil populations. It is possible that the programme may also be of use to biologists who may wish to determine the population dynamics of a known animal under different physical and biological conditions, and for this purpose we have included in the output figures the size-frequency and age-frequency distributions of the living population at the end of each quarter year. One experiment will serve as an example. Ten thousand animals recruited evenly over a four-week period during the month of June are grown at a constant increment of 2 units per week, which is in turn subjected to a coefficient of variation of 2. The death rate is constant at 10 per 1,000 per week, but growth is stopped annually for three months from December to February. Graphs of the input-data are shown in Fig. 1.

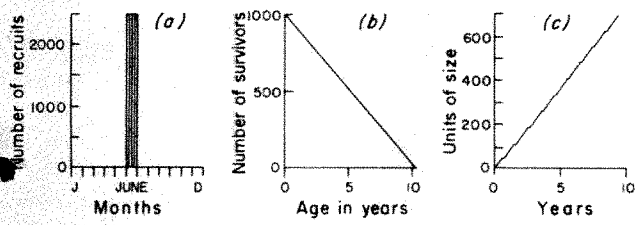

Fig. 1. Graphs of the input data. (*a*) Recruitment of 2,500 animals per week for the four weeks of June. (*b*) Constant death rate of 10 per 1,000 per week. (*c*) Constant growth rate of 2 units per week (growth stopped each year during the three months December–February). This growth rate is subject to a coefficient of variation of 2

The size-frequency distribution of the living population (Fig. 2*a*), as it would be found at the beginning of summer, shows the sharp bursts of yearly recruitment and the effects of mortality. The peaks representing the older recruits gradually merge as a result of the increasing overlap of the size classes. This effect is caused by the coefficient of variation imposed on the growth rate.

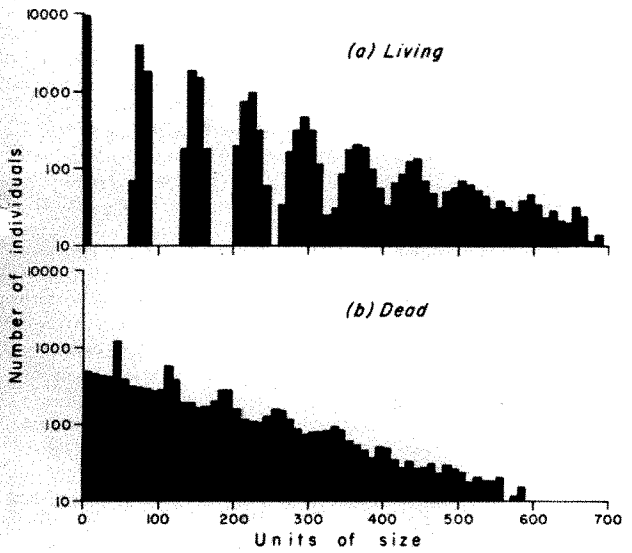

Fig. 2. Size-frequency graphs of (*a*) living and (*b*) resulting dead populations generated by the computer from the information shown in Fig. 1. The irregularity of the largest-size classes in the histograms arises from a 'Monte-Carlo' random-death effect written into the programme. The effect is apparent only with small numbers

The resulting dead population (Fig. 2*b*) also shows a series of peaks, but they represent individuals which died during periods of no growth. These peaks would have been more pronounced had the animals been subjected to increased mortality during the three winter months.

By means of this programme it is possible to generate numerous kinds of living and fossil populations. The number of combinations that may be fed into the computer is obviously very large and we are concerned that our final results should be generally useful and yet compact. If any reader has proposals that may be relevant to the project we would be glad if he would write to one of us.

Access to an '*IBM* 7094' computer without charge has been provided by the Computing Facility of the University of California, Los Angeles.

Influence of Herbicides on Respiration of Young *Pinus* Seedlings

Field and greenhouse studies with a number of herbicides have demonstrated various degrees of growth inhibition of young gymnosperm seedlings. The effects vary greatly with the chemicals and dosage used, species, age of plants, manner of herbicide application, and environmental conditions[1–4]. Considerable work has been carried out on herbicidal influences on metabolism of herbaceous plants, but very little information is available for the responses of woody plants. Triazine herbicides are generally accepted as inhibitors of photosynthesis[5,6]. Metabolism is probably altered by atrazine in red kidney bean[7] and by simazine in barley roots[8]. The extensive literature on 2,4-*D* and 2,4,5-*T* shows that metabolism varies greatly with species, age of plant, and tissues tested[9–12]. Ingle and Rogers[13] have shown that dalapon may reduce phosphate uptake while it does not alter respiration materially. EPTC causes some increase in respiration of mung beans and corn embryos after relatively long exposure to the herbicide[14]. Experiments have now been extended to evaluate the short-time effects of the active and inert ingredients of commercial formulations of several herbicides on respiration of tissues of woody plants. Herbicides and corresponding commercial formulations were obtained as: 2,4-*D* (esteron 10-10), 2,4,5-*T* (esteron 2,4,5-*OS*), 2,4-DEP (falone 44-*E*), EPTC ('Eptam 6 *E*'), CDEC ('Vegadex'), CDAA ('Randox'), simazine (simazine 50 *W*), atrazine (atrazine 50 *W*), ipazine (ipazine 25 *E*), prometone (prometone 25 *E*), dalapon ('Dowpon'), and sesone (sesone).

Respiration of three-day-old *Pinus resinosa* L. seedlings was determined in a Lardy-type Warburg manometer. The centre well of each vessel contained 0·2 ml. of 20 per cent potassium hydroxide and a piece of filter paper. Each vessel contained 1·0 ml. of 0·1 M acetate buffer (*p*H 4·7) and 1·0 ml. of herbicide suspension. Distilled water was substituted for herbicides in controls. Oxygen uptake was determined at 15-min intervals for 150 min.

At 4,000 p.p.m. of active ingredient, commercial formulations of DCPA, simazine, or sesone had no significant effect on the oxygen uptake of the recently emerged seedlings in a short time period. Dalapon at 4,000 p.p.m. showed a slight inhibitory effect. Atrazine depressed respiration, but it did not show an inhibitory effect with *p*H 6·5 phosphate buffer. Similar results were found with commercial formulations of 2,4-*D* and 2,4,5-*T*. Herbicides provided commercially as oil forms, including ipazine, prometone, EPTC, CDEC, CDAA, 2,4-DEP, 2,4-*D* and 2,4,5-*T*, all depressed respiration at *p*H 4·7.

The foregoing experiments suggested the possibility of blocking of oxygen supply or of gas diffusion in the Warburg vessels. Experiments were therefore continued to evaluate separately the influence of active and inert ingredients contained in commercial formulations of herbicides. Mixtures of total inert ingredients were used.

Two separate experiments were conducted on effects of inert ingredients alone. In the first of these the dosages of inert ingredients, at concentrations adjusted for 4,000

p.p.m. of active ingredient, were as follows: 2,4-*D* (1,700 p.p.m.), 2,4,5-*T* (2,100 p.p.m.) EPTC (1,300 p.p.m.), CDAA (4,500 p.p.m.), CDEC (4,600 p.p.m.), ipazine (12,000 p.p.m.), prometone (12,000 p.p.m.), and 2,4-DEP (5,100 p.p.m.). This experiment showed that the inert ingredients of 2,4-*D*, 2,4,5-*T*, EPTC, CDEC, and CDAA had no significant effects on oxygen uptake. In contrast, the inert ingredients contained in formulations of ipazine, prometone, and 2,4-DEP markedly inhibited respiration. As emphasized earlier, however, the concentrations of inert ingredients of ipazine and prometone in this experiment were very high.

In the second experiment the effect of inert ingredients was tested at concentrations of 4,000 p.p.m. of the inert ingredient. Hence the dosages of inert ingredients of ipazine, prometone, and 2,4-DEP were lower than in the first experiment, while those of 2,4-*D*, 2,4,5-*T* and EPTC were higher. At 4,000 p.p.m. the inert ingredients of prometone and 2,4-DEP still depressed respiration, but the inhibition was lowered. EPTC inert ingredients also significantly decreased respiration at 4,000 p.p.m. Inert ingredients of 2,4-*D* also depressed respiration in short-time experiments, while those of 2,4,5-*T* apparently delayed the effect.

These experiments emphasized that metabolism is altered to varying degrees by either active or inert ingredients of commercial herbicide formulations. In summary, respiration was inhibited primarily by the active ingredients of 2,4-*D*, 2,4,5-*T*, EPTC, CDEC, and CDAA and by the inert ingredients of prometone, and ipazine formulations. There may also have been an interactive effect of inert and active ingredients of CDEC and CDAA. Further experiments are needed to evaluate these possible interactions.

Effects of Seed Germination-stimulants on the Witchweed *Striga euphrasioides* (Vahl) Benth.

PARASITISM in some species of *Striga* has often been questioned. According to Williams[1] *S. euphrasioides* is one of the unlikely exceptions to the group of obligate parasitic species. It was, therefore, felt desirable to investigate its seed germination and compare it with similar investigations on certain species of *Striga* and *Orobanche* that are recognized as root parasites.

Stock collections of seeds were made from mature dry capsules of several plants. For each experiment seeds were removed from the stock in two batches and one of them was washed in running tap water for 48 h. Both batches of seeds were surface-sterilized in chlorine water for 10 min and sown on agar nutrient media (*p*H 5·8). A modified White's medium[2] containing 4 per cent sucrose and 1 p.p.m. indole-3-acetic acid served as basal medium. The effects of gibberellic acid and kinetin on germination

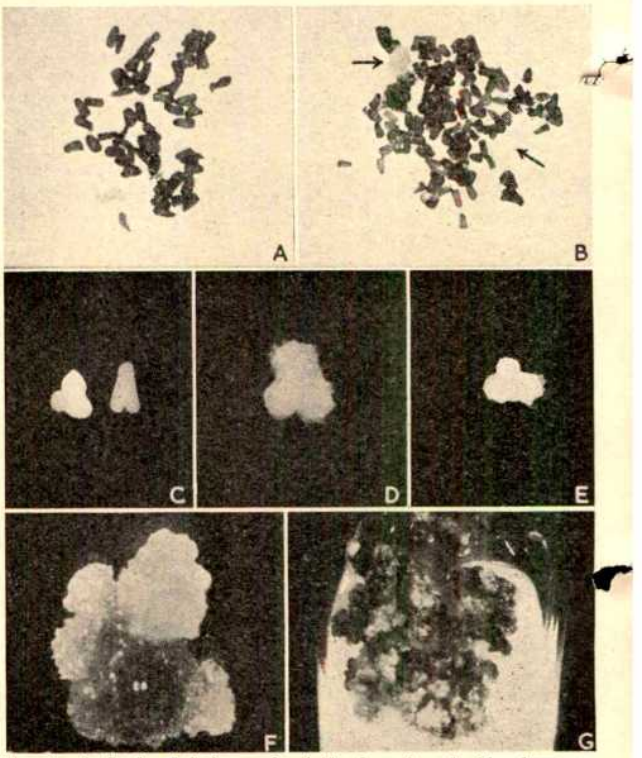

Fig. 1. *A*, Seeds of *Striga euphrasioides* from 3-week-old culture on modified White's medium (WM) (×*c.* 7); *B*, seeds from 2-week-old culture on WM+10 p.p.m. kinetin; two seeds show emergence of embryos (arrow-marked) (×*c.* 5); *C*, embryos removed from 12-day-old culture on WM+10 p.p.m. kinetin (×*c.* 10); *D*, embryo from 24-day-old culture showing proliferation (×*c.* 9); *E*, 5-week-old culture of proliferating embryo on WM supplemented with 10 p.p.m. kinetin (×*c.* 8); *F* and *G*, 5-week-old and 3-month-old cultures of embryo calli on WM supplemented with 400 p.p.m. casein hydrolysate +15 per cent coconut milk (*F*, ×*c.* 8; *G*, ×*c.* 0·9)

were investigated. For each treatment thirty-six cultures were raised in two replicates. Half the number of cultures were grown in diffuse daylight (8–10 ft.-candles) and the other half in the dark.

Unwashed seeds failed to germinate under any experimental conditions. Germination of water-washed seeds was helped by daylight. In subsequent experiments, therefore, only washed seeds were used and incubation in the dark was abandoned.

On the basal medium water-washed seeds lay dormant up to 6 weeks after sowing (Fig. 1*A*). Addition of 5, 10 or 12·5 p.p.m. gibberellic acid to the medium did not help in overcoming dormancy. If, however, the medium was supplemented with 10 p.p.m. kinetin the testa in some of the seeds ruptured within 10–12 days after sowing and the embryos were completely released (Fig. 1*B*). Four days later, root hairs appeared on the elongated radicle. About 18–20 days after sowing the cotyledons formed a callus tissue (Fig. 1*C*, *D*).

With a view to inducing organ formation the proliferated embryos were transferred to media supplemented with one or more of the following substances: kinetin, casein hydrolysate and coconut milk. In treatments with 10 p.p.m. kinetin no organs developed (Fig. 1*E*). Individually as well as in concert, both 400 p.p.m. casein hydrolysate and 15 per cent coconut milk elicited the best growth of the callus tissue. It formed several new mounds along its periphery and grew into a nodulated mass (Fig. 1*F*, *G*). However, shoot-buds did not develop in cultures. A similar response to kinetin treatment was also shown for *Striga asiatica*[3]. Presumably, exogenous factor(s) other than kinetin may be required for shoot morphogenesis. In *Orobanche hederae*, for example, contact with the root of its host, *Hedera helix*, was indispensable for the initiation of shoots[4]. Contrarily, in *Orobanche aegyptiaca* shoot apices differentiated *in vitro* in the absence of any host plants[5].

Briefly, mature dry seeds of *S. euphrasioides* can be caused to germinate by washing in running water (48 h) followed by kinetin treatment. Shoot-buds do not develop in tissue cultures derived from such embryos. Development of shoot-buds may require some factors other than kinetin.

We thank Prof. P. Maheshwari, F.R.S., and Dr. Ian M. Sussex for advice and encouragement. We also thank Mr. S. V. Ramaswamy (Central College, Bangalore) for providing the seeds and Mr. P. S. Rao for discussions.

ENTOMOLOGY

'Paper Factor' as an Inhibitor of the Metamorphosis of the Red Cotton Bug, *Dysdercus koenigii* F.

MATERIALS composed of American paper-pulp have been shown to contain an extractable, heat-stable lipid which exhibits high juvenile hormone activity when topically applied or otherwise brought into contact with the European bug, *Pyrrhocoris apterus* L. (Heteroptera; Pyrrhocoridae[1,2]). The active principle is synthesized by certain species of pulp trees—more particularly, the American balsam fir (*Abies balsamea*). The 'paper factor' (PF) proves to be an extremely potent analogue of the juvenile hormone of *Pyrrhocoris apterus*[3]. Yet, so far, it has proved completely inactive when tested on other laboratory insects including two other species of Heteroptera—*Oncopeltus fasciatus* (Lygaeidae) and *Rhodnius prolixus* (Reduviidae)[1,2].

Pyrrhocoris apterus is a benign species which feeds by its sucking mouthparts on lime (linden) seeds. However, the family Pyrrhocoridae includes some of the world's most troublesome insect pests—notably the 'red cotton bugs' (*Dysdercus* sp.) indigenous to India, Africa, and Australia. Sláma and Williams (p. 414, ref. 1) have considered the possibility that PF "may be effective in the selective destruction of at least certain of these pests, as well as any other insects which show the same hormonal sensitivities as *Pyrrhocoris apterus*".

The purpose of the present communication is to report that the 'red cotton bug', *Dysdercus koenigii*—a considerable pest in India and North Africa—is sensitive to PF.

The experiments were performed on an extract of PF prepared at Harvard University from 250 paper towels ('Scott' Brand 150). The towels were packed into a large glass column (11 cm outside diameter × 115 cm long), soaked overnight in absolute methanol, and then perfused with a total of 5 l. of solvent. The methanolic extract was reduced to dryness to obtain 7·4 g of a viscous sludge from which PF was extracted with 4 × 50 ml. portions of petroleum ether (b.p. 35°–60° C). The latter was filtered and the solvent evaporated to obtain 2·9 g of viscous greenish-yellow oil. Without further purification, this crude preparation of PF was used in the present study.

With the support and encouragement of Prof. B. R. Seshachar, Head of the Zoology Department at the University of Delhi, PF was tested on the same laboratory culture of *Dysdercus koenigii* which has been subjected to detailed investigations in recent years[4]. Individual larvae were isolated within 30 min after moulting to the fifth instar. The insects were provided with water-soaked swabs of cotton wool, but were otherwise starved during the first 28–36 h at 27°–28° C. A measured droplet of an acetone solution of PF was then applied to the mid-dorsal region of each of 10 individuals in each test group. Alternatively, groups of 10 individuals were placed in glass containers in the presence of a 9-cm disk of Whatman No. 1 filter paper impregnated with a known amount of PF. After these manoeuvres, each group was provided with cottonseed and water to provoke development[4].

Table 1. EFFECTS OF PAPER FACTOR ON FIFTH-INSTAR *Dysdercus* LARVAE

PF extract	Percentage of PF-treated individuals showing different effects			
	Imaginal inhibition			Incomplete ecdysis
	Adults	Adultoids	Sixth instar larvae	
Topical application of:				
0·01 μg	30	70	0	0
0·05	20	80	0	0
0·1	0	100	0	0
0·5	0	50	50	0
1·0	0	30	30	40
4·0	0	0	20	80
Contact with paper* impregnated with:				
0·1 mg	0	80	10	10
1·0	0	60	20	20
2·0	0	20	20	60

* A 9 cm disk of Whatman No. 1 filter paper.

The results, summarized in Table 1, show that the PF inhibited the metamorphosis of the insect in two ways: (i) by inhibiting the development of imaginal characters in the sixth instar individuals into which the PF-treated fifth instar larvae moulted, and (ii) by preventing complete extrication of the PF-treated fifth instar larvae from the old larval cuticle during the ecdysis. The degree of imaginal inhibition and failure in the extrication of the moulting individuals was a function of the dose of PF, and a topical application of 4 μg at the outset of the fifth instar caused complete suppression of metamorphosis. Most of the treated larvae failed to extricate themselves from the old cuticle during moulting and died in the process. A small number of individuals, however, moulted into a supernumerary sixth larval instar showing complete inhibition of the imaginal characters.

When the topical application was decreased below 4 μg (Table 1), the number of individuals showing incomplete ecdysis decreased and a progressively larger number of larvae moulted into apparently normal adults, save for a failure of the wings to attain adult size and form. Many of these 'adultoid' individuals lived for weeks without further moulting, and some were capable of mating and laying fertile eggs.

When the topical application was reduced to 0·05 or 0·01 μg, a few larvae were able to transform into normal adults. But even at such low doses, the majority of individuals moulted into 'adultoids' which showed partial inhibition of wing development—a finding which indicates that the wings are far more susceptible to inhibition by PF than are other imaginal characters.

As recorded in the lower part of Table 1, the effects of the topical applications were duplicated when three groups of ten larvae were reared throughout the fifth instar in contact with PF-impregnated filter paper; the experiment was repeated five times with substantially the same results.

The quantitative aspects of the present investigation indicate that low doses of PF have less extensive and less lethal effects on *Dysdercus* than on *Pyrrhocoris apterus*[2]. The difference in the effects between the two species was, however, far less evident at higher dose-levels. Thus, in the case of *Pyrrhocoris*, metamorphosis and sexual maturation were completely blocked by the topical application of 1 μg[2]. This same result was achieved in the present study by 4 μg of a PF extract that was one-third as active as that used in the earlier study.

The ability of PF to block the metamorphosis and selectively to kill an economically important pest such as *Dysdercus koenigii* is of considerable interest. Though the hormonally active principle is known to be present in only trace amounts in these crude extracts[2], the

'starting material' is available on an essentially unlimited scale in the form of American newspapers and other paper products. More highly purified preparations of PF promise to be effective in the selective control of *Dysdercus koenigii* and, presumably, of other economically important Pyrrhocoridae. This proposition is at present being tested in Delhi.

MICROBIOLOGY

Production of Yeast Cell-wall Lytic Enzymes on a Semi-defined Medium by a *Streptomyces*

THOUGH a great many results on the lysis of bacteria have appeared, little information has yet been presented concerning the organisms which have lytic activity toward the cell walls of the fungal mycelium. Some of these investigations demonstrated the production of microbial enzymes capable of lysing fungi. A knowledge of the action of enzymes on fungal mycelium may, perhaps, give some idea of the composition of some of the cell wall structures.

During the research in our laboratory for the micro-organism causing the lysis of fungal cells, a number of actinomycetes were found to have strong lytic activity toward the cell walls of some fungi[1–3]. Some information was later presented in relation with the formation of the lytic enzymes[4,5] and the mechanism of the action of one of the strepzymes on the cell walls[6].

A wide variety of culture media and growth conditions have been used by us in preliminary investigations in an attempt to define reproducible conditions for the production of the lytic enzymes. Considerable difficulty has been experienced in obtaining consistently good yields of active filtrates, and this problem has apparently been encountered by other investigators. In our previous experiments[1–3], and in those of other workers[7–9], the isolated strains of *Streptomyces* and *Micromonospora* were inoculated in media in which different kinds of living or dead fungal cells were present. The cells employed in these studies were in the form of pressed baker's yeast, that is, dried brewery yeasts or laboratory grown *C. utilis* cells. Normally, the appropriate amount of cells were added to a salt solution and the complete medium was autoclaved before inoculation with the lytic actinomycetes. Cultures were grown either in the laboratory in shaken flasks or in a pilot plant in stirred and aerated tanks: in either case the cultures were grown at 28° for 6–8 days. In most cases after this incubation period the cells could not be detected microscopically. The organism caused the fungal cells to dissolve completely. It was assumed, therefore, and later demonstrated, that the culture fluid contained lytic factors (enzymes). After it was centrifuged or filtered to remove all the cells, the clear solution of the supernatant was used as the crude enzyme preparation.

Various attempts made in our laboratory to produce the lytic enzymes by growing the lytic organism on defined synthetic or semisynthetic media failed. Other workers stated clearly that yeast cell wall lytic enzymes were only formed when the culture medium contained as a substrate the fungal cells[10]. The organisms often grew well on the least complex media, but produced very small amounts of lytic enzymes or even none at all.

The procedure of adding cells of yeast or moulds to the growth media has certain advantages for the consistent production of lytic material and was used in part of the present work. However, in obtaining material for the purification of the enzymes, it was found that the use of complex media caused variation in the formation of the various enzymes usually present in the lytic preparation, and this interfered with many of the investigations under way in our laboratory. Furthermore, any alterations in the type of fungi (brewery or pressed yeast) or in the type of growth of the cells produced in the laboratory used as the substrate for growth and production of the enzyme often led to significant variations in the activity of the crude preparations. These media often gave rise to variable and unpredictable results and a more defined medium was studied in an attempt to obtain consistent results.

The disadvantages of the fungal cell containing media have now been partially eliminated. As a result of some investigations of the chitinase activity of various *Streptomyces* we found that the lytic activity on the cell walls of various yeasts was high, using filtrates of the growth medium of some *Streptomyces violaceus MR*. This is one of the lytic organisms used in our preliminary studies[8] and is characterized by the production of a potent extracellular enzyme system (showing chitinase and proteolytic activity) which can dissolve a variety of organisms; it was grown on a medium of the following composition: chitin (Koch-Light), 5 g; yeast extract (Difco), 0·5 g; sodium nitrate, 1 g; potassium orthophosphate, 2 g; $MgSO_4 \cdot 7H_2O$, 1 g; sodium chloride 1 g; and distilled water, 1 l. Inoculation was made with vegetative cells of the organism previously grown on slants of a medium containing glucose-yeast-malt extracts. The *Streptomyces violaceus* was grown aerobically in Erlenmeyer flasks agitated by a shaking machine at 28° C. 6–8 days after inoculation, the culture fluid was separated centrifugally from the cellular material. The supernatants were collected and the crude lytic enzyme preparation obtained after precipitation with 70 per cent ammonium sulphate and redissolution in one-twentieth of the volume of distilled water. The activity of the best preparations obtained with this medium was comparable to that obtained with more complex media containing fungal cells. This preparation was very stable when stored at −20° C, and able to digest cell walls of a number of yeasts, such as *Saccharomyces fragilis* (Fig. 1), *Saccharomyces cerevisiae* and *Candida utilis* with the formation of protoplasts under stabilized conditions. Preliminary experiments have shown that it is possible to obtain about 100 per cent protoplast formation with the yeast tested in less than 45 min using the conditions previously described[11].

An investigation is now in progress in our laboratory on the method of separation of some of the more important enzymes involved in the digestion of the fungal cell walls, to enable us to make further studies of their specificities.

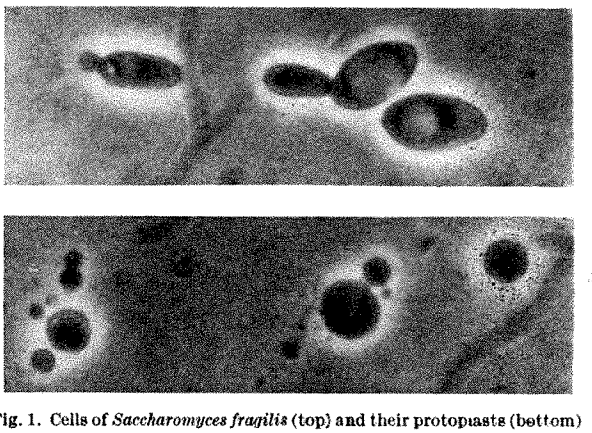

Fig. 1. Cells of *Saccharomyces fragilis* (top) and their protoplasts (bottom)

Results on the enzymatic properties of these will be presented elsewhere.

VIROLOGY

Neoplasms induced by Rous Sarcoma Virus in New World Monkeys

AT one time, tumour viruses were believed to be species-specific, but tumour induction *in vivo* and cell transformation *in vitro* have made this concept inapplicable to experimental situations. Rous sarcoma virus will not only induce tumours in the original host and other avian species but will also cause *in vivo* and *in vitro* malignant transformation of mammalian cells. The induction of sarcomata in Old World non-human primates by Rous sarcoma virus preparations of the Carr-Zilber and Schmidt-Ruppin strains has been reported by four research groups[1–5]. In most of the *in vivo* experiments with primates 'tissue minces' from Rous sarcoma virus-induced chicken sarcomata were used for inoculation and the published reports gave no clear indication that the tumours were truly invasive and/or metastasizing.

Inoculation of partially purified Rous sarcoma virus of the Schmidt-Ruppin strain (RSV-SR) induced invasive metastasizing immature sarcomata in all of five new-born marmosets, *Saguinus* sp., inoculated during the first 24 h of life. Each animal was injected subcutaneously and intramuscularly with 0·25 ml. of a cell-free inoculum of RSV-SR which had been prepared from material supplied by Dr. E. H. Bernstein of University Laboratories, Inc., Highland Park, New Jersey. University Laboratories used the following method for preparation of their RSV-SR: a 10 per cent extract of chicken tumours induced by RSV-SR was prepared in 0·15 M potassium citrate and 100 mg per cent hyaluronidase by intermittent homogenization for 1 h. The homogenate was centrifuged at 7,600 r.p.m. for 15 min and the supernatant, sealed in ampoules, was shipped to this laboratory in dry ice. Material was either used directly from the ampoules or was further concentrated. For concentration the contents of several ampoules were thawed, pooled, and centrifuged at 30,000 r.p.m. for 30 min; the supernatant fluid was discarded. The sediment was ground together with 'Alundum' with a pestle and mortar and was resuspended in a twentieth or a fifth of the original volume of Hanks's balanced salt solution containing 5 per cent foetal calf serum. The suspensions were centrifuged at 2,000 r.p.m. for 20 min and the top two-thirds of the supernatant was frozen at −65° C. The '20×' and '5×' concentrates were used for inoculation within 1 month of preparation.

The results of inoculation of new-born marmosets are given in Table 1. Tumours developed in all animals within 20–90 days after inoculation of virus, and all died from their malignant disease between 35 and 117 days. Live tumour cells from one of the animals were inoculated into its twin when they were 39 days old, and within 2 weeks this animal developed a large sarcoma at the inoculation site.

Table 1. INOCULATION OF NEW-BORN MARMOSETS WITH PARTIALLY PURIFIED ROUS SARCOMA VIRUS

No. of animals inoculated	RSV-SR inoculum*	Days after inoculation: Tumour first observed	Death
1	Unconcentrated	90	117
1	5×	30	65
3	20×	20,24,25	35,39,53
1	5×10^6 live tumour cells	7	14

* See text for explanation.

All tumours were immature sarcomata showing positive fat staining of most cells, but no clear differentiation between a liposarcoma and an embryonal rhabdomyosarcoma could be made. The tumours infiltrated the surrounding tissues without a clear demarcation and many tumour cell emboli were seen in the lungs. Definite histological evidence was found of tumour invasion of the lung parenchyma from the tumour cell emboli. No other metastases have so far been found. Preliminary electron microscopic studies have not revealed any virus particles in the tumour cells.

Tumour tissue, kidney and normal muscle tissues obtained at autopsy were grown in cell culture; the original outgrowth and cells after several tissue culture passages of both tumours and normal tissues were karyotyped. The chromosomes of all tissues could easily be identified as marmoset chromosomes. A number of inconsistent chromosomal aberrations were observed in sixty-six tumour cells so far investigated, but a specific marker has not appeared. The detailed data of these experiments, the results of recent investigations on the antigenic analysis of the tumour cells, and the presence or absence of virus in the tumours and other tissues will be published later in a more extensive report.

This work provides a laboratory model of virus-induced tumours in primates. The tumours were produced by cell-free virus preparations; they were truly invasive and metastasizing and they ultimately killed the animals. One tumour was successfully transplanted by transfer of living cells to a twin. Similar experiments can be performed by any laboratory equipped with standard animal-house facilities, as maintenance of marmosets does not require either specialized facilities or generous space. The animals are well characterized, as wild-caught marmosets have been maintained and studied both in this and other laboratories for the past few years. Marmosets are available in large numbers and at reasonable cost; they are sufficiently small that large numbers can be kept in a limited space, and at the same time they are large enough for the serial bleedings and other surgical procedures to be performed. The animals breed in captivity and a colony of pairs maintained specifically for this purpose provides a regular supply of new-born animals. The baby marmosets can be handled within a few hours of birth and can be either returned to the parents for rearing or hand-reared.

Plaque Formation with a Phlebotomus (Sandfly) Fever Virus in Baby Hamster Kidney (*BHK* 21) Cells

BABY hamster kidney cell line *BHK* 21, clone 13 (ref. 1), has been used for a plaque assay method for phlebotomus fever viruses. The technique used was a modification of the method described by Russell[2] for herpes virus.

Cells were grown in Eagle's medium containing double amounts of amino-acids and vitamins, 10 per cent tryptose phosphate broth (Difco) and 10 per cent unheated calf serum (ETC). When a confluent sheet of cells was formed, they were dispersed with equal volumes of 0·02 per cent versene solution and 0·25 per cent trypsin (Difco). The cells were suspended in ETC medium; washing was not necessary. They were then counted and the cell suspension adjusted to contain 10^7 cells per ml. The cells can be used immediately or stored at 4° C for up to a week.

Aliquots of 2×10^6 cells in 0·2 ml. ETC were placed in bijou bottles and 0·2 ml. of virus dilution were added. The cell-virus suspension was then shaken gently at 37° C for 30 min. After shaking, 4·5 ml. of ETC were added to each bottle, the contents mixed and poured into 60 mm glass Petri dishes, which were then incubated in a humidified atmosphere containing 5 per cent carbon dioxide at 37° C.

After 5 h of incubation, the ETC medium was removed and the cells were overlaid with 8 ml. of Eagle's medium containing the sodium salt of carboxymethyl cellulose (CMC) in a final concentration of 0·75 per cent and 10 per cent unheated calf serum (ECMC). The overlay medium (ECMC) was made up as follows: 1·3 times normal strength Eagle's medium, 75 ml.; calf serum, 10 ml.; 5 per cent CMC in distilled water, 15 ml. It was of advantage to dissolve 750 mg of CMC in 15 ml. of distilled water in a 150 ml. bottle and autoclave. The Eagle's medium and calf serum were then added. Thorough shaking was necessary to gain a uniform ECMC solution. It was possible afterwards to use a pipette for distributing the overlay medium.

After the addition of the ECMC overlay, the Petri dishes were incubated as before, care being taken not to move them during incubation. 4–5 days later, the ECMC was removed and the cell sheet was either fixed in methanol for 5 min and stained with 1 : 10 Giemsa for 30 min or stained unfixed with 0·1 per cent crystal violet. The stain was then poured off and the plates were gently washed in a bowl of tap water, left to dry and the plaques were counted.

The phlebotomus fever viruses used in this study were:

Sicilian type: 46th mouse passage
Naples type[3,4]: 58th mouse passage

The Sicilian type of virus produced plaques which were irregular in outline and of 1–2 mm in diameter after 4 days of incubation (Fig. 1). The average titre was 7×1[illegible] P.F.U./ml. as compared with $7{\cdot}4 \times 10^8$ LD_{50} in 2–4-day-old suckling mice inoculated intracerebrally. In a plaque reduction test, 1 ml. of a Sicilian virus dilution containing 300 P.F.U. was mixed with 1 ml. of fourfold dilutions of immune sera prepared in mice against the homologous virus and the Naples virus. The serum–virus mixture was incubated at 37° C for 1 h and then 1 ml. of the mixture was inoculated into *BHK* 21 cells, as already described; two plates were used per serum dilution. The homologous serum gave a 50 per cent plaque reduction titre of 1 : 180, whereas no neutralization was obtained with the Naples serum.

Attempts to produce plaques with the Naples type have so far proved unsuccessful.

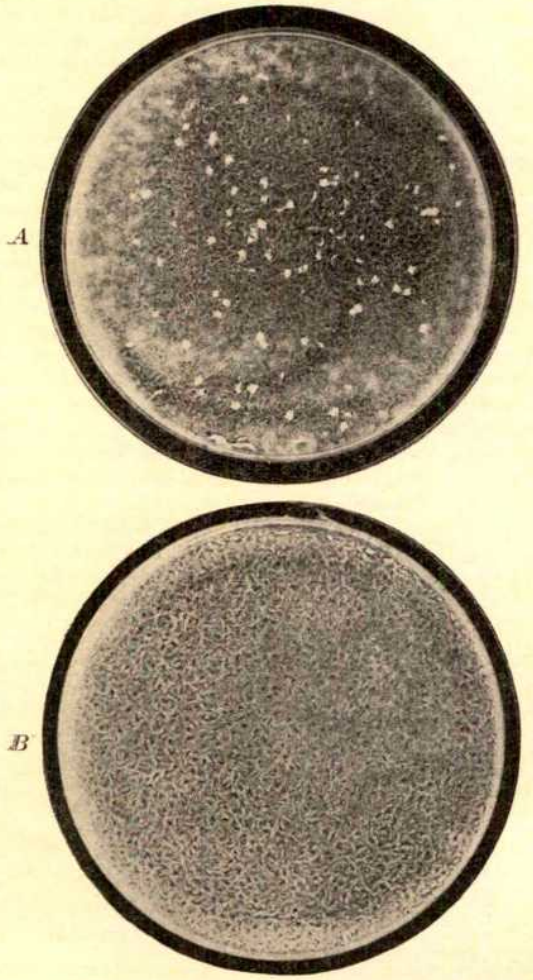

Fig. 1. *A*, Type of plaques produced by Sicilian type of phlebotomus fever virus in *BHK* 21, 10^{-5} dilution of virus, 4 days after inoculation. *B*, Control, cells treated with diluent only

CYTOLOGY

Cytoplasmic Localization of Phytohaemagglutinin in Peripheral White Cells

SALINE extract of the red kidney bean (*Phaseolus vulgaris*) possesses a factor which increases the rate of cell division in cultures of peripheral white cells[1], and a factor which agglutinates red cells[2]. Reciprocal absorption shows that the two factors are separate and the mitogenic moiety has been further characterized as a mixture of proteins, the predominant one having a molecular weight of about 128,000 (ref. 3). The mitogenic extract therefore lends itself to labelling with fluorescent compounds. Such a marker would be valuable in tracing the mode of action of the mitogen(s) since it is still not known whether the leucocyte agglutination, apparently inseparable from the mitogenic activity[4], is also necessary to the mitogenic activity, nor whether the substance acts extra- or intra-cellularly, or both.

To pursue this question a commercial preparation of phytohaemagglutinin (PHA—Burroughs Wellcome Lot No. K4971) was labelled with fluorescein isothiocyanate[5] (FITC—B.B.L. Batch No. 401670) at a fluor-protein ratio of 1 : 40 and cleared of unconjugated FITC by passing it through a 'Sephadex *G*-25' column. The conjugate was

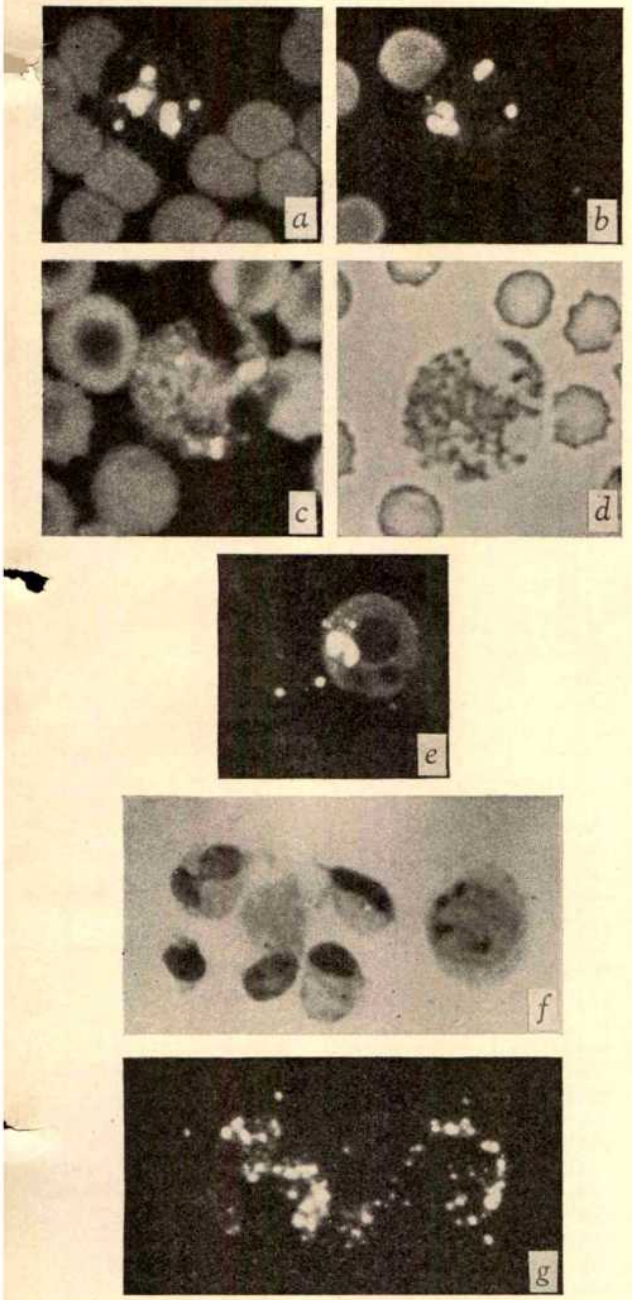

Fig. 1. Fluorescein conjugated phytohaemagglutinin in (*a*) and (*b*) polymorphonuclear neutrophils; (*c*) an eosinophil before and (*d*) after staining to show displacement of the eosinophilic granules by the fluorescent inclusions; (*e*) an early transformed cell; (*f*) and (*g*) a clump of transformed cells (× 440)

added to whole-blood cultures before and after absorption with red cells[6]. Control cultures contained unlabelled PHA, FITC alone and the separate reagents added simultaneously. Those cultures showing mitotic activity with the lowest necessary concentration of conjugate were investigated. It was possible to detect conjugate inside the white cells and, in cultures using unabsorbed PHA, coating the red cells within 15 min after inoculation. At this early stage, white cells of all types (Fig. 1*a–d*) contained fluorescing conjugate. At later stages (Fig. 1*e–g*) PHA could be seen in the characteristic blast-like cell of PHA-stimulated cultures—coarse chromatin with prominent nucleoli and basophilic vacuolated cytoplasm. At all stages fluorescence was confined to the cytoplasm and took the form of spherical inclusions situated apparently at random throughout the cytoplasm, and not associated with nuclear structures or the cytoplasmic membrane. The appearance of the white cell inclusions was the same whether or not red cell-absorbed PHA was used.

It appears, therefore, that the haemagglutinating and mitogenic factors are indeed separate, but that both contain molecules capable of conjugation with FITC. It also appears that the mitogenic fraction is ingested, not only by the small mononuclear cells presumed to be the precursors of PHA cells[7–9], but also by granulocytes. Without isolated or pure populations of the various cell types it is not possible to say whether the presence of the conjugate is followed by morphological changes in all cells; nor whether the well-recognized clumping of white cells in PHA-stimulated cultures is associated with an exchange of materials essential to the blastoid transformation and mitosis[10]. It was noteworthy that the characteristically persistent eosinophils were usually to be found at the later stages singly situated but surrounded by transformed cells. The similarity between immunological reactiveness of round cells[11] and PHA transformation, and the role of eosinophils in the earliest stages of the *in vivo* antigen–antibody response[12], suggest that heterogeneous cellular interaction may form a component of transformation in PHA-stimulated cultures.

The heterogeneous cellular distribution may also simply be a reflexion of the heterogeneity of a population of conjugated proteins not all of which are mitogenic and may be explained as the result of non-specific pinocytosis with no implications as to the necessary future development of the ingesting cell.

Finally, it is noteworthy that a phenomenon most remarkably associated with leucoagglutination and with an increase in mitotic activity should be associated with an initiator exclusively intracytoplasmic in its localization. This suggests an indirect effect of PHA. Increase in the number and size of lysosomes and histochemical changes indicating an increase in anaerobic glycolysis[7] may be the result of an uncoupling of synthetic metabolic pathways similar to those used in immunological and phagocytic[13] functions of white cells which culminate in γ-globulin production and cell enlargement. The passage of a threshold in size and metabolic activity may then lead to mitosis and division.

These possibilities can now be explored further by use of the labelled PHA, and later experiments will investigate the specificity of the reaction using antisera to PHA, the behaviour of agglutinins and mitogens from other sources and the behaviour of the different cell types in isolation and in various combinations before and after treatment with limiting amounts of PHA.

GENETICS

Synthesis of Ribonucleic Acid by Human Chromosomes and a Possible Mechanism of its Repression

IT has recently been suggested that a genetic basis for cellular differentiation in multicellular organisms might be reflected in the distribution pattern of inactivated deoxyribonucleic acid (DNA) in the chromosomes[1]. Inactivated DNA is characterized by three features, namely, heterochromatinization, late replication at the time of doubling, and inactivity of synthesis of ribonucleic acid (RNA). To substantiate this hypothesis, we are now studying the pattern of DNA and RNA synthesis of chromosomes in human cells of various origin by means of autoradiography. In studying the synthesis of RNA by human chromosomes, we encountered a dilemma. The chromosomes are identifiable only in metaphase as are most somatic cell chromosomes in multicellular organisms. During metaphase and anaphase, however, synthesis of RNA completely ceases in all the cells of multicellular organisms so far investigated[2-7]. It is not, therefore, feasible at present to study the pulse labelling pattern of RNA on metazoan chromosomes except polytenic ones. Previous investigators[6,8] have studied RNA synthesis mainly in meiotic chromosomes as these chromosomes remain visible throughout the meiotic cycle. However, they are not chromosomes of differentiated somatic cells in which we are interested. Hsu reported synthesis of RNA in intermitotic nuclei of mammalian somatic cells[9], in which the Barr body was shown to be inactive in the synthesis of RNA. In general, however, the chromosome is not identifiable as a distinct morphological unit in the intermitotic phase of metazoan cells. To overcome this dilemma, we decided to label the cell just before division and examine the distribution of the label at metaphase which immediately follows the labelling. The interval between the labelling and the examination was chosen so as to be sufficiently short to prevent secondary diffusion of the labelled RNA from the site of the synthesis. If the labelled RNA is not released immediately after its synthesis and does persist during mitosis, it would be expected that the label incorporated at late *G2* and prophase would also remain detectable on the metaphase chromosomes.

Leucocytes, from peripheral blood of a normal woman, were collected after addition of phytohaemagglutinin (Difco). They were cultured for 72 h in a medium (tissue culture medium 199, Difco), with penicillin and streptomycin, and squash preparations were made at the termination of the culture. Uridine-^{3}H or thymidine-^{3}H was introduced (0·5 μc./ml.) 3 or 6 h, respectively, before the cells were fixed. All the cultures were subjected to colchicine treatment (10^{-6} M) during the last 3 h. The specimens were stained with acetic acid-orcein, washed for 10–12 h in running water and autoradiographed by dipping them into Kodak '*NTB*-3' emulsion.

In autoradiographs labelled with thymidine-^{3}H, we found metaphase chromosomes with heavy labelling on one of the *X*-chromosomes, identifying this as the late replicating *X*-chromosome. In contrast, however, in metaphase chromosomes labelled with uridine-^{3}H, the *X*-chromosome was free from radioactivity (Fig. 1) while all the other chromosomes were detectably labelled. Structures other than chromosomes showed little labelling. This finding indicates that (1) RNA that is synthesized on the chromosome just before division is not released from the site of synthesis during mitosis, and (2) one of the *X*-chromosomes is inactive in RNA synthesis. The results not only demonstrate the feasibility of this method for investigating the distribution of genetically active and inactive loci in metazoan chromosomes, but also suggest a possible mechanism of genetic repression. In the autoradiographs, it was shown that RNA attaches

Fig. 1. Autoradiograph of human chromosome, 3 h after introduction of uridine-^{3}H. The cells, derived from the peripheral blood of a woman, were cultured for 72 h. The arrow indicates the genetically inactive *X*-chromosome

firmly to the metaphase chromosomes that are completely repressed in RNA synthesis. Since the turnover rate of RNA synthesis on the chromosome should be regulated both by the rate of RNA synthesis and the rate of removal of the products from the template, failure or suppression of removal of RNA from the template DNA should be followed by repression of RNA synthesis. It is possible to test experimentally the presence of this mechanism in differential inactivation of genes, by introducing a labelled precursor of RNA just before or at the time of gene inactivation and examining at later stages the persistence of the label at the inactivated loci of the chromosomes. If RNA masks the template DNA at the inactivated loci, it should be detectable by means of autoradiography. Experiments are now in progress with the view of substantiating this hypothesis.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, April 25

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "Breakdown of Large Air-gaps and Effect of Voltage Wave Shape" opened by Dr. F. D. A. Boylett and Dr. D. F. Oakeshott.

PLASTICS INSTITUTE, LONDON SECTION, REINFORCED PLASTICS SUB-GROUP (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. P. Lynch: "The Advances of Hot Press Moulding in the U.K.".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Prof. S. Thorarinsson: "An Island is Born".

Tuesday, April 26

ROYAL SOCIETY OF ARTS, COMMONWEALTH SECTION (at John Adam Street, Adelphi, London, W.C.2), at 5.15 p.m.—Prof. J. A. Lauwerys and Dr. Elsie C. Graham: "Basic English as an International Language With Special Reference to Scientific Study in the Commonwealth".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "Problems in the Design and Installation of Surge-Proof Transistorized Control Equipment" opened by Mr. R. F. Eade, Mr. D. Harrison and Dr B. E. Noltingk.

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in Committee Room 11, House of Commons, London, S.W.1), at 5 30 p.m.—Discussion on "Fisheries Research" initiated by Sir Frederick Brundrett, K.C.B., K.B.E., and Dr. H. A. Cole.

SOCIETY FOR ANALYTICAL CHEMISTRY (in the Meeting Room of the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Prof. R. E. Wainerdi (U.S.A.): "Automated Systems for Extra-Terrestrial Nuclear Activation Analysis".

Wednesday, April 27

BIOMETRIC SOCIETY (at the Wellcome Building, Euston Road, London, N.W.1), at 2.30 p.m.—Prof William F Taylor "On the Estimation of the Risk of Foetal Death"; Dr R. M Cormack: "Tests for Equal Catchability".

POLAROGRAPHIC SOCIETY (in the Metallurgy Lecture Theatre, Royal School of Mines, Prince Consort Road, London, S.W.7), at 2 45 p.m.—Dr. M. E. Peover: "Polarographic Characteristics of Organic Compounds in Organic Solvents". 4.45 p.m.—Eleventh Annual General Meeting.

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Annual General Meeting.

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Annual General Meeting, followed by Dr. G. D. Robinson: "Another Look at Some Problems of the Air-Sea Interface" (Presidential Address).

INSTITUTION OF ELECTRICAL ENGINEERS (joint meeting with the Railway Engineering Group of the Institution of Mechanical Engineers, at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5 30 p.m.—Mr. G. Gilbert and Mr. H E. H. Davies, "Pantograph Motion on a Nearly-Uniform Railway Overhead Line"; Mr. T. A. Willetts and Mr. D. R. Edwards: "Dynamic Model Studies of Overhead Equipment for Electrical Traction (Part 1—Simple Catenary Equipment)"; Mr. T. A. Willetts, Mr. C. E. Allen and Mr. D. R. Edwards: "Dynamic Model Studies of Overhead Equipment for Electric Railway Traction (Part 2—Sagged Simple Catenary Equipment)".

CHALLENGER SOCIETY (joint meeting with the Glaciological Society, at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 5.45 p.m.—Dr. Wilford Weeks "Toward an Understanding of the Physical Properties of Sea Ice".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Two papers on "The U.K. 3 Satellite". Mr. W. M. Lovell: "Data Handling and Telemetry Equipment"; Mr. F. P. Campbell: "The Satellite and its Ground Checkout Equipment".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E.–I.E.E. MEDICAL ELECTRONICS GROUP (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Discussion on "Physiological and Psychological Hazards of High Intensity Sound and Light" opened by Mr. B. Shackel.

Thursday, April 28

BOROUGH POLYTECHNIC (at Borough Road, London, S.E.1), at 10 a.m.—Symposium on "Friction and Wear—Can We Afford It?"

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. A. R Ubbelohde, F.R.S.: "Melting and Freezing of Metals"; Dame Kathleen Lonsdale, F.R.S., Mr. E Nave and Mr. J. F. Stephens: "X-ray Diffraction and Mass Spectrometer Studies of a Chemical Reaction in a Single Crystal".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.15 p.m.—Dr. M. Zelen: "Applications of Exponential Models to Problems in Cancer Research".

INSTITUTE OF PETROLEUM, EXPLORATION AND PRODUCTION GROUP (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. Charles Weinaug (U.S.A.): "The Role of Viscous Fingering in Miscible Fluid Displacement".

INSTITUTION OF CIVIL ENGINEERS, HYDROLOGICAL GROUP (at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Aquifer Field Assessment" introduced by Dr. J. Ineson.

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Sir Harrie Massey, F.R.S.: "Scientific Research in Space" (Fifty-seventh Kelvin Lecture).

Friday, April 29

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 9 15 a.m.—Conference on "Tyres".

UNIVERSITY OF LONDON (at the Royal Veterinary College, Royal College Street, London, N.W.1), at 5 p.m.—Prof. Sir William Weipers: "Lethal Factors in Experimental Intestinal Obstruction".*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. G. W. Carter: "Distribution of Mechanical Forces in Magnetized Material"; Mr. C. J. Carpenter "A Note on the Distribution of Mechanical Forces in Magnetized Material" (discussion on Prof. Carter's paper); Mr. B. D. Popovic: "Evaluation of Magnetized Energy Density in Magnetized Matter".

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Annual General Meeting.

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. F. Hoyle, F.R.S.: "The Nature of the Quasi-Stellar Objects".

Monday, May 2

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 2.30 p.m. and 5 p.m.—Colloquium on "Current Topics in Tropospheric Propagation".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Annual General Meeting.

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting, followed by Mr. A. Mott. "The Changing Structure of the U.K. Chemical Industry".

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Annual General Meeting, followed by Dr. W. T. Norris: "M.H.D. Generation of Electricity".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (with an honours degree in pharmacology, physiology, biochemistry or zoology and also a higher degree or evidence of original research in an appropriate field) IN PHARMACOLOGY—The Clerk to the Council, School of Pharmacy, University of London, 29/39 Brunswick Square, London, W.C.1 (April 27).

JUNIOR LECTURERS (2) (with an honours degree in physiology with zoology, chemistry or physics, or a medical qualification) IN PHYSIOLOGY—The Registrar, King's College (University of London), Strand, London, W.C.2 (April 29).

LECTURER IN EDUCATION; and a LECTURER IN MATHEMATICS—The Principal, Bede College, Durham (April 29).

ASSISTANT LECTURER IN BIOCHEMISTRY—The Registrar and Secretary, The University, Bristol (April 30).

ASSISTANT LECTURER IN MATHEMATICS (applications are particularly invited from candidates with interests in approximation theory or numerical analysis or probability and statistics, although candidates with interests in other fields will be considered)—The Secretary, University of Lancaster, Bailrigg House, Lancaster (April 30).

ASSISTANT LECTURERS (2) IN BIOCHEMISTRY—The Registrar and Secretary, The University, Bristol (April 30).

LECTURER IN CHEMISTRY (ORGANIC)—The Registrar, The University, Manchester, 13, quoting Ref. 88/66 (April 30).

LECTURERS or ASSISTANT LECTURERS (2) (with a particular interest in political, historical or economic geography, and able to lecture on the regional geography of South East Asia, the Monsoon Lands or Eastern Europe) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, University College of Wales, Aberystwyth (April 30).

POSTDOCTORAL FELLOW IN THE DEPARTMENT OF CHEMISTRY for work on molecular structures by microwave spectroscopy—Prof. J. Sheridan, Department of Chemistry, University College of North Wales, Bangor, North Wales (April 30).

SENIOR LECTURER IN THE DEPARTMENT OF MOLECULAR BIOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (April 30).

LECTURER (medical qualifications not essential, but preference will be given to candidates with special experience in electron microscopy) IN ANATOMY—The Secretary of the University Court, The University, Glasgow (May 1).

CHAIR OF BACTERIOLOGY—The Secretary, University of Edinburgh, Edinburgh (May 3).

LECTURER IN PURE MATHEMATICS—The Registrar, King's College (University of London), Strand, London, W.C.2 (May 6).

READER IN NUMERICAL ANALYSIS IN THE DEPARTMENT OF MATHEMATICS—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (May 6).

READER (preferably with a special interest in either functional or classical analysis) IN PURE MATHEMATICS—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (May 6).

LECTURER IN ARCHAEOLOGY—The Secretary of the University Court, The University, Glasgow (May 7).

LECTURER or ASSISTANT LECTURER (Probationary) IN PHYSICS—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (May 8).

CHAIR OF HIGHER EDUCATION—The Registrar, The University, Manchester, 13, quoting Ref. 81/66/Na. (May 9).

CHAIR OF SOCIOLOGY—The Secretary, University of Stirling, Stirling (May 9).

DIRECTOR (highly qualified scientifically with a marked aptitude for administration and negotiation with public bodies and others) OF THE INSTITUTE OF GEOLOGICAL SCIENCES, LONDON—The Natural Environment Research Council, Establishments Division, State House, High Holborn, London, W.C.1 (May 9).

CHAIR OF CELL BIOLOGY—The Secretary of the University Court, The University, Glasgow (May 13).

CHAIR OF SOCIOLOGY—The Secretary of the University Court, The University, Glasgow (May 13).

SENIOR LECTURER or LECTURER (preferably with an interest in either entomology or parasitology) IN THE DEPARTMENT OF ZOOLOGY—The Inter-University Council, 33 Bedford Place, London, W.C.1 (May 13).

ASSISTANT LECTURER or LECTURER (preferably with a special interest in comparative physiology) IN THE DEPARTMENT OF ZOOLOGY—The Registrar, The University of Liverpool, Liverpool 3, quoting Ref. CV/22 (May 14).

CHAIR OF VIBRATION STUDIES IN THE INSTITUTE OF SOUND AND VIBRATION RESEARCH—The Deputy Secretary, The University, Southampton (May 14).

LECTURER IN CHEMICAL ENGINEERING or BIOCHEMICAL ENGINEERING—The Registrar, University College of Swansea, Swansea (May 14).

LECTURER (preferably with research experience in spectroscopy or chemical physics subjects) IN PHYSICAL CHEMISTRY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (May 14).

RESEARCH DEMONSTRATORS (with research interests either in organic or physical chemistry) IN CHEMISTRY—The Registrar, University College of Swansea, Swansea (May 14).

LECTURER (non-medical) IN CHEMICAL MICROBIOLOGY—The Registrar, The University, Liverpool, quoting Ref. CV/16 (May 20).

SENIOR LECTURER IN THE DEPARTMENT OF HISTOLOGY—The Registrar, The University, Liverpool, 3, quoting Ref. CV/23 (May 20).

RESEARCH FELLOW IN THE DEPARTMENT OF MATHEMATICAL PHYSICS for work in the field of elementary particle physics (consideration will also be given to candidates with other interests)—The Assistant Registrar (Science and Engineering), The University of Birmingham, Birmingham, 15 (May 21).

RESEARCH FELLOW (with a degree and postgraduate research experience in biochemistry and preferably some knowledge of physiological teaching) IN THE DEPARTMENT OF BIOCHEMISTRY to investigate the mechanism of enzymic adaptation to contractile activity in skeletal muscle under the supervision of Prof. S. V. Perry—The Assistant Registrar (Science and Engineering), The University of Birmingham, Birmingham 15 (May 21).

LECTURER IN INORGANIC CHEMISTRY at Makerere University College, University of East Africa, Uganda—The Inter-University Council, 33 Bedford Place, London, W.C.1 (May 27).

SENIOR FELLOW IN THE DEPARTMENT OF THEORETICAL PHYSICS, Research School of Physical Sciences, Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 27).

RESEARCH ASSISTANT (Biochemist or Pharmacologist) to work at Naples and University College, London, on investigations of the nervous transmitter systems of octopus, under the general supervision of Prof. J. Z. Young—The Secretary, University College, Gower Street, London, W.C.1 (May 28).

RESEARCH ASSISTANT (Experimental Psychologist or Zoologist) to work at Naples and University College, London, on investigations of the learning mechanisms of octopus, under the general supervision of Prof. J. Z Young—The Secretary, University College, Gower Street, London, W.C.1 (May 28).

SENIOR LECTURER or LECTURER IN PURE MATHEMATICS at the Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 30).

POSTDOCTORAL RESEARCH FELLOW IN SOLID STATE CHEMISTRY or PHYSICS at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, June 1).

LECTURER (with a degree or an equivalent qualification in which emphasis is on mining with adequate supporting geology, and preferably practical experience in the mineral industry) IN MINERAL TECHNOLOGY, University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar of the University (New Zealand and London, June 15).

SCIENTIFIC OFFICERS (2) (with at least a good honours degree in botany or zoology, and for one post a knowledge of biochemistry an advantage) TO STUDY NEMATODE PARASITES OF PLANTS—The Secretary, Rothamsted Experimental Station, Harpenden, Herts, quoting Ref. 1051/69 (June 30).

ASSISTANT LECTURER or LECTURER IN PSYCHOLOGY—The Registrar, Portsmouth College of Technology, Hampshire Terrace, Portsmouth.

COMPUTER ENGINEER (with experience of large valve computers)—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1.

DEPARTMENT RESEARCH ASSISTANT (Biochemist) to work on metabolism of the eye in relation to disease—Dr A. Pirie, Nuffield Laboratory of Ophthalmology, University of Oxford, Walton Street, Oxford.

GRADUATE to study the kinetics of metabolic processes in relation to the synthesis of plasma lipoproteins—Dr. G. L. Mills, Courtauld Institute, Middlesex Hospital Medical School, London, W.1.

RESEARCH FELLOW (with postgraduate research experience) IN QUANTUM ELECTRONICS for work involving a theoretical and experimental study of the scattering of laser light by the atmosphere—Prof. W. A. Gambling, Department of Electronics, The University, Southampton.

SCIENTIFIC INFORMATION OFFICER (able to write good English, and preferably with a botanical or agricultural degree or a knowledge of or aptitude for foreign languages) for duties which will include preparation of abstracts for the journal *Plant Breeding Abstracts*, editing and classification of biological literature, and dealing with scientific inquiries—The Director Commonwealth Bureau of Plant Breeding and Genetics, School of Agriculture, Cambridge.

SENIOR LECTURER or LECTURER (well qualified academically with proven research and teaching ability, and preferably a knowledge of, or experience in, the chemical industry) IN INORGANIC CHEMISTRY—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 10/G.

VISITING LECTURER IN GEOGRAPHY—Prof. W. B. Johnston, Department of Geography, University of Canterbury, Private Bag, Christchurch, New Zealand.

THIRTY YEARS AFTER

IT is a source of great pleasure that Prof. Peter Kapitza is about to pay a brief visit to Britain after an absence of thirty years. In a very real sense, he has a claim on the goodwill and even the affection of those who still marvel at what physics accomplished in the first few decades of this century. Those who do not remember the thirties will nevertheless be eager to welcome somebody who worked at the Cavendish in those heroic days. And even those of Kapitza's contemporaries who may have thought that Rutherford was spending too much of the meagre resources of the laboratory on Kapitza's equipment for generating strong magnetic fields will not stint their welcome now. For was not Kapitza the man who ran the informal club at which the Young Turks at the Cavendish plotted the next steps forward—positron, neutron, artificial disintegration and the rest? Was not Kapitza a Fellow of the Royal Society in 1929? And best man at the Chadwicks' wedding? With the passage of time, these are the things that people remember. As Kapitza himself explained to Rutherford in a letter written after he had failed to return from the Soviet Union in the summer of 1935, "after all, we are only small particles of floating matter in a stream which we call Fate. All we can manage is to deflect slightly our track and keep afloat . . .".

Kapitza has been away too long, and he will find that many things have changed. For one thing, the Cavendish is no longer the centre of the Universe, even though some of its buildings may have lasted unreasonably well. It remains a splendid laboratory for research and teaching, but the most lasting monument to what happened there in the time of Rutherford may be the way in which his students have helped to create a dozen comparable laboratories. And physics has grown with such vigour and success as to transcend the boundaries of single laboratories. Even if, in the thirties, Rutherford's strategy on spending money had been different, and if the Cavendish had been quicker off the mark with its first cyclotron, the effect on recent history would only have been transient. It is unthinkable, for example, that different decisions then could have enabled Britain now to build for itself a proton–synchrotron to match the 200-GeV machine soon to be built in the United States.

If the place of the Cavendish has changed, so has that of Britain in the world. The country is no longer the self-contained scientific community of the thirties. The traffic from Britain—and the rest of Europe—to and from the United States is increasingly valuable. Links between European laboratories are already strong and promise rapidly to grow stronger. Most often, the consequences of this growing interdependence are stimulating. The disadvantages are few, if any, for it remains to be demonstrated that even the unplanned emigration of scientists is in the long run a disadvantage.

The changed status of British science accords with the changed status of the British economy. In 1935 Britain was more prosperous than most countries except the United States. Now the country finds it more difficult than most to maintain the standard of prosperity to which Western Europe has become accustomed. Technically, British industry can no longer expect to tackle everything, but must deploy its effort carefully between computers and aircraft, ships and steelworks. So there is a preoccupation with science and technology, and with attempts to harness these forces of innovation to the growth of the economy. Nobody need be surprised that things have gone like this, but nobody need be despondent either. Britain remains a nation of great talent. That has not changed. But Kapitza may notice some of the discomforts of changing status. Support for scientific research is growing, but it should grow faster. Post-graduate education and training are spreading, but not quickly enough. And there is such a concern to turn science into quick prosperity that it is no wonder that British pride in achievement is often tinged with uncertainty.

There is evidence that Kapitza is also worried by these things. Earlier this year, in *Komsomolskaya Pravda*, he made the plain statement that "we must not be afraid to say that in the past few years the gap in science between the Soviet Union and America has not been narrowing". This sentence has been widely quoted, for obvious reasons, but it followed a careful analysis of the reasons why the Soviet Union has not reaped all the industrial and economic benefits that might have been expected from the massive expenditure on science and technology in the past thirty years. Kapitza's conclusion was that "in organizing the process of the assimilation of new technologies by industry, the approach must be purely individual, without any cut and dried rules, and the character of the people concerned and the nature of the external conditions must be taken into account in each particular case. Questions of finance and personnel are, of course, settled by an appropriate decision, but the successful assimilation of new technologies depends on good relations between pupils and teachers and on their common interest in success . . .".

The irony is that this applies almost as well in Britain as in the Soviet Union. In both countries, it would seem, the climate of society is such that scientists and technologists do not contribute all they might to industrial prosperity. The merit of Kapitza's argument is the emphasis it puts on psychological factors, and in particular on the importance that scientists and technologists should somehow be able to believe that their efforts could effect great changes What he is saying is that in the application of science and technology, as in all other creative activity, success depends on the extent to which it is possible to engage the imagination and the enthusiasm of talented people. It appears that it is equally easy to escape from this truth in Britain and in the Soviet Union, though perhaps for different reasons. Is it too much to hope that one benefit of Kapitza's visit will be a resolve to study this common problem from the two very different points of view of Britain and the Soviet Union?

Kapitza's reflexion on the "gap" between the United States and the Soviet Union raises wider issues. Two things need saying. First, the harvest of scientific research in the Soviet Union is indeed much less than might have been expected from the effort devoted to it since the Second World War. There is nothing wrong with the

quality of the Russian work or the character of Russian scientists—far from it—but there could well have been more of it. Secondly, Russian science remains more isolated than it need be and should be from what happens elsewhere in the world, and this is true even though there have been enormous improvements in the past decade in the freedom with which Russian scientists travel abroad or invite colleagues to visit them in the Soviet Union. It is still something of a rarity for research students and their more senior colleagues to spend long periods at each other's laboratories, for example, and it is hard not to link these circumstances together. In other words, may it not be that Russian efforts in recent decades would have been even more successful if it were not for the obstacles which still remain to a free intellectual traffic between East and West? Quite simple experience will suggest that there is good cause to fear something of the kind, and if the Soviet Union is contributing less than it might to the rapid progress of science, everybody loses. This is why another benefit to be sought from Prof. Kapitza's visit is a still further liberalization of the rules for exchanging science and scientists between the Soviet Union and everywhere else.

LUCKY THIS TIME?

THE annual meeting of the British Association is usually a disappointment. Each year for several years, well-wishers have been hoping for the best and have been denied it. Most of the participants, who would obviously not be there if they did not wish to be, must have been puzzled to know why an institution that gave them pleasure should have been denounced as a bore by so many of those not wishing to attend. The trouble has been that the external influence of the meeting has been steadily diminishing. A century has gone since Huxley and Wilberforce fought over the *Origin of Species*. As things are, the association is neither a learned society nor an indispensable channel for the communication of science to the world at large. Over the years, it has grown in on itself. It has lacked a cutting edge.

This is why it is good, and a surprise, to be able to record that things could well be different. Plans for the meeting which begins at Nottingham on August 31 this year include some promising innovations. Briefly, the Association is going to see whether it can somehow arrange for an open discussion of three public issues in which science and technology are deeply engaged—water conservation in Britain, supersonic aircraft and the development and use of drugs. The intention is to confront public policies on these issues with the criticisms of unofficial persons, professional scientists and others. Obviously the success of these meetings will depend on whether their chairmen can avoid capture by received doctrine on the one hand and cranks on the other. On supersonic aircraft, for example, a course will have to be steered between the vested interests of the aircraft manufacturers and the frequently ill-considered arguments of those who denounce all noise produced by agencies other than nightingales. But if things go well, the result could easily be a better understanding of some important public issues. That would be valuable in itself, but the general officers of the Association are after bigger fish. Plainly, they are hoping that they have found a reason for the Association's continued existence. With luck and good management, they may be right.

MANAGEMENT OF INDUSTRIAL RESEARCH

Suits

Speaking of Research. By Dr. C. Guy Suits. Pp. xii+466. (New York and London: John Wiley and Sons, Inc., 1965.) 57*s*.

SPEAKING of Research is a collection of addresses that Dr. Guy Suits has delivered to a variety of institutions in the United States. Although some of these may have been available in that country, their availability in Britain is very limited. Their collection into one volume provides a unique opportunity for Dr. Suits to review the progress, over a period of twenty years, of one of the most outstanding and successful industrial research laboratories in the world. Most scientists are familiar with the pioneering researches of Irving Langman and their effect on the fortunes of the General Electric Company. The more recent achievements of the laboratory are less well known, and it is therefore all the more interesting that some glimpse of the history of these achievements should come from the pen of Dr. Suits. The author claims that his crystal ball may often appear cloudy and crazed because the articles are produced with subsequent amendment and the benefit of hindsight. They are all the better for remaining unaltered, because it does give the reader the benefit of seeing how difficult it is to look ahead in science and technology and confidently to predict the course of events. Some people think this can be done with precision, but the more eminent the leader of a large research enterprise, the more modest he is in claiming unquestioned ability to forecast the course of events ahead.

It is inevitable that some subjects are dealt with in more than one address, but this adds interest to the account, for it gives the reader an opportunity to chart the course of events over a period of years. Many of the chapters deal with the nuclear power topic which General Electric has been engaged on for a very long period. Little has appeared and thus these accounts, though not detailed, give a conspectus of new points of view that must have guided the thinking of General Electric during the past two decades. Maybe the most valuable and illuminating are those essays on the management of scientific research. Dr. Suits comes down in favour of a certain amount of broad planning of basic research. His reasonable thesis is that the interests of General Electric are wide but in spite of diversity are not in fact so wide that wide choice of areas of study should not be defined. The hope expressed is that wise guidance can give the freedom necessary for highly original work of high quality and yet of great potential development if in fact the basic work turns out to be fruitful. Certainly, the more recent record of the laboratory would substantiate this approach to planning. Although it is not the most important, the detailed account, with interesting quotations from laboratory notebooks, of the successful attempts to produce diamonds is one of the most interesting. Here is a case where the conditions for the existence of diamonds were known, but the problem of transforming graphite to diamonds in a finite time was a matter of the utmost difficulty and might easily have eluded those engaged in the work. There is, maybe unfortunately, little reference to the synthesis of borazon and nothing about its potential as an exceptionally hard material.

One of the shorter addresses deals with postgraduate training in physics. For its research laboratory General Electric almost exclusively recruits Ph.D.s, because Bachelors of Science are not highly trained enough for pioneering work in an advanced laboratory. However, Dr. Suits is worried about the length of time needed to obtain the degree of Ph.D. and yet at the same time he deplores the tendency to specialize at the expense of a broad training, including formal instruction. His opinion is that if something has to go it is the amount of origina

research, for he says that the introduction to industrial research is best conducted in the industrial research laboratory itself.

The final address on selectivity in research is packed with thoughts that are of great general interest, not only in industrial research but also in government or government-sponsored research and development. The first basic problem is that in the United States research and development in the industrial field only increase at 10 per cent per year in dollars, whereas research and development for the country as a whole grow at a rate of 20 per cent. The 10 per cent barely copes with the normal increase in costs and in salaries. In these circumstances, this means that an industrial laboratory has to try to become more productive and this can only be done by a much more critical selection of projects. Fashion in research is attacked vigorously and a slavish following of fashion without good reason is reckoned to be one of the best ways of decreasing productivity. For example, Dr. Suits considers research into lasers, and particularly their applications, is a field where far too much research has been done without there being a prior appreciation of the value of the application of research. Another danger is to try to keep a finger in every pie as a kind of insurance policy. Dr. Suits considers this a waste of money and talent. He is surprisingly critical of the attempts to inject science into those industries that have been around virtually for centuries. What can be done in these industries has already been done. The problems involved in the support of big science come in for some scathing criticism too. Bigness is what matters rather than the criterion as to whether it is good science too. Even more surprising is the analysis of the situation where the research venture is completely successful but when this point is reached no one can find an application for the knowledge so acquired. Dr. Suits admits in his speech that his tongue is sometimes in his cheek in making these remarks; nevertheless the questioning is very necessary at present not only in the United States but in Britain as well. This is a volume to be read with great interest by everyone interested in the management of research and development and also in engineering.

HARRY MELVILLE

SOCIAL IMPLICATIONS OF NUCLEAR POWER

A Peril and a Hope

The Scientists' Movement in America, 1945–47. By Alice Kimball Smith. Pp. xiv+591. (Chicago and London: The University of Chicago Press, 1965.) 10 dollars; 72*s*.

A PERIL and a Hope is an excessively long and detailed account of what is described as the scientists' movement in America, 1945–47. It is concerned more especially with the way in which scientists connected with the development of the atomic bomb and with nuclear power awoke to the social and political implications of their work and sought to influence national policy. Its scope is, in time at least, more limited than that of Robert Gilpin, in *American Scientists and Nuclear Weapons Policy*, but it is not limited to questions of the use of nuclear weapons. It is nearer in scope to A. H. Compton's *Atomic Quest*, which at some points it amplifies and corrects. The real interest and value of the book lie in its contribution to the continuing discussion of the influence of science and of scientists on public policy, the limits of that influence and the mechanism by which advice is most effectively tendered. Much of it is strictly relevant to conditions in the United States, and here the excessive detail makes it more difficult to bring out the relevance of the experience described to conditions in Britain. Even so, it should contribute to a clearer understanding of that experience, and the book includes, moreover, as appendixes, the important Jeffries report of November 1944 on the prospects of nucleonics and the French report of June 1945 on nuclear power and nuclear weapons, neither of which appears to be easily accessible in Britain.

The book throws some fresh light on the struggle in the United States to free nuclear energy from military control and to avoid the domination of nuclear research by secrecy or security restrictions. It also illuminates the initial approaches to the international control of nuclear activities, but its chief value seems to lie in pointing out how much is demanded of scientists who are seriously concerned about the social consequences of their work. To influence public policy effectively requires much more than goodwill, more even than clear understanding of the scientific and technical factors and their implications; it demands an understanding of the political process also and a readiness to accept the conditions of effective participation. Mrs. Smith might perhaps have told her story more briefly and effectively, but at least in conclusion she puts the issues and the price demanded succinctly and unmistakably.

R. BRIGHTMAN

PHYSICAL PRINCIPLES OF MAGNETISM

The Physical Principles of Magnetism

By Prof. Allan H. Morrish. (Wiley Series on the Science and Technology of Materials.) Pp. xv+680. (New York and London: John Wiley and Sons, Inc., 1965.) 125*s*.

THE magnetic properties of materials is a field of investigation in which many important and significant developments have taken place during the past 25 years. The unified account of magnetic phenomena in solids, which *The Physical Principles of Magnetism* provides, will therefore be welcomed by the increasing number of physicists and engineers who wish to acquire a comprehensive knowledge of this branch of solid-state physics.

After an introductory chapter on classical electromagnetic theory, the first portion of the book deals mainly with paramagnetic systems. This is followed by a chapter on the magnetic properties of an electron gas, and accounts are given here of such topics as Pauli spin paramagnetism, the de Haas–van Alphen effect and the magnetic properties of superconductors. The remainder of the book is devoted to an extensive discussion of magnetic materials in which the magnetic carriers are strongly coupled by exchange forces. Ferromagnetics, antiferromagnetics and ferrimagnetics are each treated separately and in considerable detail.

The author has dealt with the subject mainly in a theoretical way. Experimental results and data are, however, included to illustrate and compare with the theory, but experimental methods and techniques are rarely described. Wherever possible, phenomenological approaches have been adopted to the topics discussed. Thus, for example, magnetic resonance is explained in terms of a precessing dipole, while the Weiss molecular field is used as a basis for the theory of ferromagnetism. For a complete understanding of a number of sections of the book, however, an acquaintance with solid-state theory and a good working knowledge of quantum mechanics are essential. The subject matter is presented in a clear and coherent manner, and the text is adequately illustrated with well-prepared diagrams. Since this is a book devoted solely to magnetism, the use of c.g.s. units is perhaps appropriate, since it is still fashionable for experimentalists to use these units when quoting their results. For the benefit of readers who are familiar only with the M.K.S. system, a conversion table is provided in an appendix. A useful feature of the book is the inclusion of a

bibliography and a set of problems at the end of each chapter.

The sections of the book describing magnetic resonance phenomena are particularly interesting and, taken together, give a comprehensive account of the way in which this comparatively recent technique has been used to investigate magnetic systems. The discussion of paramagnetic resonance in crystals containing transition metal ions is commendably concise, while the chapter on nuclear magnetic resonance contains all the essential physics of this phenomenon. In view of their applications in wave guide systems, a more detailed description of ferrimagnetic microwave devices could have been justified, while some of the theory in the rather lengthy discussion of resonance in strongly coupled dipole systems could have been condensed.

The chapters dealing with ferromagnetism are well written and merit special mention. A remarkably complete discussion of the theories of ferromagnetism is given, and this includes some of the more recent work that has been done on this difficult topic. The section on spin-waves is very informative. The domain structure of ferromagnetic materials receives ample coverage and a good description is given of the various mechanisms which participate in the magnetization process. There are short, but valuable, sections on permanent magnet materials and ferromagnetic alloys.

Although material published since about the beginning of 1964 is not included, this is a well-worth-while publication on magnetism which can be recommended as a text-book for the theoretician and a useful reference work for the experimentalist. G. D. ADAM

BIOLOGY OF NEUROGLIA

Biology of Neuroglia

Edited by E. D. P. de Robertis and R. Carrea. (Progress in Brain Research, Vol. 15.) Pp. xi+297. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 95*s*.

IN Volume 15 of Elsevier's present series on the progress of brain research, Dr. E. D. P. de Robertis and Dr. R. Carrea edit the proceedings of the tenth Latin American Congress of Neurosurgery, which was held at Buenos Aires in 1963 and was devoted to an inter-disciplinary symposium on the "Biology of Neuroglia". The organizers of this symposium selected topics dealing mainly with the ultrastructure and function of neuroglia, particularly in relation to cerebral oedema. It is appropriate that the pioneer morphological studies of Hortega and Cajal are acknowledged in *Biology of Neuroglia* by the particularly elegant demonstration of neuroglial staining methods provided by Dr. M. Polak. Dr. de Robertis points out in his introductory chapter that these earlier morphological investigations of the Spanish school provided no information about the function of neuroglia in the nervous system, whereas this symposium is mainly concerned with those recent advances that have added to our knowledge of the ultrastructural organization and electrolyte-regulating functions of the neuroglia.

The enzyme histochemistry of normal and reactive astrocytes is authoritatively discussed by Dr. R. L. Friede, with particular reference to the role of these cells in pathological processes and their response to sodium ions. Dr. Igor Klatzo and his colleagues demonstrate the leakage of fluorescent-labelled protein from cerebral capillaries in cerebral oedema. Drs. J. Miquel and W. Haymaker discuss the significance of the glycogen accumulation seen in heavily irradiated astrocytes; they attribute this deposition to the effects of radiation-induced anaerobic metabolism. As a future problem they might consider it worthwhile to determine whether the astrocytic activities of uridine diphosphoglucose glycogen synthetase and phosphorylase are altered by irradiation.

Possible routes for the entry or transport of water and ions in the brain are presented by Drs. H. Davson and M. Bradbury, while Dr. A. Lazanksy considers the same problem in the retina. Drs. H. M. Pappius and L. Bakay discuss—in their respective contributions—the intra- or extra-cellular distribution of water in various forms of experimentally induced cerebral oedema. Dr. J. A. Zadunaisky and his colleagues report their ultrastructural and electrolyte investigations on neuroglia in the incubated brain; they conclude that the neuroglial cells are particularly concerned with osmotic and ionic regulation within the brain. The changes in astroglial and oligodendroglial volume after exposure to anoxia or hypothermia are illustrated in an interesting presentation by Drs. H. Collewijn and J. P. Schadé. Amino-acid transport within the brain is discussed by Dr. E. Levin and his associates. The electrical responses of cultured neuroglial cells are described by Dr. I. Tasaki; such stimulation initiates a slow wave of contraction in these cells.

The functional and metabolic symbiosis of neuroglia and neurones is discussed by Dr. Svaetichin and his co-authors and by Dr. R. Galambos. The latter author briefly but comprehensively reviews the functions of neuroglial cells in response to injury, in myelination and demyelination, in synaptic transmission and in Hydén's neuronal-satellite metabolic system.

Clearly it is impossible to include every discipline in a symposium of this sort, but it is to be regretted that Dr. R. M. Torack and his co-workers could not present their recent electron-histochemical studies on neuroglia in this volume.

The production of *Biology of Neuroglia* and the profuse illustrations are in accord with the customary excellent standards of the Elsevier Publishing Company. I have only a minute personal axe to grind: I dislike edited discussions presented in an informal verbatim manner.

This book can be thoroughly recommended as an excellent guide to those interested in the progress of contemporary research on neuroglia. C. W. M. ADAMS

INTRODUCTION TO BIOLOGY

Molecular Biology of the Gene

By Dr. J. D. Watson. (Biology Teaching Monograph Series.) Pp. xxii+494. (New York and Amsterdam: W. A. Benjamin, 1965.) 11 dollars, cloth; 6.50 dollars, paperback.

MOLECULAR Biology of the Gene offers more than the title promises. It is a modern introduction to the 'New Biology' and is, in fact, based on introductory lectures given to students of biology at Harvard. It dwells primarily on the analytical rather than the descriptive side of biology, emphasizing equally the genetic and the biochemical aspects. It begins with a description of the cell theory and cell division which leads on to the Mendelian laws and the concept of evolution. In the next chapter a summary of cell biochemistry is presented, with special reference to *E. coli*, the best understood organism at the molecular level. There follows an extensive discussion of the importance of chemical bonds (especially weak bonds) in the interaction of cell constituents, of biochemical thermodynamics and of the concept of template surfaces which operate in the synthesis of protein molecules.

The following chapters are concerned with the fundamentals of modern genetics, the arrangements of genes and chromosomes, gene structure and function, chromosome mapping, recombination, a description of the biochemistry of DNA, of the transcription of RNA on DNA templates and the role of RNA in protein synthesis. Further chapters deal with the replication of viruses, the genetic code, the regulation of protein synthesis, differentiation, the biochemistry of antibody formation, and the final chapter discusses cancer from the point of view of the geneticist.

The book is an outstanding achievement, written by one of the central participants in the modern development of biology. The presentation is clear, authoritative and vivid. The colourful yet concise style is illustrated by the following headings: "Avery's Bombshell" (referring to the discovery that nucleic acids can carry information); "The Twenty-five Year Loneliness of the Protein Crystallographers" (referring to the long lag period before X-ray crystallography yielded major results); "Much More Must be Learned about Ribosomes" (referring to the lack of information on the basic properties of their structure). The book is further enlivened by excellent diagrammatic illustrations. The account is well balanced; achievements as well as gaps in our knowledge are recorded. The approach is altogether highly original. This makes the book profitable not only for the beginner but also for expert biologists of all descriptions including biochemists and geneticists. It was produced within six months and is therefore as up to date as is possible nowadays.

H. A. KREBS

REFLEX ACTIVITY AND THE CENTRAL NERVOUS SYSTEM

Compensatory Adaptations, Reflex Activity and the Brain

By Ezras A. Asratian. Scientific and Translation Editor, Prof. Samuel A. Corson. (International Series of Monographs on Cerebrovisceral and Behavioural Physiology and Conditioned Reflexes, Vol. 1.) Pp. xv + 194. (London and New York: Pergamon Press Ltd., 1965.) 80*s*. net.

THE basic object of *Compensatory Adaptations, Reflex Activity and the Brain* is to extend the interpretation of Pavlov's work in an attempt to explain reactions in the central nervous system as arising out of conditioned and unconditioned reflexes. Thus, among other subjects, spinal shock, restoration of activity after damage to the spinal cord or the brain, and certain metabolic disturbances associated with central nervous exclusion are considered. Conditioned reflexes are suggested to be not restricted to individual neurological levels, but to have a number of associated extensions to the medulla, mid-brain and the cerebral cortex, together with common afferent and efferent pathways.

There are six chapters in the volume, the first four of which are based on a series of lectures given in British universities during 1957–58, but intimate reference to each chapter is not necessary in this review, for the subject matter is not restricted solely to individual sections.

Spinal shock is the subject of the first chapter, the mechanism of its causation affording the main topic. The evidence proclaimed supports Sherrington's views with some qualification. Related changes in the medulla and the parietal cortex are described, their recognition being the outcome of more modern forms of investigation, for example, electro-encephalography.

The use of terms such as 'irritation' and 'stimulation' rather suggests active factors in related causes of reactionary phenomena, as against a negation of function in the form of release of activities of other structures, where inhibition or suppression reigned beforehand.

The claim that the intensity of spinal shock shows some tendency to vary in accordance with the segment of cord damaged is noteworthy; for example, a greater degree of shock is induced by posterior hemisection than lateral hemisection of the cord. It would appear that proprioceptive disorganization has more bearing than the interruption in conduction of other afferent stimuli.

Compensatory mechanisms in the return of activity following disablement of experimental dogs would not necessarily indicate true recovery, but a process of adaptation. This seems a more likely explanation of the intensification of their positive conditioned reflexes and a decline of their inhibitory conditioned reflexes (p. 61). Enforcing an animal to apply a reconditioned structure, for example, the arm of the monkey (p. 63), surely is to be expected to expedite return of available activity within the limb, when the opposite limb has been put out of action by restrictive measures such as splinting or bandaging, or by amputation. Return of movement is recorded in animals where the following experiments have been undertaken: ambulation, where the forelimb on one side and hind limb on the opposite side have been amputated; cross anastomosis of vagus and median nerves; lateral hemisection of the spinal cord; dorsal hemisection of the spinal cord; longitudinal section of the cord. Moreover, recovery of mobility is abolished should the animal be subjected later to removal of the cerebral cortex or decerebration.

To record that the inability of activity to appear in animals subjected to cortical excision or decerebration could in any way be an interference with reflex action is a most restricted attitude. Generalized loss of cerebral cortex, in terms of cortical functions, is so disabling that a restricted aspect cannot be determined on this premise.

It is noted that attention to endocrine dysfunction is given some consideration, for not only is this mentioned but illustrations of affected glands occur. Changes in the ovary, pituitary and thyroid are to be seen. Yet the endocrine disorders arising out of these effects are not discussed. The introduction of the destruction of the whole cortex as a means of supporting the hypothesis propounded is a strange dismissal of the many functions assignable to that part of the brain.

The work is certainly worthy of perusal, though the English demands a most careful analysis, for often the sentences are too long. At a price of 80*s*., however, I would not recommend it for other than the most objective attention.

HARVEY JACKSON

THE LIFE OF FISHES

The Life of Fishes

By N. B. Marshall. (The Weidenfeld and Nicolson Natural History.) Pp. 402 + 43 plates. (London: Weidenfeld and Nicolson, 1965.) 63*s*. net.

THE Editor of *Nature* invites reviewers to suggest a separate title for their reviews, but in the case of *The Life of Fishes* a more apt title than that of the book itself would be difficult to find. Perhaps it would be more accurate to refer to the "Lives of Fishes", for one result of reading this book is to be impressed by the diverse ways in which fishes have become adapted to deal with the manifold facets of life in water, of parcelling out the environment among themselves, and of the ways in which these animals have become masters of their environment.

The scope of this book is immense, even though the author has limited himself to the short and medium time-scales in the lives of fishes. As if this was not enough, however, Mr. Marshall also treats the reader to a masterly review of the long time-scale as seen in the results of evolution manifest in the morphological diversity of living fishes. His final chapter, devoted to a succinct account of the classes and orders of fishes, will be highly valued by students who would otherwise have to seek widely for their information.

But the essence of the book is its concern with fishes in their environment, and not least of all with interactions between the fishes, as mates, as food or even to form near 'super-organisms'. Since his approach is a dynamic one, the author has reduced, so far as possible (and very successfully), the purely anatomical elements necessary to understand the physiological, behavioural and ecological specializations of fishes. To a large extent this has been achieved by the use of clear figures and diagrams.

The first, and largest, section of the book deals with the day-to-day existence of adult fishes. It gives particular emphasis to basic life processes, and to the prob-

lems of motion and respiration peculiar to a dense and not especially well-oxygenated medium. Here, too, are chapters dealing with that fascinating, multi-purpose organ, the swimbladder, and that equally fascinating but still somewhat mysterious 'seventh sense', the lateral line sensory system. Sound production, hearing, sight, electrogenesis and luminescence are all dealt with in broad but satisfactory detail. Although these different subjects are perforce considered separately, never once is the reader left with the feeling that they are being viewed in isolation. The first section concludes with three chapters treating of the ways in which the lives of fishes are conducted on a broader scale. In these chapters, above all, we see the functional integration of the various anatomical, physiological and sensory systems described in earlier sections. Shoaling, migration, courtship, commensalism, mimicry and coloration are all given particular attention, and woven into the persistent theme, devices for survival.

The second section of the book deals with the many aspects of reproductive biology, and the early life-histories of marine and freshwater fishes. Since less is known about these phases in fishes, it is a relatively short section, but none the less it gives a good coverage of what is known. Again the emphasis is on life and the means of ensuring it, this time more on the strategic than the tactical level.

Finally, the geographical and large-scale ecological background to fish life is described in three chapters covering the deep oceans, the shallow seas, and the freshwater habitats. This is no mere description of the stage and backdrops, for, quite rightly, the actors intrude to demonstrate how they have coped with and often capitalized the vagaries of their world.

Naturally, specialist ichthyologists will feel that some aspects of fish life have received too little attention from the author. Personally, I would have liked to see more space given to the freshwater fishes of Africa and South America, since in many respects these species provide synoptic microcosms of the problems (and their solutions) covered in the book. But such complaints would be churlish. Specialists will also find some errors of fact, and omissions of work which they consider important, but these are infrequent.

No one can fail to profit from this remarkably lucid, integrated and, above all, biological account of the largest and ecologically most complex group of living vertebrates.

P. H. GREENWOOD

REGENERATION AND RELATED SUBJECTS

Regeneration in Animals and Related Problems

Edited by V. Kiortsis and H. A. L. Trampusch. (An International Symposium sponsored by NATO'S Division of Scientific Affairs and held at Athens, Greece, April 1964.) Pp. xxiv+568. (Amsterdam: North-Holland Publishing Company, 1965.) 120*s*.

THE subject of regeneration naturally finds a place in most text-books of embryology which usually contain an account of the phenomenon itself and a brief survey of significant experiments in the field. For the interested student such accounts are altogether too brief and will lead him to the standard larger texts on the subject. Unfortunately, these can be comfortably counted on the fingers of one hand and constitute little more than a weekend's reading. The Lagonissi conference on "Regeneration in Animals and Related Problems" has provided the opportunity to create a useful addition to the literature on regeneration.

It is perhaps questionable whether the proceedings of any conference can be welded into a readable whole. Invariably the contributions will be uneven in length, diverse in style and unequal in their scientific merit. That *Regeneration in Animals and Related Problems*, containing as it does more than forty contributions, has much of the unity of a general text says much for the skill of the organizers of the conference and the care with which the book has been edited. English readers should be warned that about one in four of the articles is in French.

Of the three sections into which the book is divided, the general section is the most disappointing. This rests more in the placing of the articles than in their content. Herland-Meeve's article on asexual reproduction might well have been placed in the invertebrate section, and it would have been convenient for the reader to have had the notable contribution by M. Singer on nervous control of amphibian limb regeneration alongside that by C. S. Thornton on the influence of wound skin on blastema cell aggregation, which is some 300 pages farther on. Of the two major sections the one on invertebrates is more uniform in its subject matter and slightly more scholarly in its presentation. Here, indeed, is a happy mixture of general reviews and original research papers. Less satisfactory, possibly because the subject matter did not lend itself to a tidy classification, is the section on vertebrates and related problems. One or two articles here seem to be rather short for a book of this kind and do not seem to add much to the understanding of the larger and more exciting problems of regeneration. However, many of the major aspects of limb regeneration in amphibians are dealt with and there are, in addition, excellent articles on such apparently diverse topics as the repair of skin wounds in mammals (D. W. James), compensatory renal hyperplasia (R. J. Goss) and the relation between regeneration and tumour growth (F. Seilernaspang and K. Kratochwil).

Apart from a passing reference to the trials of Prometheus, the influence of Athens appears in the use of the words "Antiphon" and "Colophon" to head introductory and concluding sections by A. E. Needham. Non-musical readers may be puzzled but they will not be disappointed if they read on. "Antiphon" is a good guide to the contents of the book for the intending purchaser. "Colophon" puts in a plea for regeneration as a discipline in its own right. This is a somewhat sad note on which to end. The study of regeneration has so much to offer biologists in general that one must hope that articles on the subject will long continue to be available to a wide audience, not only by the publication of proceedings of conferences devoted to regeneration, but also in biological journals covering a wider range of subjects.

As the conference was sponsored by the Division of Scientific Affairs of the North Atlantic Treaty Organization, the absence of contributions from biologists of the U.S.S.R. and other countries outside the Organization is understandable; it is nevertheless regrettable in a symposium claimed to be international.

F. S. BILLETT

QUATERNARY STUDIES IN THE UNITED STATES

The Quaternary of the United States

Edited by H. E. Wright, Jr., and David G. Frey. (A Review Volume for the VII Congress of the International Association for Quaternary Research.) Pp. x+922. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1965.) 200*s*. net.

THE adjective 'monumental' is often undeserved, but *The Quaternary of the United States* merits it on several counts—whether it be for its 932 pages of large quarto, its 55 authoritative chapters, or the feat of its two editors in assembling together the work of eighty-eight authors in time to have this volume ready for the Seventh Congress of the International Association for Quaternary Research in Colorado in September 1965.

The book is divided into four sections of which the first and largest comprises twenty accounts of the Pleistocene stratigraphy of natural regions of the United States. This is a storehouse of up-to-date information. If the diligent reader comes to the conclusion that some of the chapters conflict with others in their correlations and the degree of multiplicity which they accord to a multiglacial hypothesis, he should also appreciate that when this state of affairs ceases to exist there will be little need for a book of this sort.

Part 2 is devoted to biogeography and it is to be noted that there are two fundamentally different methods of approach. The chapters devoted to the records of pollen analysis or to Pleistocene mammals exemplify the palaeontologist's concept of using fossils to provide the answers to questions of speciation, extinction, and changes in geographical distribution relative to alteration of climate.

There is another approach: that of the student of living plants and animals, who reconstructs from the disjunct distribution patterns of present-day species and sub-species earlier unbroken areas of occurrence or the existence of biological 'refugia' and puts forward theories of speciation or sub-speciation. The relation of these to the Pleistocene history of glacial advances, pluvial periods and times of aridity obviously must remain speculative in the absence of a fossil record. The chapters on Rocky Mountain plant geography and on insects exemplify the second approach, but there are also several attempts to combine modern distributional studies with the fossil record, such as it is.

Archaeology makes up the third section of the book, understandably the smallest, since America is very much a new world. Claims are made that man may have been for 25,000 years or more in North America, but there is no really firm evidence beyond about 15,000 years. One realizes how important radiocarbon dating has been as a complement to stratigraphy in establishing the antiquity and sequence of cultures, starting with that of the Clovis points and ending in recent history.

The fourth and final group of contributions is "Miscellaneous Studies", and here are discussed a number of fascinating problems the implications of which extend far beyond the United States, as does the choice of evidence used to develop the themes. It is not possible to do more than list the topics, but isotope geochemistry, palaeopedology, volcanic ash chronology, palaeomagnetic stratigraphy, dendrochronology, palaeohydrology, tectonics and changes of sea-level are matters which concern students of the Quaternary the world over.

The book is supplied with abundant references at the end of each chapter, summarized in a final index of about 1,800 authors; illustrations are mainly very good and there are commendably few typographical errors. Its price of £10 in the United Kingdom has only been made possible by generous financial support from the U.S. National Science Foundation and all students of the Quaternary should welcome the chance of acquiring a work which will remain a standard reference for a long time.

F. W. SHOTTON

STATISTICS AND ECONOMICS

Contributions to Statistics

Edited by C. R. Rao. Pp. 528. (New York and London: Pergamon Press; Calcutta: Statistical Publishing Society, 1965.) 120*s*. net.

Essays on Econometrics and Planning

Edited by C. R. Rao. Pp. 354. (New York and London: Pergamon Press; Calcutta: Statistical Publishing Society, 1965.) 100*s*. net.

CONTRIBUTIONS to Statistics and *Essays on Econometrics and Planning* have been produced in honour of the distinguished Indian statistician, Prof. P. C. Mahalanobis, for his seventieth birthday. There are thirty-three papers in the volume on statistics and twenty in that on economics. The contributors consist mainly of people who have worked with Mahalanobis at some time, or who have worked on some of the methods and problems, both theoretical and practical, that Mahalanobis has developed. Some of the papers have been written specially for these volumes, while others are based on papers read at meetings, or have been published elsewhere. The topics cover a wide range, and the standard varies from original research by Kolmogorov to vague generalities by relatively unknown writers.

Contributions to Statistics contains eight papers on experimental design and related topics. These include a paper by Bose on combinatorial properties of partially balanced incomplete block designs, and there are two other papers on this topic; there is an interesting exposition by Finney on screening processes, also a paper on asymptotic regression by workers in Geneva. The eight papers on probability and estimation problems include a paper by Kolmogorov on limit distributions, and one by Rao in which he discusses a new criterion for estimation from large samples. There are also included papers by Linnik and Kallianpur, and one by Tintner on Mahalanobis's generalized distance.

The field to which Mahalanobis has contributed so notably is, of course, in sampling, and this is reflected in the eleven papers on this topic. In a comprehensive paper on the work of Mahalanobis in this field, M. N. Murthy of the Indian Statistical Institute discusses in detail the methods of sampling and reduction and control of error that Mahalanobis devised. The other papers include one by Dalenius on lattice sampling using Lahiri's method, and one by Deming on interpenetrating networks of samples. There are several other papers exemplifying and developing techniques originally conceived by Mahalanobis. There are two papers on sequential quality control and two on fractile analysis, a graphical method for comparing groups developed by Mahalanobis as recently as 1958.

Essays on Econometrics and Planning also contains a varied assortment of papers. It includes a paper by Frisch on a parametric solution of the Hicksian model, and a paper by Stone on his models for demand projections; there is also an interesting paper by Myrdal on underemployment. Georgescu-Roegen discusses the problems of measurement and scale, and there is a note by Wold on the problem of interpretation in multivariate models. Balogh analyses the problem of "Planning in Britain" in relation to the Conservative Government since the Second World War, and Goldsmith has a paper on the "National Balance Sheet of the Soviet Union".

There are six papers in which the particular problems of India are discussed. These include valuable statistical-economic papers by Nair Patel and Sastry, and one by M. Mukherjee, who discusses in detail the particular contributions of Mahalanobis in a paper entitled "Scientific Approach in Planning". The volume also includes several papers of a very general nature and of rather variable quality on philosophy and the purpose of economics and planning.

Both volumes are prefaced by a foreword by C. D. Deshmukh, a former president of the Indian Statistical Institute, and concluded with a note by the editors on the "Scientific Contributions of Mahalanobis", and a bibliography. We have here an impressive outline of the work of Mahalanobis, from some of his early work on meteorology and anthropometry to the founding of the Indian Statistical Institute in 1931, and the journal *Sankhyā* in 1933, his extensive work on the sampling of crops commencing in 1937, and the development of survey techniques, an important part of which was the institution of the National Sample Survey to provide periodic estimates of social and economic factors affecting the economy of India.

M. A. WALKER

Studies on the Piriform Lobe

By F. Valverde. Pp. vii+131. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1965.) 60*s*. net.

WITHIN the term 'piriform lobe', Dr. Valverde includes the olfactory bulb, parolfactory structures, piriform cortex and amygdala, together with their projection systems. The first part of this work consists of several experiments with lesions in various parts of the forebrain and the resulting degeneration stained by the Nauta method. The second part comprises Golgi studies of the relevant areas.

Attempting, as it does, to provide comprehensive coverage of the whole system of central olfactory connexions, Dr. Valverde's monograph achieves considerable unity of purpose, although there are inevitably many places where important topics are only superficially treated. No one familiar with neuroanatomical techniques can fail to recognize the enormous amount of painstaking observation which has gone into both the fibre degeneration experiments and also the Golgi studies, and it is notable that there are few workers in this field who have attempted a combined investigation using these two methods.

In the first part of this work, dealing with the degeneration studies, it must be admitted that a certain amount of coherence is lacking. It is not at all clear why the experiments are presented in the order in which they appear, and the text is made difficult to follow by the somewhat unnecessary fragmentation of the amygdaloid projection, and also by the detailed account of degeneration in unrelated systems.

The second part, comprising the Golgi material, is far more coherent, and the central olfactory connexions are followed serially from the olfactory bulb through the olfactory tubercle and piriform cortex to the amygdala and medial forebrain bundle. The very lucid descriptions are complemented by an outstandingly clear set of illustrations, covering every point mentioned in the text —a comment which applies equally to the first part of the book.

On the whole, *Studies on the Piriform Lobe* clearly summarizes present knowledge on this area, while adding further information at several points. It should be welcome at a time when the attention of research workers in many different fields is being directed once again to the phylogenetically older parts of the forebrain.

G. RAISMAN

Hypnotic Susceptibility

By Ernest R. Hilgard. Pp. xiii+434. (New York: Harcourt, Brace and World, Inc., 1965.) 9.50 dollars.

A LARGE number of studies designed to investigate various hypnotic phenomena have been carried out by Ernest Hilgard and his co-workers on a considerable number of college students during the past eight years. Individual differences in 'hypnotizability' have been a major area of interest and in the course of their investigations several scales were developed for the quantitative assessment of hypnotic susceptibility. This book is the outcome of these investigations, and is primarily concerned with a description of the various scales, together with a discussion of the data obtained from their use.

There are three general purpose scales and a scale for yielding profiles of hypnotic ability. Convincing statistical evidence is given concerning their validity and reliability. The items used in the construction of these scales and the resulting data provide the basis for an excellent and comprehensive discussion of many of the major hypnotic phenomena. Indeed, the whole subject of hypnosis is most carefully examined.

The latter part of the book is concerned with the relation of hypnotic susceptibility to a number of personality variables such as age, sex, intelligence, psychiatric diagnoses, attitudes to hypnosis and responses to various personality inventories. Although some significant correlations do emerge, they are insufficient to characterize the hypnotizable person clearly. One of the final chapters is written by the wife of the author, who makes some very interesting inferences from clinical case studies.

The presentation of these susceptibility scales is the central point of the book. However, it also provides a comprehensive and up-to-date review of present-day knowledge on this ill-understood subject. It is a valuable book not only to those concerned with the more academic aspects of psychology, but also to those who make use of hypnosis in the clinical field. A considerable amount of space is given to statistical procedures, which does tend to make it heavy reading for those not specifically interested in this aspect, but a brief and succinct summary is given at the end of each chapter.

A. L. PARKER

Readings in Animal Behaviour

Edited by Prof. Thomas E. McGill. Pp. x+592. (New York and London: Holt, Rinehart and Winston, 1965.) 96*s*.

THIS book is intended as a survey of research in the broad field of animal behaviour, presented in the form of fifty-five representative research papers and reviews, of which all but three were published within the past ten years. It is intended for advanced students of zoology and postgraduates. The contributions are fairly equally balanced between behavioural genetics; the neural and hormonal control of behaviour; the development of behaviour and imprinting; sensory processes, communication and orientation; learning and motivation; and studies of social behaviour, ethology and evolution. Thus there are some seven or eight articles covering each of these areas of research. Very sensibly, less than a fifth of these papers is theoretical. The student to whom the book is addressed, then, receives a handsome collection of original sources which have been chosen to illustrate not only a number of different approaches to the analysis of animal behaviour, but also several strategies in the dissemination of the results of behavioural research.

Probably this approach is of more value in the United States, where the pressures on library facilities for students are greater than they are in Britain, but the editor is to be congratulated on his happy choice of readings. Reviews by F. A. Beach, R. A. Hinde, W. H. Thorpe, N. Tinbergen and others accompany texts by V. G. Dethier, K. von Frisch, H. F. Harlow, H. Lissman, D. S. Lehrman and T. C. Schneirla, to mention only a few of the selected authors. Although the research which is represented is of varying fundamental importance, almost all of it is of high quality; most comparative psychologists will find it pleasant to have this collection on their shelves.

A. D. BLEST

Polychaeta of the Far Eastern Seas of the U.S.S.R.

By P. V. Ushakov. (Keys to the Fauna of the U.S.S.R., No. 56.) Translated from the Russian by Jean Salkind. Edited by Rae Finesilver. Pp. xxvi+419. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 121*s*. 6*d*.

THIS is an exact translation of Prof. Ushakov's important book as it appeared in 1955. Most of the text consists of keys and brief diagnoses of the forms, but there are introductory chapters on the biology of the polychaeta and the zoogeography of the Far Eastern forms. Users of the translation would be wise to bear in mind the warning given by Prof. Ushakov in his preface, that his work is an interim report on a rapidly developing field: "All the families inhabiting U.S.S.R. seas should be largely revised in the near future". The latest reference in the extensive bibliography is dated 1953, and valuable studies of Far Eastern polychaeta, including taxonomic revisions with zoogeographical implications, have appeared since then.

G. P. WELLS

TECHNOLOGICAL MANPOWER AND POSTGRADUATE STUDY

By PROF. JAMES GREIG

Department of Electrical Engineering, King's College, London, W.C.2

FEW subjects which have received as much intensive and sustained study in recent years as has that of scientific and technological manpower in Great Britain can have proved themselves to be more tantalizingly elusive.

Educational aims, professional requirements, recruitment, utilization and national needs are factors which, together with their interrelations, have been investigated and assessed. Many valuable statistical data have been collected and analysed and forecasts have been prepared, but it is evident that inherent uncertainties and ambiguities have rendered much of the work indefinite and inconclusive.

The Committee on Manpower Resources for Science and Technology which is charged with the duty of advising the Government on the matter has recently submitted a report in which the problems to be investigated are restated, the lines of action being followed are described and certain recommendations for immediate action are made*. The scope of the Committee's investigation is described as covering such matters as statistical sources; factors affecting the choice of a scientific or technological career; preparation for employment in the context of a rapidly changing technology; the better utilization of scientific and technological manpower; and the relevance of technical supporting staff.

On the statistical side, a survey is in progress utilizing the data of the Census of Scientific and Technological Qualifications of 1961 which, in due course, will be supplemented by a similar census in the present year. From these data, together with the triennial surveys of the Ministry of Labour which have been carried out since 1956, a general assessment will be made of the supply-and-demand position at the present time and also in relation to employers' forecasts for 1968. Statistics from the University Grants Committee, the education departments and the professional institutions will provide information about the inflow of educationally qualified personnel. The requirements for particular disciplines and technologies will be estimated, and it is pointed out that such estimates must be related not only to employers' forecasts but also to rates of economic expansion suggested by national policy.

The factors influencing the choice of subjects of study at school or in higher education are clearly matters of direct concern to the Committee. In the field, investigations are being made by the Schools Council in relation to England and Wales, and the Council for Scientific Policy has initiated a study of the flow of candidates from schools into scientific and technological courses in higher education.

The fact that so very few schoolmasters had the first-hand knowledge of applied science or technology that would enable them to present these subjects in a stimulating and inspiring way was a very severe handicap and one which means must be devised to overcome.

The relationship of the educational system to the requirements of employers is being investigated from two points of view. Starting with consideration of the problem of stating the requirements of industry in terms relevant to education, it is proposed to enquire into whether, and at what stage, there should be a change of emphasis in university or college of technology courses to match industrial needs more closely. An examination is also being made of the extent to which individuals from different academic disciplines are in practice interchangeable. The report commends the policy of retention by the colleges of advanced technology, as they become universities, of sandwich courses in which periods of industrial training are interleaved with academic studies.

Postgraduate courses are considered to have an important part to play in enabling science graduates to become technologists and in educating graduate technologists in specialist subjects. Appreciative reference is made to the encouragement given to the development of suitable courses by the Awards Committee of the Science Research Council by its allocation of awards to technology.

The findings of the Arthur Report, which is entitled "Enquiry into Longer Term Postgraduate Courses for Engineers and Technologists"†, have been considered by the University Grants Committee, by the Postgraduate Awards Committee of the Science Research Council and by professional institutions concerned with technology, and from this consideration it is clear that industry must formulate its needs for postgraduate courses more clearly if educational institutions are to meet them more satisfactorily.

The scope of the enquiry with which the Arthur Report deals has been limited to full-time courses of at least one month's duration. Basic information as to the number and type of courses being run in the session 1964–65 and in the previous session was obtained from a questionnaire sent to vice-chancellors, principals and heads of technological departments. The questionnaire was comprehensive in that it comprised the nature and duration of courses, the subject coverage, the qualification awarded and staffing, together with personal data on students and observations as to industrial support. Questionnaires were sent to 161 university departments, ten colleges of advanced technology and to thirty other colleges. A full complement of returns was obtained and, from the analysis of these, factual information was derived which is summarized in one chapter of the Report. In the session 1964–65 there were 264 separate postgraduate courses run in 120 university or college departments. Three of the courses were concerned predominantly with management, twenty-seven were conversion courses, while 234 represented advanced studies. The total number of students was 1,966 giving an average of some seven students in each course. Of these, 1,642 were pursuing courses of at least a full session duration and the remaining 324 were following shorter courses —just less than 45 per cent were from overseas.

In the same session there were 2,723 postgraduates engaged in research in some branch of technology. Analysis by type of course showed the larger numbers of students to be as follows:

Mechanical engineering	389	Aeronautical engineering	178
Civil engineering	345	Chemical engineering	166
Electrical engineering	306	Production engineering	143

A table setting out the sources of financial assistance to United Kingdom students showed that of 897 who had supplied information, 274 had awards from the Department of Scientific and Industrial Research, 207 were

* Committee on Manpower Resources for Science and Technology. A Review of the Scope and Problems of Scientific and Technological Manpower Policy. Pp. ii+17. (Cmnd. 2800.) (London: H.M.S O., 1965) 1s. 6d. net.

† *Enquiry into Longer Term Postgraduate Courses for Engineers and Technologists, 1964–65.* By H. Arthur, Department of Education and Science. (London, H.M.S.O.) 4s. 6d. net.

supported by their employers, 163 had scholarships and 121 had local education authority awards.

Two short sections of the Report describe in outline the arrangements for discussions with industrial representatives and with academic staff, and these are followed by a fairly detailed presentation, appropriately sub-divided, of views emerging from the discussions. The author emphasizes that it has been his aim to assemble the wide range of views with some sort of coherent and logical pattern and to present them objectively.

It is clear that relatively few students on the type of postgraduate course under review are sponsored by industry and this may be taken as an indication that industry does not regard existing courses as meeting a real or urgent need.

For industrial staff engaged on production work, management is of primary concern and there is increasing recognition of the need for such a staff to have further education and training in efficiency techniques and general management. Much management training is carried on internally by the larger industrial organizations and this is often supplemented by short courses in universities and colleges. Long postgraduate courses in management, pursued immediately after graduation, are not favoured by industry, as it is believed that such studies can be pursued more effectively after some industrial experience, while at a later stage there are all the problems of releasing men of some seniority.

For staff engaged in research, development and design it might be expected that postgraduate studies dealing with advanced fundamental or specialist topics would be recognized as meeting a real need. The numbers sponsored by industry in such courses are, however, still small.

On the research side the facilities and the fund of expert knowledge in the laboratories of the large organizations are great and sustain the claim that the new graduate can acquire all the specialist knowledge which he requires more effectively within the organization than by attending a postgraduate course in an academic institution. From the industrial side the criticism is made that many postgraduate courses merely constitute extensions of the first-degree course and have little relevance to the needs of industry. Some university engineering departments conceive their main function as the pursuit of fundamental knowledge, and this, too, may be regarded as rather remote from the immediate requirements of industry. Although there are some notable exceptions, industry has not shown any great eagerness to recruit from the output of postgraduate courses. From the academic side it is suggested that industry is just not sufficiently forward looking. The incompatibility of those views and the resulting situation suggest that there is, both in the universities and in industry, a regrettable lack of appreciation and of understanding of the partners' interests and problems.

Although the support for courses of 9 months' duration or longer has been meagre, the demand for shorter, more specific courses has been considerable, and this, in some instances, has led to the organization of a full session's course into a series of short self-contained units for which single-units students could be accepted. The short course may well find increasing application in the form of the periodic refresher which the increasing rate of technological advance will inevitably demand.

With regard to the financing of students on postgraduate courses, it is pointed out that the trend in certain of the newer universities towards a more general type of engineering first-degree course might well accentuate the need for postgraduate studies, and if expansion should occur on a major scale as an integral part of engineering education, there could be little justification for expecting the burden to be borne by industry. The conditions of award for Science Research Council grants and the scale of the awards attracted some criticism from the university side.

Interchange of staff by secondment between industrial organizations and university departments, although accepted as desirable, was practised on only a very small scale.

It was evident that the means for co-ordinating industrial needs and for disseminating information about the availability of courses were inadequate and the provision of some form of clearing-house had been suggested.

One of the most interesting incidental observations in the first of these two documents relates to technical supporting staff. Recognizing the danger of serious neglect of educational development for technicians, the Committee on Manpower Resources welcomes the inclusion in the Manpower Survey of 1965 of questions which will yield information for the United Kingdom as a whole about the utilization and the demand for technicians. The comment is made that when a picture of the national need for technicians has been formed it may be possible for the first time to ascertain how far the present provision for their education and training is sufficient.

The results of this enquiry will be valuable in themselves, but it is important that they should be linked with the more fundamental investigation which is described as the "identification of motivations, character and abilities relevant to science and technology and the factors which govern the choice by individuals of a scientific or technological career". Insufficient attention has been directed in the past to the qualities which go to the making of the first-class technician and to the cultivation of his skills within the educational system. His industrial training, like his function, has been ill defined and there is here an area in which the activities of the Industrial Training Boards could be of especial benefit.

The factual information furnished in the Arthur Report reveals a situation which commands attention. Nearly one hundred courses out of a total of 264 with four or fewer students is a statistical fact calculated to invite the condemnation of the educational administrator. From the discussions there appears to emerge a state of misunderstanding almost amounting to mistrust between industry and the universities, a state of affairs quite unrecognized by many familiar with both sides of the partnership.

Some lack of mutual understanding there certainly is, but it is not of a major character. The Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom convened in December 1965 a joint conference with the Confederation of British Industry under the title "Industry and the Universities—Aspects of Interdependence". In the course of the conference, reference was made to a proposal to try to establish some permanent lines of communication between the Confederation and the universities, and at the conclusion of the meeting the chairman stated that the matter would be further explored. Such a development could facilitate in a most effective way the interchange of ideas and, equally importantly, their interpretation.

When, as at present, there is a persistent shortage of qualified scientific personnel, it is scarcely to be expected that industry will willingly release men for postgraduate studies which are in the nature of a long-term investment. The short *ad hoc* course which is of more immediate application does receive support, but the statement in the Report that "many postgraduate courses offered by academic institutions are criticized by industry as being merely extensions of the first degree course . . ." does demonstrate failure to appreciate the real issues.

The man whose mental calibre and personal qualities give promise of research ability requires, after completing his first degree in engineering, an introduction to modern powerful mathematical techniques and he must acquire a knowledge of the physics of the solid state, of thermodynamics and hydrodynamics, sufficiently advanced and fundamental to enable him to co-operate effectively with mathematicians and physicists. Such rigorous

fundamental knowledge can best be acquired when absorptive powers are at their peak and when mathematical manipulative skill is freshly developed and readily exercised—that is to say, immediately after graduation. A course of postgraduate study dealing with such topics can provide the young research engineer with the most powerful tools of his trade and with the skill to use them.

The cogent observation is made in the Arthur Report that "There is a strong feeling that postgraduate courses seeking to give information and experience of a really advanced nature need to draw on an active and successful research programme. This indeed is the context within which many postgraduate courses are offered by university departments. . . ."

It is precisely for this reason that the maintenance of postgraduate courses of an advanced fundamental character should be encouraged, notwithstanding smallness of numbers in individual schools. Such courses give research specialists the opportunity to engage in advanced teaching and, indirectly, expose the graduate student to the stimulus and the challenge of research. They also often serve as a preliminary requirement to entry on a programme of research leading to the Ph.D. degree.

Courses of a specialist technological character or concerned with advanced design methods fall into an entirely different category. Advanced mathematical techniques will, of course, be involved, together with physical phenomena and physical theories, sometimes of a highly specialized character, but these will always be developed directly in relation to industrial application. It is the introduction of the industrial factors that renders these studies more readily assimilable by students who have had some industrial experience.

The advanced fundamental type of course does not, as a rule, require the appointment of specialist staff or involve the provision of particularly expensive equipment. The specialist technological course may, however, be expensive on both those counts.

Courses which are either introductory to research or which contribute to the more effective pursuit of research, advanced development or design, lie clearly within the area of the Science Research Council's responsibilities, and the furtherance of their development necessarily implies the exercise of some directive influence and control.

The development of postgraduate study was greatly fostered and encouraged by the recognition by the Department of Scientific and Industrial Research from 1957 onwards of many such courses for purposes of postgraduate awards.

For some time prior to the publication of the Arthur Report, the Council has been conducting a review of the courses of postgraduate study to which approval has been given and, following the review, the Council withdrew approval from a number of courses for which the numerical support had been very small. In the interests of the efficient and economic utilization of resources this action, aimed at achieving some measure of rationalization, was fully justified. There does, however, appear to have been some lack of recognition of the important differences between the claims of courses of a fundamental character and those of specialist technological type. The unrestricted multiplication of closely similar courses of specialist technological type, with only small numbers of students, is clearly indefensible on economic grounds. The same considerations do not apply to the fundamental type of course, and any policy of rationalization which fails to take account of the long-term importance of such courses may well prove to be false economy.

CONTROL OF WEATHER AND CLIMATE

By PROF. R. C. SUTCLIFFE

Department of Meteorology, University of Reading

IN the United States, over the past few years, great expansion has repeatedly been urged in research in atmospheric science, and especially in that part of the science directly relevant to weather and climate. There is a parallel interest also in the U.S.S.R., a point which is not overlooked in American advocacy and, through various organizations, there has been notable initiative in international circles. By its Resolution 1802 (1962), the General Assembly of the United Nations called for the development of world programmes. The World Meteorological Organization as a special agency of the United Nations was called on to look to its parish and bring meteorological services up to date; it has responded by the adoption of the concept of the World Weather Watch, an ambitious and costly scheme of continuous global surveillance of the atmosphere. At the same time the International Council of Scientific Unions, as the non-governmental body representing academic interests, was invited to develop a complementary research programme, which is now taking shape through the rather slow but generally irresistible machinery of international committees. A further pressure comes from the United Nations Economic and Social Council through its Advisory Committee on the Application of Science and Technology to Development. In its Second Report published a year ago (May 1965), "Improved Weather Forecasting" and "Weather Modification and Control" are included in a list of a "limited number of especially important problems of research or application".

In Great Britain, not much has yet been heard outside committees and corridors of a national response to these weighty international developments, but this must come before long as the British position in international programmes becomes defined. It is therefore against this background of world interest in meteorology as a whole that we may examine a valuable report recently submitted by the Committee on Atmospheric Sciences to the United States National Academy of Sciences on the special subject of weather and climate modification*. In Britain the subject has barely crossed the threshold of scepticism to be fathered by respectable scientists. Neither have commercial rainmakers succeeded in selling their services to British interests, private or public, on any significant scale. But the tremendous potential of a capability to control the weather and climate has impressed itself so forcibly in the United States, and in the U.S.S.R., as to make the subject a major plank in the national scientific platform. By contrast, a new brochure on *Research in the Meteorological Office* makes no mention of the subject except as a "distant speculative prospect". This may well be a correct description, but the time is ripe for a national reappraisal.

The United States report is presented in two volumes, the first being a summary with recommendations sufficiently brief to be worth the attention of anyone interested

* *Weather and Climate Modification: Problems and Prospects.* 2 volumes. Pp 28 and 198. (National Academy of Sciences, Washington, D.C., 1966) 5 dollars.

in American thinking on world science. The second volume, a review of research and development, provides within its compass of nearly 200 pages quite the most penetrating and most up-to-date appreciation of many of the central problems of weather and climate that has appeared for some time. Every meteorologist will find profit in reading it, even if the control of the atmosphere presents no appeal.

It is not easy further to summarize this survey, for which Volume 1 is itself already the summary of a summary, but a few salient points may be quoted. First, as a measure of the seriousness of purpose, there are the dollars. In 1965 the support from Federal funds for "Weather Modification Programmes" was almost 5 million dollars out of a total for meteorological research of 84 million dollars, all within a total budget for meteorological services and research of 430 million dollars. Comparable figures for the U.S.S.R. are estimated in the report at 20, 70–80 and 700–800 million dollars, respectively: "The Soviets have assigned a higher priority for weather modification than we [the U.S.A.] have". (In Great Britain the overall effort per head of the population is lower by a factor of ten, and that directed specifically to weather modification is not identifiable.) The formal recommendation on this matter reads: "We recommend that immediate steps be taken by agencies to raise the support [for weather modification] from the 1965 level of $5 million to at least $30 million by 1970". This is large-scale research by any standards.

Among the scientific and technical findings, by far the most significant of the positive conclusions refers to the now much-tried, if not always well-tried, seeding by silver iodide. This stems directly from the pioneer experiments of Schaefer in 1946 when real supercooled clouds were first visibly modified. Since that time there has been much careful research and much more inadequately documented activity, but hitherto, of the many independent national and international bodies to study the evidence, probably none has been more than encouragingly non-committal. Now a definite step—one hopes it is a step forward—has been taken with the words: "We find some evidence for precipitation increases of as much as 10 or even 20 per cent over areas as large as 1,000 square miles over periods ranging from weeks to years". A large number of commercial operations are evaluated, and even these, for all their incompleteness as scientific evidence, are given a guarded but definitely favourable report. The qualifying remarks and critical comments do, however, still give the impression that no decisive scientific step forward has in fact been taken, that the evidence is still confusing and unreliable, and that the favourable verdict was perhaps a little swayed by the feeling that after 20 years an expert body must do something more than sit on the fence.

Setting aside the risk that their scientific opinion may be misquoted to mislead the public into useless expenditure, one feels, however, that their verdict is fair. Uncertain and equivocal as much of the evidence may be, there are far too many positive indications to permit the matter to be dropped if the outcome is as important as is believed. Thus the formal recommendations call for "several carefully designed, randomized seeding experiments". "We recommend that attention be given immediately to careful monitoring and regulation of operational programmes for weather modification."

The report, of course, ranges far wider than the area of cloud seeding for increasing local rain. "Experiments in lightning suppression are beginning to show some promising results." "With respect to both hurricane and tornado modification, no practical success can be expected before the development of adequate theories. . . ." "The dissipation of supercooled fogs and low stratus clouds over limited areas is operationally practicable."

On the modification of world climate, we have the welcome view that "As long as our understanding is thus limited, to embark on a vast experiment in the atmosphere would amount to gross irresponsibility". (This philosophy did not, however, prevent the testing of nuclear devices.) Much weight is given to the promise of theoretical mathematical models for testing the effects of modifications with the conclusion that "In 10 years our computer requirements may grow by two or three orders of magnitude". "We recommend, therefore, that all necessary steps be taken to encourage the computer industry to respond to these prospective requirements."

Among other items for attention come "A comprehensive exploration of hurricane energetics", "A comprehensive investigation of hailstorms", water budgets, boundary-layer exchange processes, theoretical models of condensation and precipitation mechanisms, meteorological effects of atmosphere pollution. . . . The need for the greatest care in statistical evaluation calls for "much more direct and continuing communication between statisticians and experimenters". "The tropics have been grossly neglected." There are numerous other opinions and proposals of far-reaching importance in a report which is as nearly unbiased as any interested group could be expected to be. The National Academy's Panel on Weather and Climate Modification has worked closely with a corresponding official body, the Commission on Weather Modification of the National Science Foundation, which has issued almost simultaneously its own special report†, in addition to the seventh annual report on *Weather Modification* from the Foundation to the President of the United States‡. All these are substantial publications, overlapping in many ways but supporting each other in the general thesis that weather control is a field of study calling for the most serious attention. To quote from the seventh annual report: "In 1965 the key words are no longer 'whether' and 'when': they are 'what', 'how' and 'who' ".

The report of the Special Commission of the National Science Foundation has sections and recommendations on the "Biological Aspects", "Statistical Aspects", "The Human Effects", "Legal and Legislative Effects", as well as "International Relations and Finance", raising questions of public policy of much novelty and interest, going far beyond the scope of this brief review.

Already there have been political repercussions, and in February this year two Bills were introduced in the U.S. Senate calling for the development of large programmes in weather modification. In one of these an expenditure of 155 million dollars in three years is contemplated. There is therefore every reason to be confident that research and experiment on something like the grand scale envisaged will in fact go forward in the United States, and doubtless also in the U.S.S.R.

How is it, one may ask, that these countries can justify an investment of effort towards a defined practical goal on a scale which makes that in many other leading countries seem trivial? There is one consideration which, although certainly not the only one or even the major one, is sufficient. Knowledge on how to improve the climate of one's own country can scarcely fail to imply knowledge on how to impair that elsewhere, and there could be no more potent weapon. Obviously, as the world stands at present, the two major powers cannot afford not to keep abreast of knowledge of this kind. For other countries there will be the usual hard choice of priorities, but the fact that weather control is not at the moment of pressing urgency does not mean that it can safely be ignored.

RANDOM SCANNING OF TAXONOMIC CHARACTERS

By PROF. R. R. SOKAL and PROF. F. J. ROHLF
Department of Entomology, University of Kansas, Lawrence, Kansas

ONE of the principal impediments to the development of numerical taxonomy[1] is the difficulty biologists have of measuring and recording taxonomic characters at speeds and in quantities commensurate with the ability of modern computers to process these data[2]. A simple possible solution would be to record agreement in visible structures over randomly selected minute areas of the images of pairs of organisms. Such a procedure would be feasible by means of optical scanners applied to photographs, films, microscope slides, or drawings. The following preliminary investigation evaluates the feasibility of such an approach.

Random masks, made from twenty-five IBM cards each perforated with twenty-five randomly chosen holes, were placed over black-and-white drawings of two groups of 'organisms'. One group consisted of twenty-nine 'species' of Caminalcules (Fig. 1), imaginary animals generated by J. H. Camin to study taxonomic and phylogenetic principles[3,4]. The second group comprised published illustrations of pupae of thirty-two species of culicine mosquitoes[5]. Labelling was deleted from these drawings (Fig. 2). The illustrations were enlarged by a third and mounted with morphological reference points aligned in a standard position. Each illustration was overlaid with all masks and each of the 625 holes was scored '1' when a black line appeared through it and '0' if no black showed. Illustrations were compared on the basis of matching scores for corresponding masks and holes. Matrices of distance coefficients were computed and clustered[1].

The resulting phenogram (dendrogram of phenetic relationships[6]) of the Caminalcules is shown in Fig. 3. The 'genera' previously established by orthodox taxonomists and by conventional numerical taxonomy[4] were again classified correctly. An exception is the separation of species 21 from genus *B* which is peculiar to the distance

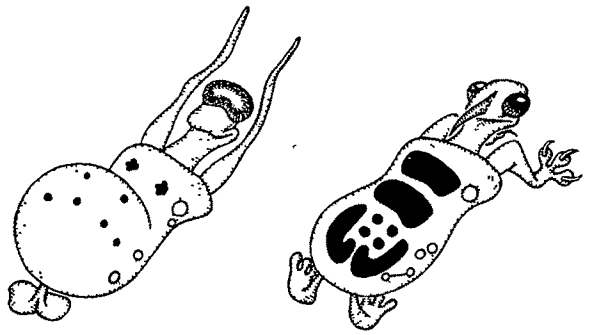

Fig. 1 'Species' 1 and 12 of the Caminalcules, an imaginary group of animals. All twenty-nine 'Recent' species are illustrated elsewhere (ref. 4)

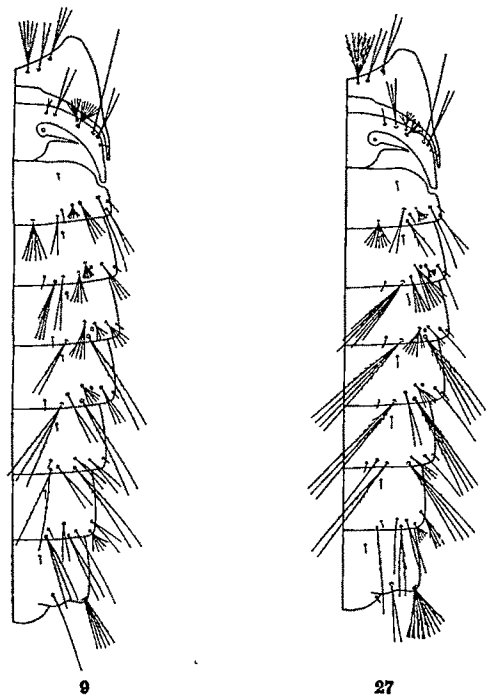

Fig. 2. Pupae of mosquito species 9 [*Aedes* (*Ochlerotatus*) *excrucians*] and 27 [*Culiseta* (*Culiseta*) *inornata*] as modified from Darsie (ref. 5) for random scanning

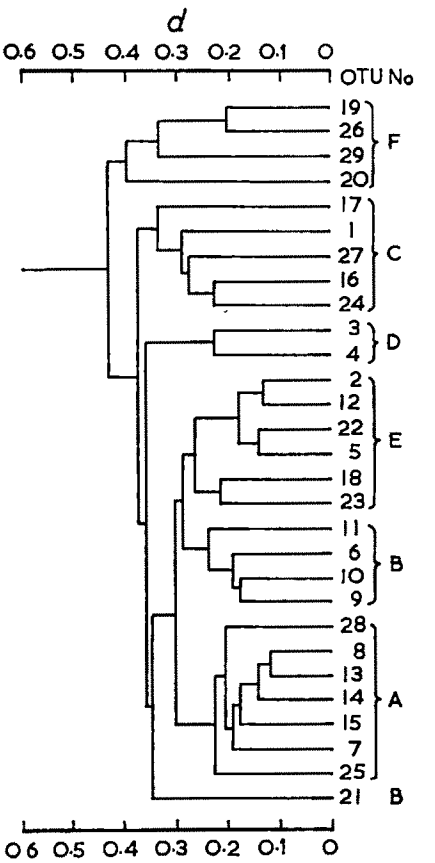

Fig. 3. Phenogram of the Caminalcules computed from a distance matrix based on the random scanning method. Clustering by the unweighted pair-group method using arithmetic averages (ref. 1). The similarity scale is shown as the abscissa. Numbers at the tips of the phenogram correspond to 'species' code numbers. Capital letters to the right of brackets indicate 'generic' groups recognized by teams of orthodox taxonomists and by a conventional numerical taxonomic investigation (ref. 4)

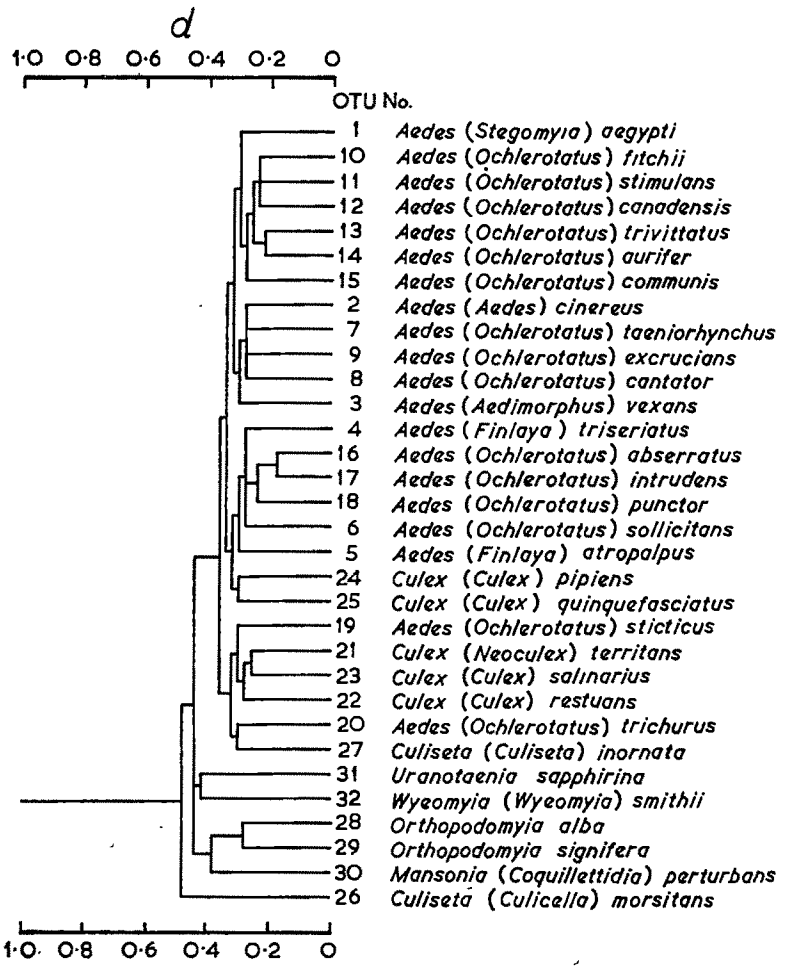

Fig. 4. Phenogram of the images of the pupae of thirty-two species of culicine mosquitoes (ref. 5). This phenogram has been computed from a distance matrix based on the random scanning method. Species code numbers and names are given at the tips of the phenogram. Clustering method and explanatory comments as for Fig. 3

function and is not a consequence of the random scanning[4]. Genus *D* is, however, separated from genus *E* with which previous orthodox and numerical classifications had placed it. Closer study revealed that group *D* had 'evolved' an elongation in which the body grew anteriorly, obliterating the neck. Since the drawings were positioned by the 'shoulders' for reference, species in groups *E* and *D* did not expose 'homologous' structures to the mask. Programmed transformation of the images, stretching some parts and compressing others to increase overall similarity, might have overcome this problem.

In the mosquito study the genera emerged quite satisfactorily, except that species 24 and 25 (*Culex*) are placed with *Aedes*, while species 19 and 20 (*Aedes*) are placed with *Culex*. A study by conventional numerical taxonomy[4] showed better assortment of the genera *Aedes* and *Culex*, but split up the genus *Orthopodomyia* which was retained by the random scanning method. Species 31 (*Uranotaenia*) was more distant in the conventional numerical study than by random scanning. On the whole, the relations between the classifications arrived at by random scanning and conventional numerical taxonomy are as good as can be expected by separate numerical taxonomic investigations[7].

The random scanning method clearly yields meaningful classifications. Whenever phenetic taxonomies are acceptable[6], the method described here may provide a rapid and reliable approach. Problems of size and orientation of organisms remain to be worked out, but should not present insuperable technical difficulties. The implications of the success of the method are that experience and insight into the presumed biological and phylogenetic significance of characters may be less important for obtaining satisfactory classifications than had been generally supposed.

This investigation was supported by a grant and also in part by a U.S. Public Health Service research career programme award, both from the National Institute of General Medical Sciences, to R. R. S. The computations were carried out on an IBM 7040 digital computer at the University of Kansas Computation Center using the *NTSYS* programmes developed by F. J. R. We thank Prof. C. D. Michener and Prof. J. H. Camin for their advice, and William G. Hanis for technical assistance.

A REVIEW OF THE OLDOWAN CULTURE FROM OLDUVAI GORGE, TANZANIA

By MRS. M. D. LEAKEY
National Museum Centre for Prehistory and Palaeontology, Nairobi, Kenya

THE discovery of a primitive stone industry in Bed I at Olduvai Gorge was first recorded in *Nature* on December 26, 1931. The name Oldowan was later given to this culture, which had been shown to precede the so-called 'Chellean'[1]. Various authors have since used the terms 'Pebble Culture' or '*Civilisation à galets aménagés*' for analogous industries. But these names are misleading, for, as my husband pointed out when describing Oldowan choppers, "specimens occur which have been made from nodules of chert and others from rough irregular lumps of quartz and quartzite, and there seems little doubt that sites containing this culture might be found when tools made from water-worn pebbles are entirely absent"[2]. The aforementioned terms are primarily concerned with the nature of the materials often used to make choppers, rather than stressing the dominant tool types, and their use has led to misconceptions regarding the Oldowan cultural assemblage, taken as a whole.

During the recent Wenner-Gren symposium on "The Systematic Investigation of the African later Tertiary and Quaternary", held at Burg Wartenstein, the question of alternative terminology for the Oldowan was debated

at some length. The term was considered by some to be inapplicable to areas outside East Africa, particularly to North Africa, where the tools so far recorded consist only of choppers, and where a number of Oldowan cultural elements such as small flake tools appear to be absent. It should be borne in mind, however, that although the existence of small tools in the Oldowan was tentatively recorded during the pioneer work at Olduvai, choppers were then considered to be the essential characteristic of the industry. This conception persisted until systematic exploration of sealed living sites was undertaken. When comparable sites are found and excavated in other areas, it is likely that additional tool forms will be found, similar to those of the Oldowan from Olduvai Gorge.

In the description of the Oldowan published in 1951[3], it was stated that a total of seventy-three tools were obtained *in situ* from four different levels in Bed I, one of which is described as a boulder bed. This level is now known to be within Bed II and to contain an industry rather more evolved than the typical Oldowan. It was also noted that small rough end-scrapers and utilized flakes probably formed part of the Oldowan assemblage. This has been fully confirmed and it has also become evident that there is a considerable diversity of tool types and close conformity within certain groups of tools, indicating that tool-making had already attained a measure of standardization, even at the period represented by the lower levels of Bed I, which can now be dated in the region of 1·75 million years with some degree of confidence[4].

In order that the cultural assemblage may be more generally understood, and because some months must still elapse before the full report on the excavations can be completed, it seems desirable to issue a preliminary report on the additional elements which have come to light as a result of detailed study of the assemblages recovered from sealed living sites in Bed I and the base of Bed II during the excavations of the past few years.

The cultural material discussed in the present article extends in time span from the earliest known occupation level in Bed I to a horizon a few feet below the aeolian tuff[5] in the lower part of Bed II. This represents a period of desiccation, and coincides with a break of some magnitude in the cultural and faunal sequence. Whereas there are no appreciable differences to be seen in the stone industry from the material at present under review, analysis of material from higher levels in middle and upper Bed II, now in progress, indicates that a change in cultural tradition took place at a time corresponding to the deposition of the aeolian tuff. Similarly, study of the faunal remains has revealed that a number of mammalian genera commonly found in Bed I do not occur in levels above the aeolian tuff, while other species and genera appear in these deposits for the first time[6].

The present re-evaluation of the cultural material is based on assemblages obtained from four excavated sites, which occur in the following stratigraphic sequence:

HWK East, level 1	Base of Bed II
FLK North, levels 1–6	Top of Bed I
FLK I, level 22 (*Zinjanthropus*)	20 ft. below the top of Bed I
DK I, levels 1–3	Immediately overlying the basalt (formerly regarded as the base of Bed I)

The following artefacts were obtained from these sites:

	HWK East, level 1	*FLK* North, levels 1–2	3	4	5	6	*FLK* I, '*Zinjanthropus*' level	*DK* I, levels 1–2	Total
Tools	51	134	28	19	31	6	60	155	484
Utilized material	65	196	49	27	32	22	145	205	741
Unmodified flakes, etc., including waste	32	516	94	20	92	95	2,358	889	4,096
									5,321

Each site represents an undisturbed living floor where occupational remains were found *in situ*, sealed in by subsequent deposits. The artefacts were invariably associated with a considerable number of broken mammalian bones and with natural, unmodified cobbles and other stones imported to the living sites by artificial means, but lacking evidence of utilization. These have been termed 'manuports'.

The assemblages recovered from all the sites excavated in Bed I and the base of Bed II are remarkably homogeneous. Such changes as do occur, within the period, do not seem to be of sufficient importance to justify any subdivision of the Oldowan. Variations exist, but these appear to have been caused by differences in the raw materials used, rather than by alterations in techniques or in preferred tool types. There is, however, considerable variability in the proportions of the components of the assemblages, not only at different sites and at different stratigraphic horizons, but also within different areas of a single living site.

This zoning of material is particularly evident at *FLK* I, on the occupation surface where the skull of *Australopithecus* (*Zinjanthropus*) *boisei* was found. Here, a densely concentrated mass of flakes, chips and small flake tools, together with smashed animal bones, occurred within a roughly circular area approximately 20 ft. in diameter. On the marginal areas of the site, the stone tools were generally of heavy-duty dimensions and were associated with a number of manuports, while the mammalian remains, consisting largely of non-marrow containing bones, were noticeably less broken. (There is usually a clear distinction in size and weight between tools classed as 'heavy' or 'light' duty. To ensure consistency in classification of the few borderline specimens, however, those in which the mean diameter exceeds 50 mm have been classed as heavy duty, and those in which it is 50 mm or less, as light duty.)

The characteristic elements of the Oldowan, as now re-defined, are as follows: (1) *Tools*—Choppers (side, end, bilateral, pointed, chisel-edged, polyhedral and discoidal); spheroids and sub-spheroids; proto-bifaces; scrapers, heavy and light duty; proto-burins. (2) *Utilized material*—'Anvils'; hammerstones; cobblestones; nodules and blocks; light-duty flakes, etc. (3) *Unmodified flakes and other fragments* (including waste). (4) *Unmodified cobblestones, nodules and blocks* imported to the living sites by human agency, but lacking evidence of utilization ('manuports').

Characteristics of the Industry

Tools

(*A*) *Choppers.*

Side. Usually made on cobblestones, the butt being formed by natural cortex, or else on blocks and nodules with a relatively thick butt. Flaking is usually bifacial, forming a jagged edge. Chipping and blunting from utilization are also generally present on both faces. The maximum measurement is bilateral and exceeds the length from the working edge to the butt.

End. As above, but the maximum length is from the working edge to the butt.

Bilateral. Oblong specimens with truncated, blunt ends; the lateral edges are bifacially flaked, to form two roughly parallel cutting edges.

Pointed. Usually side choppers, in which there is a well-defined medial point on the working edge, formed by the intersection of two deeply indented flake scars.

Chisel-edged. May be either side or end; the working edge is relatively narrow and is rotated so that it lies burin-wise, at right angles to the upper and lower faces.

All the aforementioned may be combined with hammerstone utilization on the butts.

Polyhedral. Angular implements with three or more cutting edges, usually intersecting. In fresh specimens, the edges project considerably, but when extensively utilized, they may be so blunt and reduced that the implement resembles a sub-spheroid. The edges are jagged and the utilization is generally bifacial. Whereas the majority of the choppers in the first five categories

are made on well-rounded cobblestones, the polyhedral variety is more often made on irregular-shaped nodules, in which advantage has been taken of natural projections in order to make a number of relatively short cutting edges.

Discoidal. A bifacially flaked jagged edge is present either on the whole or on the greater part of the circumference. These tools are generally made on parts of cobblestones, which appear to have been split in two and the halves then radially flaked. The majority retain part of the cortex surface on one face, while the opposite face is flaked over the whole surface and is markedly less convex.

(*B*) *Spheroids.* Stone balls, either faceted or pounded smooth on the exterior. The earliest recorded examples are from *FLK* North, in the top of Bed I.

(*C*) *Sub-spheroids.* Usually irregular and sub-spherical in general form. The entire surface is battered, with vestiges of ridges still visible. In some specimens the present form may have resulted either from intentional shaping or from excessive utilization of polyhedral choppers.

(*D*) *Proto-bifaces.* These are usually very crude. They are bifacially flaked along both lateral edges, in addition to the trimming at the tip. Some are high-backed with a flat undersurface and plano-convex cross-section at the working end. The butts are thick and are usually formed by the rounded surface of a cobblestone.

(*E*) *Scrapers.*

Heavy-duty. Generally made on cores with relatively steep one-directional trimming of the working edge. The lower face is flat or slightly concave and is formed by one or more negative flake scars or by a natural cleavage plane. The working edge is usually curved and relatively even, not jagged as in choppers. Utilization, when present, occurs predominantly on the convex face.

Light-duty. End and side scrapers are relatively common at certain levels. The working edges are generally rounded and are trimmed by means of fine, regular retouch, which may be either shallow or steep, depending on the thickness of the specimen. A number of hollow scrapers also occur. One or more notches may be present, generally trimmed from one direction only. They are variable in size, but none are recorded which exceed 25 mm in width or 5 mm in depth.

(*F*) *Proto-burins.* Characterized by a thick-set, relatively short working edge, at right angles to the main plane of the implement. Usually made on triangular fragments of tabular material, with the working edge at one apex. Retouch and utilization of the chisel edge is usually bifacial. These tools vary from small well-made specimens which could be termed true burins, to large crude examples with working edges up to 30 mm in width.

Utilized Material

(*A*) *'Anvils' or utilized angular blocks.* Angular, cuboid blocks or parts of cobblestones having one or more edges approximating a right angle. These edges are usually formed by natural cleavage planes or cortex surfaces, but a few specimens show a minimum of crude preparatory shaping. The particular type of utilization has caused shattering of the edges, with plunging flake scars on one or both sides. Incipient cones of percussion are sometimes evident on the flat surfaces. A small flat-based variety with a dorsal cone also occurs, particularly at the *Zinjanthropus* level at *FLK* I. The term 'anvil' is used as a convenient name for these tools, but does not necessarily imply that they were used exclusively for this purpose: some may also have been used manually.

(*B*) *Cobblestones, nodules and blocks.* Many nodules, mostly of the local vesicular basalt, together with some cobblestones and blocks, show battering and crude flaking from one or two directions, on natural sharp edges and projections. In all specimens the amount of flaking is negligible, with the greater part of the surface consisting of natural cortex. In most cases the flaking present seems to be entirely due to utilization, but there are a few specimens in which one or more flakes may have been intentionally detached in order to obtain crude, sharp edges.

(*C*) *Light-duty flakes, etc.* Flakes and other small fragments showing chipping and utilization from one or more edges, but no deliberate retouch. They may be divided into three categories: (*a*) with straight edges; (*b*) with concave or notched edges; (*c*) with convex edges. Specimens with straight or convex edges usually show chipping on both sides of the edge, while in notched specimens the chipping is generally from one direction only.

Unmodified Flakes, etc. (including Waste)

All the flakes are irregular. In a relatively high proportion of the lava specimens the cortex surface of the cobblestones from which they were struck is present on the dorsal surface. In quartz flakes there is a tendency for the striking platforms to be shattered; in other specimens the platforms are extremely variable, both in angle, form and dimensions.

It is possible to distinguish three types of flakes, as follows: (*a*) *Divergent.* Splayed outwards from the striking platform; either end or side struck. This is the most common type. (*b*) *Convergent.* Having the greatest width at the striking platform, either end or side struck. (*c*) *Approximately parallel-sided.* The platforms are generally of the same width as the body of the flake, end struck.

Resharpening flakes. These are relatively scarce and are almost certainly derived from resharpening the working edges of choppers.

Broken flakes and chips. The highest proportion of debitage from all sites consists of chips, broken flakes and other small fragments.

Core fragments. Small blocks and angular fragments apparently not derived from flakes but rather from shattering blocks of raw material.

Unmodified Stones

Manuports. Cobblestones and weathered nodules of lava, together with some blocks of quartz and other basement complex rocks, on which there is no evidence of utilization.

The salient features of the Oldowan may be summarized as follows:

The majority of choppers and other heavy-duty tools are made from lava, while the light-duty tools, such as small scrapers, are generally of quartz. At certain sites, particularly at *FLK* and *FLK* North, lava flakes are scarce, and are far fewer than the number that would have occurred had the lava tools found at these sites been made on the spot. In contrast, quartz flakes and other fragments are usually greatly in excess of the number which could have been struck from the associated quartz tools. It seems probable, therefore, that many of the quartz flakes were made expressly to be used as light-duty cutting tools, and that even those that retain undamaged edges may have been used for this purpose.

This interpretation is supported by evidence from an isolated group of artefacts found scattered around the skeleton of an elephant at *FLK* I North. These were not on a living floor and must represent the tools used for the specific purpose of cutting meat off the carcass. Quartz flakes were again disproportionately numerous, while the choppers and other larger tools were almost entirely made from lava. (It may be mentioned that experimental use of freshly struck quartz flakes for cutting meat from a carcass left little or no trace of utilization after the skin and soft tissues had been cut through. Chipping of the edges seldom occurred unless the flakes came into contact with bone.)

There is no indication that bone was deliberately worked during Oldowan times, although a few utilized bones do

occur. These have merely been abraded and polished through use and are not comparable, in any way, with the deliberately chipped and flaked bone tools which occur at sites in middle and upper Bed II.

The characteristic features of the Oldowan from Bed I and the base of Bed II may be briefly summarized as follows: More than 75 per cent of the total assemblage consists of unmodified flakes and other fragments—in which waste is included. Utilized material is normally rather more plentiful than tools, but not to a marked extent.

Choppers of various types are the dominant tools. In the case of side and end choppers, both of which were generally made on oblong cobblestones or nodules, a preference for the longer working edge obtainable on a side chopper may be inferred, since these are always greatly in excess of end choppers. The occurrence of polyhedral specimens appears to be largely controlled by the type of raw material available: they were particularly common at *DK* I when a high proportion of irregular-shaped weathered nodules were used, and scarce at *FLK* I North, where the raw material used for making choppers consisted almost entirely of smoothly rounded cobblestones. Discoidal specimens, however, indicate the beginning of a more specialized technique, in which the 'core' on which the tool was to be made was first prepared by breaking a cobblestone in two. Chisel-edged and pointed specimens are relatively scarce, but can be recognized as clearly defined types.

The average ratio of the working edge to the circumference in side and end choppers remains generally constant throughout the Oldowan, but there is considerable variation in the size of the specimens obtained from any particular level. The average mean diameter for the majority of all forms of choppers is 65 mm, but a few diminutive examples also occur, particularly at *DK* I, in which the mean diameter is 35 mm or less, and which weigh under 2 oz.

Proto-bifaces are extremely crude and the specimens show considerable diversity, both in technique and in morphology. They appear to represent some of the earliest and least skilful attempts to make bifaces, in which the methods used were still in an experimental stage, although the value of a pointed tool, with a cutting edge on the circumference, had begun to be appreciated. It is probably significant that these tools do not occur in the lower part of Bed I, and become increasingly common in the higher levels and in the basal levels of Bed II.

There are a few specimens from the top of Bed I (*FLK* I North) which can be classed as true spheroids, or artificially prepared stone balls, such as occur commonly in Bed II. Examples from the lower levels, however, are sub-spherical and, although extensively battered on the exterior, still retain quite prominent ridges.

Both heavy- and light-duty scrapers are relatively common. The former are frequently made on cobblestones and resemble choppers in overall size and weight, but may be distinguished by the nature of the working edges and of the secondary flake scars. Light-duty scrapers, which are particularly plentiful at *FLK* I, where they amount to 30 per cent of the tools, are generally made on flakes or small pieces of tabular quartz. Many are remarkable for their small size and excellent workmanship.

A number of the tools, which have been classed as proto-burins, bear such a close resemblance to the burin of more evolved industries that it has been suggested that the prefix 'proto' should be omitted. The series as a whole, however, includes a proportion of technically crude specimens which would be difficult to class as burins, without some qualification.

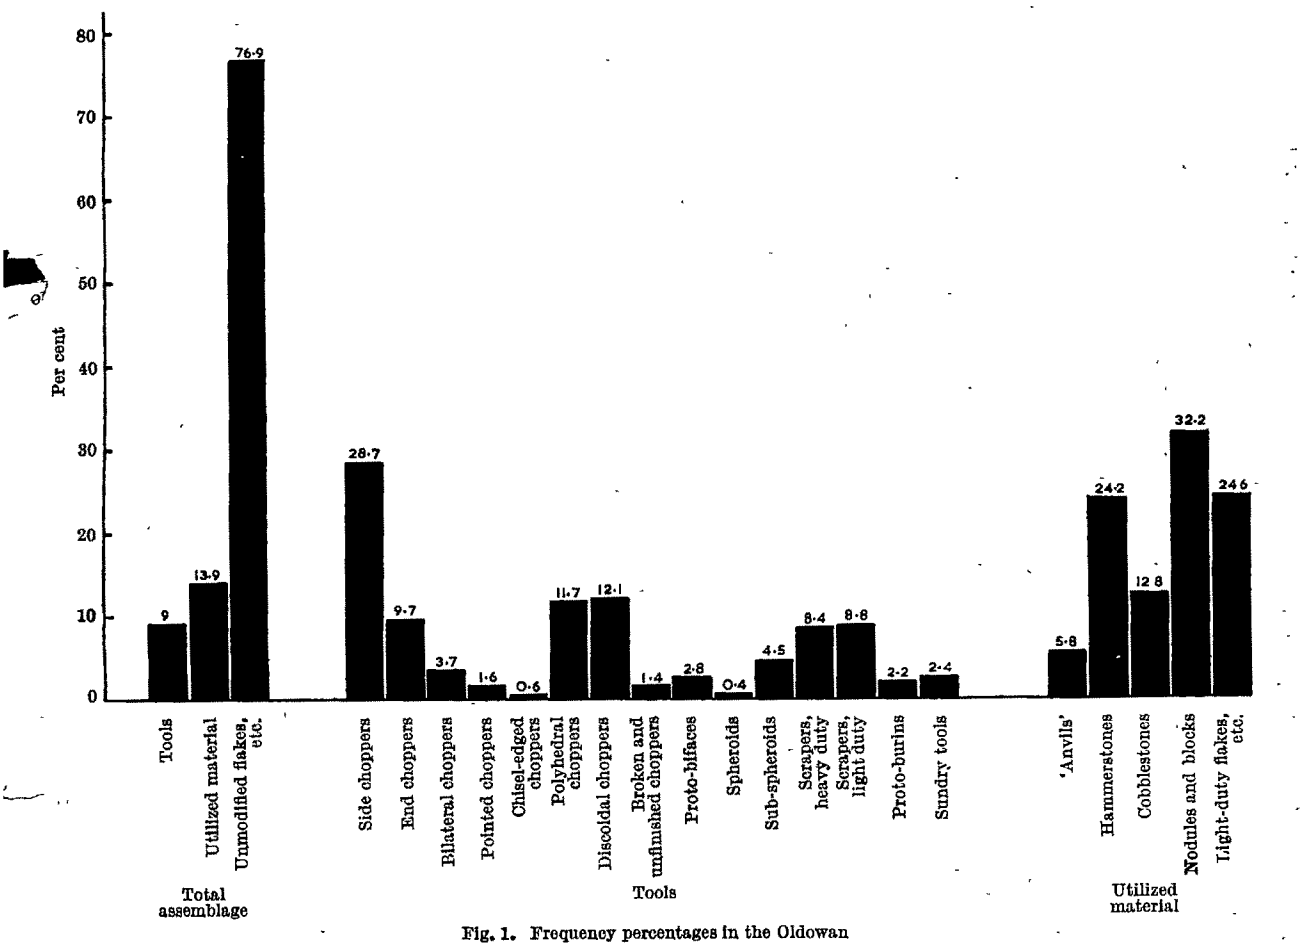

Fig. 1. Frequency percentages in the Oldowan

A statistical analysis of the material reviewed in this article is given in Fig. 1.

Finally, it must be stated that it is not possible to identify positively any one of the fossil skulls found in Bed I, or the base of Bed II, as representing the makers of the Oldowan. Hominid remains have been found on living floors, directly associated with cultural material, and also at places where there were no artefacts, although they occur elsewhere at the same horizon. Furthermore, at *FLK* I, *Homo habilis* remains appear to have come from the same occupation level on which the australopithecine '*Zinjanthropus*' was found[7]. It seems highly improbable that the two types of early hominids co-existed at the same camp, and it must be assumed that one represents the occupant of the site and the other an intruder or victim.

The debris on the *FLK* I floor and at other sites indicates that a substantial amount of meat was consumed, and in this respect the australopithecine, with a dentition evidencing a largely vegetarian diet, is unlikely to have been responsible. It appears even more improbable that a non-meat-eating creature would have required the variety of stone tools which are found in the Oldowan, or would have had the ability to make them, whereas the inception of hunting, even by the most primitive methods, would necessarily create a need for a variety of cutting tools and weapons.

Although the australopithecine may well have made simple 'tools' to meet his requirements, I am of the opinion that the larger-brained *Homo habilis*, whose hand bones also indicate a degree of manual dexterity, is most likely to have been responsible for the Oldowan.

NEWS AND VIEWS

Electronics Research and Development (Telecommunications) in the Ministry of Aviation : Mr. J. S. Shayler

MR. J. S. SHAYLER has recently been promoted to deputy chief scientific officer and appointed as director of electronics research and development (telecommunications) in the Ministry of Aviation. He was educated at William Hulme Grammar School, Manchester, and the University of Manchester, where he took an honours degree in electrical engineering in 1938. He then joined the Royal Naval Scientific Service at H.M. Signals School, Portsmouth (which later became the Admiralty Signals Establishment and then the Admiralty Signals and Radar Establishment), where he stayed until 1949, developing high-power shipborne metre-wave radar transmitters and radar displays including early work on data handling. From 1949 until 1951 he worked on search-type asdics with rapid all-round cover at H.M. Underwater Detection Establishment, Portland. He then moved to the Services Electronic Research Laboratories, Baldock, where he worked on the application of millimetre waves, particularly 8-mm waves, and was responsible for building a ground-based lock-follow 8-mm continuous wave radar, which proved the feasibility of the system and was used to measure the spectrum of aircraft returns. From 1955, Mr. Shayler worked on the project studies of the problems of operating new naval aircraft from aircraft carriers at the Naval Air Department, Royal Aircraft Establishment, Bedford, until in 1958 he became deputy head of the Blind Landing Experiment Unit at the Establishment. He was appointed head of the Unit in 1961 and continued as such until his present appointment. At the Unit he was responsible for the research and development of all aspects of landing aircraft in reduced visibility, but was particularly involved with the application of automatic landing to civil aviation.

Physics in the Queen's University, Belfast: Prof. K. G. Emeleus

PROF. KARL GEORGE EMELEUS will retire this year from the chair of physics at the Queen's University, Belfast. Emeleus studied in the University of Cambridge and stayed there for doctorate work in Rutherford's laboratory under the supervision of Prof. Chadwick. After a short time spent in Prof. Appleton's department in King's College, London, he moved in 1933 to Belfast. Prof. Emeleus has devoted his research to the field of "gaseous electronics" embracing plasma physics and electronics. At the time when he started his investigations, this field was little understood. As a consequence, Prof. Emeleus has pioneered in many subjects. His major interests included work on the particle counters of the Wilson chamber; investigations on the application and development of Langmuir probe technique; analysis of the hot and cold cathode glow discharges by means of probes; investigation of the conditions under which forbidden particle transitions can be produced in the laboratory; the introduction of the concept of the subnormal discharge and its experimental and theoretical analysis; the theory of cathode sputtering and chemical reactions in glow discharges; and, particularly, during the past twenty-five years, his thorough investigations in the field of oscillations and plasma turbulence. He was one of the first to recognize the importance of these two phenomena which are now so widely investigated. In addition to nearly one hundred original papers, Prof. Emeleus has written summarizing articles and in particular a book on the conduction of electricity through gases which, although it was first published about twenty-five years ago, is still a valuable introduction to the subject. The pleasant personality of Prof. Emeleus made it a pleasure to work with him. His sincere scientific desire and his able understanding have given the spark of scientific excitement to many of his students.

Prof. D. J. Bradley

DR. D. J. BRADLEY, at present reader in physics at the Royal Holloway College, University of London, has been elected to the chair of physics in the Queen's University, Belfast, in succession to Prof. K. G. Emeleus. Dr. Bradley is a native of Northern Ireland, where he received his grammar school education, and after a teacher training college course (1945–47) he taught in primary schools in Londonderry from 1947 to 1953. He then moved to England and, while teaching in a grammar school at Hitchin and in the London County Council Teaching Service, he took a University of London external B.Sc. (Special) in mathematics by part-time study at Birkbeck College. He followed this with an internal B.Sc. (Special) in physics with first class honours, also at Birkbeck, in 1957. In 1957 he was appointed assistant lecturer at Royal Holloway College where, under the influence of Prof. S. Tolansky, he acquired a

keen interest and skill in spectroscopy and interferometry. As a result of his research on "An Oscillating Fabry–Perot Interferometer" he took his Ph.D. degree. In 1960 he was appointed lecturer in physics in the Section of Applied Physics at the Imperial College of Science and Technology, where he extended his research interest into photoelectronics and space research. Then in 1964 he returned to the Royal Holloway College as reader in physics from where, after only two years, he will transfer to the chair of physics at Belfast. Thus, Dr. Bradley's career began in school teaching and he came into academic physics the hard way. However, this may partly be responsible for his great success as a teacher. Though beginning rather late in university teaching and research in physics, his enthusiasm and ability have carried him a very long way in a short time. He is a very skilful experimenter with a genial nature that engages the confidence of both undergraduate and postgraduate students and makes him a very congenial colleague. All who have known him will feel confident that he will be very successful in his new post.

Low-energy Electron Diffraction

ONE of the first demonstrations in Britain of the technique of low-energy diffraction was recently provided at the Sunbury Research Centre of the British Petroleum Company by Dr. R. Szostak of the Fritz Haber Institute, West Berlin. The technique is being used at a number of laboratories for the study of the structure of the few layers near the surface of a solid crystal which can be penetrated by a beam of electrons with an energy of the order of a hundred volts or less. Dr. Szostak's lecture and demonstration were concerned with the application of the technique to whiskers of iron. Dr. Szostak emphasized that iron is a difficult specimen for single crystal studies because of its $\alpha \rightarrow \gamma$ transition near 900° C and because of impurities, both inherent and induced by cutting and orientating, in massive single crystals. He has found, however, that naturally grown and well-established side faces of whiskers, formed by the reduction of iron (II) chloride in hydrogen near 800° C, offer a successful specimen. Faces exhibited have (100) and (110) orientation. Very bright diffraction patterns were achieved from targets only 0·01 in. broad and with beam energies as low as 5 electron-volts.

After heating up to 850° C the (100) faces exhibited a structure similar to the well-known domain structure of ordered alloys. The pattern expected from clean iron (100) surface was also observed after a long period of ion bombardment and annealing, but this interpretation should be treated with some caution. The addition of oxygen to this surface led to ordered oxide structures with a periodicity equal to a small integral multiple of the unit cell dimensions.

The (110) faces exhibited a great variety of more complicated super-structures and a 'clean' surface could not be obtained without a high background intensity.

Dr. Szostak said that his study of this system was only a preliminary, and that future work would involve more detailed investigation of specific aspects of these interactions.

Advances in Fluorine Chemistry

VOLUME 5 of *Advances in Fluorine Chemistry* covers only two broad topics: oxyfluorides of nitrogen and fluorides of phosphorus (edited by Prof. M. Stacey, Prof. J. C. Tatlow and Dr. A. G. Sharpe. Pp. 288. London: Butterworth and Co. (Publishers), Ltd., 1965. 75*s*.). The first topic is a thorough review of the preparations, reactions and properties of nitrosyl fluoride, nitryl fluoride, and nitroxy fluoride or fluorine nitrate. The thirty pages and 135 references cover a period from 1905 to 1963. The author of the chapter is Dr. C. Woolf, of the Allied Chemical Corporation. The presentation and format follow closely the tradition established by other contributors to prior volumes of this series. The second topic is by Dr. R. Schmutzler, of the E. I. du Pont and de Nemours Company, and is a monumental coverage of almost every known compound which has at least one fluorine atom bonded to phosphorus. The chapter covers more than 230 pages of text involving 771 references in the field. There are more than sixty tables of data which help to bring the topical material into sharp focus for the reader, and apparently no figurative stone has been left unturned to cover the available information and present it in Teutonic detail. Among the topics treated are trivalent and pentavalent phosphorus fluorides, mixed halides, oxyhalides and thiohalides; fluorophosphanes, fluorides of phosphinic and phosphonic acids and their ester and amide derivatives; the fluoroacids of phosphorus and the fluorophosphazenes. There is also a very important section on infra-red, and fluoride-19 and phosphorus-31 nuclear magnetic resonance spectroscopy with chemical shift and coupling constant data made available for literally hundreds of chemical species. Considerable emphasis has been paid to fluorophosphorus compounds as co-ordinating ligands in complexes so that this chapter, which is probably the most thorough one in the series, will also be of interest to co-ordination chemists as well as organic and inorganic fluorine chemists.

More Technical Training

SUGGESTIONS for making fuller use of technical colleges in Britain have been put forward to the Secretary of State for Education and Science by the Committee on Technical Resources—a sub-committee of the National Advisory Council on Education for Industry and Commerce. The recommendations have been warmly welcomed by the Minister, who promises vigorous action in pursuit of a number of detailed recommendations. Clearly the British Government has been overjoyed—and perhaps even surprised—to be told that at least one part of the educational system must be thought of as containing "a very considerable reserve of resources".

According to the statistics in the report of the committee, roughly 1,700,000 students—some full-time and some part-time—now attend technical colleges and other establishments of further education. Investment in these institutions since the Second World War exceeds £200 millions. More recently, the pace of growth, in buildings and in numbers of students, has been particularly quick, and the committee looks forward to even faster growth once the full impact is felt of the work of the industrial training boards now being established, and which are intended to ensure uniform standards of technical training. The same development may well make more funds available to the technical colleges.

The committee's confidence that productivity can be dramatically increased in this frequently neglected part of the educational system rests on its discovery that the sizes of classes now being taught in technical colleges and other institutes of further education are frequently much smaller than they need to be. Among some 86,000 classes of all kinds, the committee found that no fewer than 63,500 were constituted of between eleven and fifteen students. These figures compare favourably with the sizes of senior classes in secondary schools, where the character of the teaching is often very similar. In the circumstances, not even teachers in technical colleges will be surprised that the committee recommends a less generous ratio of staff to students, and a fuller use of educational plant thereby. It is less easy to understand that much of the difficulty about using technical colleges to the full should apparently stem from a misinterpretation of a government policy first laid down in 1957, and which was intended to ensure that public funds could not be spent on technical college courses unless fifteen students enrolled in the first year. Frequently, it seems, this

minimum has been interpreted as a recommended norm, with the result that large classes have been actively discouraged.

Dedijer on Sociology and Science

THE Second Annual Lecture of the Science of Science Foundation was delivered in London on April 28 by Dr. Stevan Dedijer, of the Department of Sociology in the University of Lund. Among other things, Dr. Dedijer was at pains to blame his own specalty for what he described as its neglect of studies of the link between prosperity and the investment of money in research and development, the link between economic growth and the effectiveness of research and, indeed, the whole field of what Dr. Dedijer and his sponsors call the science of science. He was able to assemble an impressive list of official reports from the United States, the Soviet Union, the United Kingdom (where both the Heyworth Report and the earlier document from the Tavistock Institute were found blameworthy) and from the Organization for European Co-operation and Development. "The social and behavioural sciences as a whole have so far neglected to identify and study the major problems and causes of the current scientific and technological revolution."

Among the causes of this neglect, Dr. Dedijer singled out the lack of time for the need to be recognized. Among the cures he recommended, the most tangible was the creation of institutes for "the science of science" in countries of all kinds. He asked that these should be concerned with the collection of information on research and development, the development of national research programmes in the science of science, the infiltration of other branches of the social sciences by the science of science, the creation of specialized units to study difficult problems, and liaison with similar institutes abroad.

Leptospirosis in Man and Animals in Australia

UNTIL recently, leptospirosis was thought not to occur in man and animals in South Australia to any significant degree. In 1953–54, Dr. J. E. McCartney, medical bacteriologist to the South Australian Institute of Medical and Veterinary Science, examined 627 sera for the presence of leptospiral agglutins, but no positive results were obtained. For many years, however, medical authorities concerned with the health of abattoir workers have noticed that febrile illnesses frequently occur which do not appear to correspond with any of the well-recognized ailments commonly seen in these workers—*Q* fever or brucellosis.

In April 1962 serum samples from 120 employees of the metropolitan abattoirs were sent for testing. Leptospiral agglutination tests were performed on these specimens and the results showed that forty-five cases had unequivocal evidence of previous infection with leptospiral organisms. It was therefore decided to set up a routine diagnostic unit at the Institute, and an immediate and comprehensive survey of abattoir workers was organized. In this survey, sera which agglutinated at a dilution of 1 : 100 or more were regarded as significant. Of 894 specimens examined, sixty-five showed leptospiral agglutinins. The groups with the highest incidence of antibodies were meat inspectors, beef slaughterers and workers in the pig hall and offal floor.

Of the clinical cases so far, sera from 140 patients have been examined. There have been eight confirmed cases of leptospirosis, all males and almost exclusively abattoir workers. One hundred and four sera from Aborigines in a variety of areas in South Australia were also examined in the course of other serological tests. No positive results were obtained, thereby confirming the validity of the testing procedure and the occupational incidence of the disease.

Evidence was also collected to determine the incidence of leptospiral disease in animals in South Australia. Animal sera which showed leptospiral agglutinins at a dilution of 1 : 300 were regarded as positive. Forty-five cattle sera were submitted by the Division of Veterinary Pathology. Of these, twelve were positive. Forty-one sera were examined, and twenty-seven were positive. The results obtained so far clearly show that both doctors and veterinary surgeons need to be constantly aware of leptospirosis as a cause of hitherto undiagnosed symptoms in man and animals. Further information is to be found in the twenty-sixth report of the Institute of Medical and Veterinary Science, South Australia (Adelaide: Government Printer, 1965).

Announcements

OPEN days will be held at the National Engineering Laboratory, East Kilbride, during May 4–6. Further information can be obtained from the Director, National Engineering Laboratory, East Kilbride.

THE third national conference of the National Conference of Standards Laboratories will be held at the National Bureau of Standards, Gaithersburg, Maryland, during May 9–12. Further information can be obtained from W. R. Tilley, National Bureau of Standards, Washington, D.C.

A BIONICS Symposium, sponsored by the Aerospace Medical Division and the Research and Technology Division of the U.S. Air Force Systems Command, will be held in Dayton, Ohio, during May 3–5. Further information can be obtained from Dr. H. L. Oestreicher, Aerospace Medical Research Laboratories Wright Patterson Air Force Base, Ohio.

AN international symposium on "Some Aspects of Strontium Metabolism", under the auspices of the Medical Research Council and the United Kingdom Atomic Energy Authority, will be held at Chapelcross during May 5–6. Further information can be obtained from Dr. J. H. Martin, United Kingdom Atomic Energy Authority, Chapelcross Works, Annan, Dumfriesshire.

A CARBON and Graphite Group of the Institute of Physics and the Physical Society has now been created by the Council of the Institute and Society. The inaugural meeting of the Group will be held in the University of Sheffield on May 5. It will take the form of a discussion meeting on "Methods of Characterizing the Pore Structure of Carbons". Further information can be obtained from the Meetings Officer, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A SERIES of one-day courses in applied social research will be held at the Tavistock Institute of Human Relations during May. The following courses will take place: stress and conflict in industry (May 2); business organization (May 3); management development (May 4); management selection (May 5); consumer research (May 9); theories of working groups (May 11); personal and executive counselling (May 12); management training (May 13). Further information can be obtained from the Course Secretary, Tavistock Institute of Human Relations, 3 Devonshire Street, London, W.1.

CORRIGENDUM. In the article entitled "Efficiency of Ion Transport Mechanisms", which was published on page 398 of the January 22 issue of *Nature*, the expression $\frac{c_{Na}'}{c_{Na}''}$ in equation (4) should be inverted to read $\frac{c_{Na}''}{c_{Na}'}$.

CORRIGENDUM. Dr. A. Gajdos has written to the Editor of *Nature* stating that the last sentence in the communication entitled "Mechanism of the Inhibitory Effect of Adenine Nucleotides on Porphyrin Synthesis by *Rhodopseudomonas spheroides*", which appeared on p. 640 of the August 7, 1965, issue of *Nature*, should read "These findings do not invalidate the conclusions of our earlier observations".

SCIENTIFIC AND INDUSTRIAL RESEARCH IN INDIA

THE fourth Five Year Plan of the Council of Scientific and Industrial Research, India, is presented in two parts*. Part I outlines the approach adopted to planning and the methods adopted by the Working Group appointed in May 1963 by the Council at the request of the Planning Commission. The salient features of the proposals are then summarized, together with the recommendations regarding co-operative research, research grants and facilities, amenities for research and research staff, co-ordination of research between the Council, universities and ministries, the supply of scientific instruments and the utilization of research results. The Working Group was to make a critical review of the progress of the programmes and schemes of the third Plan period, assess the position likely to be reached at the end of that period and formulate proposals for the fourth Plan in the perspective, where possible, of a 15-year period. The desirability of paying more attention to annual phasing was emphasized.

Four broad principles have been followed in working out the Plan and the requirements of scientific policy under the Council for Scientific and Industrial Research. (1) The national requirements have been established in terms of technological problems and research programmes drafted based on the identification of these problems. (2) After evaluating progress made so far in research, a policy has been worked out for supporting those areas which have shown promise or significance to science or for the national economy. (3) Attention has been given to broadening and diversifying the base of science and technology, for example, through the Council's pool of scientists, fellowships, scholarships, research grants, research centres and co-operative research associations. (4) Attention has been given to certain gaps in earlier programmes, for example, by strengthening research activities in some geographical areas or in certain branches of science or technology, or augmenting and creating central facilities, including library and documentation services, or again in the sphere of effective organization.

In order to put its proposals on firm ground, the Working Group held discussions at various laboratories. Besides critical studies of the laboratories over the past 10 years, it had at its disposal critical studies on their growth undertaken by the Unit for the Survey and Planning of Scientific Research. As regards the established laboratories, features of the proposals are the emphasis on project orientation of research, the time targets of the schedules and the allocation of priorities to projects—high priority being given to those projects which are vital to the national economy. Emphasis is also placed on pilot plant and development work and on the replacement of obsolete equipment. It was noted that gaps occurred in the national laboratories at three levels: in multi-purpose laboratories to meet the requirements of an area or to develop and utilize natural resources; in certain areas of research in which India possesses considerable experience and expertise but establishment of well-defined institutions is necessary to organize research properly to utilize fully available resources; in areas where research is needed but sufficient trained personnel are not available.

It is to meet these three requirements that the Plan envisages first the establishment of five new institutes: a Fire Research Station; a National Institute of Oceanography; a National Science Library; a National Institute for Research in Electrical Engineering; and an Institute for the Study of Social Relations in Science. Five new Regional Research Laboratories are proposed, at Uttar Pradesh, Madhya Pradesh, Kerala, Rajasthan, and Punjab. Eight fields are specifically proposed for new projects: birth control; pesticides, insecticides and agricultural chemicals; marine engineering; automation; meat and fish technology; packaging; substitute materials for electrical appliances; and materials research.

The Plan also provides for the formation of co-operative research associations for tea and cement, and a larger allocation is recommended in the Scientists' Pool to bring back young scientists at present in advanced countries. Besides increased grants to research schemes, the establishment of centres of research in universities (in consultation with the University Grants Commission) is proposed, and funds are to be allocated for sending exceptionally brilliant scientists for training abroad in various specialized fields. Definite provision is to be made for the creation and expansion—both centrally and regionally—of facilities such as libraries, documentation services, service units for routine analysis, and facilities for maintenance and repair of equipment, instruments and calibration. The India National Scientific Documentation Centre and the Publications and Information Directorate are to be further developed, the third Museum of Science and Technology, initiated at Bombay during the third Plan, will be completed during the fourth Plan, and the engineering and design unit will be developed as a fully fledged institution. The Industrial Liaison and Extension Unit at the Council's headquarters is to be reorganized and resources provided for the evolution of an effective programme of international collaboration. Provision is also included for medical help for research staff, accommodation and other facilities.

In 1963–64 the Council provided 24·7 lakhs of rupees for 623 university research schemes and 31·3 lakhs of rupees for 1,428 fellowships, as well as sanctioning block grants of 190,000 rupees to the School of Earthquakes, Roorkee University, 25,000 rupees to the School of Dyestuffs, Bombay University, and 508,000 rupees to the International Meteorological Centre. Proposals are detailed for fifteen different stages to increase collaboration between the Council and the universities, and co-ordinating units on the lines of that already established for defence are to be set up for the Ministries of Health, Industry, Steel and Mines, Commerce, Works, and Civil Aviation. Other proposals relate to the Central Scientific Instruments Organization, and include the establishment in each National Laboratory of a strong instrument division.

Of the total expenditure of Rs. 204·69 crores proposed for the fourth Plan, Rs. 60·69 crores is for the committed expenditure of the Council of Scientific and Industrial Research over the five years. The revised estimates provided for expenditure of 339 million rupees on established institutes and laboratories; 336 million rupees on those started in the second or third Plans; 19 million rupees on science museums; 35 million rupees on co-operative research associations; 74 million on the Scientists' Pool, research grants and fellowships; 40 million on research centres; 146·5 million on central facilities; 24 million on scientific and technical units at headquarters; 21 million on international science collaboration; 91 million on new institutes; 87·5 million on new projects; 184 million on amenities; miscellaneous items bring the total to 1,444 million rupees.

BROADCASTING POLICY AND A UNIVERSITY OF THE AIR

ALTHOUGH the White Paper *A University of the Air* was mentioned in the House of Commons in the debate on broadcasting policy on March 3, that debate was concerned with broadcasting policy generally. Of special interest in the debate was the reply of the Postmaster-General, Mr. A. Wedgwood Benn, who stressed the central problem of the finances of the British Broadcasting Corporation. Mr. Benn pointed out that the Corporation could no longer rely on increased revenue from a growing number of television licences. Because the 1954 Act left the Corporation dependent on a fixed licence to compete with programme contractors granted a monopoly of advertising revenue and for whom expansion was highly profitable, it looked as if the Corporation would require a further increase of £1 in the licence in 1966 and another in the next 4 years. Furthermore, for a comprehensive system of local broadcasting a further 5*s*. would be required—it was estimated that licence evasion already amounted to the equivalent of an extra 10*s*. licence. After referring to such alternatives as increased borrowing or an Exchequer grant, Mr. Benn said that the Corporation had now put before the Government proposals which it believed could or might stabilize the licence fee for another 2 years or more without cutting its services; while considering these proposals, the Government was dealing further with the evasion of licences. He also affirmed the Government's intention to introduce legislation to deal with pirate radio companies. On hours of broadcasting, a final decision would have to wait until further discussions had been held with the Corporation.

Mr. Benn stated that he thought that the role of publishing in broadcasting, making outlets available for independent experimental education programmes, was important—it was here that he mentioned the University of the Air. He indicated that he was discussing with the Independent Television Authority the possibility of opening up outlets, under a provision in the 1964 Act, for universities such as Strathclyde, and independent institutions and units which at present had no access to the television screen. Mr. Benn welcomed the development of closed-circuit television and regarded the awakening of public understanding of the possibilities of local radio as a most significant development. Besides the B.B.C., the commercial radio companies, and genuine community stations, including local authorities, were interested in local stations, and the White Paper on a University of the Air also referred to the part which local stations might play. As to a fourth channel, Mr. Benn estimated that this could involve a capital cost of about £30 million and many million pounds a year to run. Here was a question of priorities. On colour television, the Government had accepted the advice of the Television Advisory Committee to use the PAL system of transmission on the 625-line standard. Subject to acceptance at the Oslo Conference in June, colour television on B.B.C. 2 would start with about 4 hours a week towards the end of 1967; the cost was estimated at £1–7 million a year. The cost of sets was estimated at £250 each initially with a consumer expenditure over the first 3 or 4 years of £100 million and a net gain of £10 million in exports.

The White Paper itself* argues that an open university of the air, if it were imaginatively to use new teaching techniques and teacher/student relations, would contribute to the improvement of educational, cultural and professional standards generally, by making available scholarship of a high order to those who look and listen. As is pointed out, it will enable some to accept the full discipline of study and acquire degrees and other qualifications; and it will benefit students in many other parts of the world as well as those studying in the United Kingdom. It is suggested that it will help to meet the urgent need in the developing countries for a highly trained corps of men and women, equipped to provide leadership in national life. At a time when capital resources are scarce, it would provide higher and further education for many without involving vast expenditure on buildings. The proposals are based on the report of an Advisory Committee of which Miss Jennie Lee, Joint Parliamentary Under-Secretary of State, Department of Education and Science, was chairman.

The University would require its own administration centre but would make full use of existing agencies, such as the extra-mural departments of universities, the Workers' Educational Association and local education authorities. It would primarily offer general courses leading to a degree which would be conferred by the university of the air in its own right. A working party should be established to examine the possibility of courses leading to degrees and other qualifications with a technological element. The presentation of courses would involve a combination of television, radio (particularly from local stations), correspondence courses, programmed instruction, tutorials and practicals, short residential courses, and study and discussions at community viewing or study centres. The project requires peak viewing on a television service with national coverage, estimated at least two hours on five evenings a week Enrolment would be open to everyone on payment of a registration fee and no formal entrance requirement would be imposed. The university, which would have its own vice-chancellor and governing body or council, would require a professional staff of about 40–50 and would arrange for regular surveys to assess the effectiveness of courses, and the size and type of audiences following them.

LATEX

A MEETING of the Phytochemical Group on "The Distribution and Biochemistry of Latex in Plants" was held on January 6 at the School of Pharmacy, University of London. The opening paper on the distribution of latex in the plant kingdom was given by Dr. C. R. Metcalfe (Royal Botanic Gardens, Kew). Latex, produced in specialized laticiferous cells, is found in about 12,000 species, but these are restricted to about twenty scattered families of angiosperms. With the aid of an extensive series of photomicrographs of sections of laticiferous plants, Dr. Metcalfe explained the differences between articulated and non-articulated laticifers and showed examples of their distribution in the plant. Although many articulated laticifers frequently occur in the phloem, non-articulated laticifers are sometimes dispersed throughout all plant tissues including the xylem.

The most important commercial laticiferous plant is *Hevea*, and the next four papers dealt with aspects of the

structure and biochemical properties of *Hevea* latex. The ultra-structure of *Hevea* latex as gleaned from electron-microscope investigations was described by Dr. P. B. Dickenson (National Rubber Producers Research Association, Welwyn). Three characteristic features found are rubber particles, lutoid particles and Frey-Wyssling particles. The rubber particles are globular or bean-shaped and show a black boundary which is an adsorbed phospholipid-protein layer. Lutoid particles in young latex vessels contain bundles of long microfibrils with a hollow core; these microfibrils, which are protein, cannot be seen in lutoids from more mature latex vessels. The Frey-Wyssling particles which are inclusions in a much larger organelle are large lipid globules and contain tubules with spiral thickening in a complicated internal structure.

Dr. B. G. Audley (National Rubber Producers Research Association) described some recent biochemical investigations of rubber latex. The glycolytic conversion of glucose to either lactate or ethanol requires both the white fraction and the bottom fraction of latex; the function of the latter fraction probably being to supply reduced co-enzymes. However, the bottom fraction could not be replaced by $NADPH_2$ in a latex system which converts β-hydroxymethylglutaryl co-enzyme *A* to rubber, and in this case bottom fraction appears to stimulate rubber synthesis by oxidizing inhibitory unesterified co-enzyme *A* through a phenolase mediated reaction.

The conversion of mevalonate to rubber by *Hevea* latex was reviewed by Dr. B. L. Archer (National Rubber Producers Research Association). Mevalonate is converted to isopentenyl pyrophosphate (IPP) in the aqueous phase which is then incorporated into rubber at the surface of the rubber particles. Dimethylallyl pyrophosphate (DMAPP) stimulates the incorporation of IPP into rubber by a suspension of washed rubber particles. The inhibitory effect of DMAPP on IPP incorporation by latex is explained by the reaction of these two compounds, which is catalysed by enzymes in the latex, to form farnesyl pyrophosphate, an inhibitor of rubber biosynthesis.

Dr. J. F. Pennock (Department of Biochemistry, University of Liverpool) described the isolation of α, γ- and δ-tocotrienols both in the free form and as esters from *Hevea* latex. Only the free tocotrienols and not the esters had previously been found in other tissues. In contrast, the tocopherol fraction of leaves of *Hevea* did not contain any tocotrienols but only the saturated compounds, α-, β-, γ- and δ-tocopherols. Both latex and leaf lipids were found to contain plastochromanol, a cyclic compound related to plastoquinone. It was suggested that the tocotrienols were possibly intermediates in the biosynthesis of tocopherols.

Proteolytic enzymes in latex were discussed by Dr. P. Dunnill (Department of Botany, University College, London). Although plant and animal proteases have similar specificities for artificial substrates, they differ in the amino-acid sequences at the active sites; however, ficin and papain show close similarities in their amino-acid compositions. When proteases are present in laticiferous plants they are markedly concentrated in fruits and seeds. Since laticiferous vessels do occur in cotyledons, it seems that the hydrolysis of storage protein for conversion to other protein at great speed at critical stages in the life-cycle represents the most important role and may account for the very high protease concentration in latices.

The latex of *Papaver somniferum* contains the alkaloids thebaine, codeine and morphine. Results of recent experiments on the inter-relationships of these compounds were discussed by Prof. J. W. Fairbairn (School of Pharmacy, University of London). Analysis of whole plants showed variations over short time periods in the alkaloidal content, and the total of thebaine plus codeine alternately rose and fell, but instead of a corresponding accumulation of morphine there was an apparent disappearance. These results were confirmed by experiments in which [U-^{14}C]-tyrosine was incubated with isolated poppy latex. It was concluded that there was an additional non-tyrosine route to the alkaloids and that morphine is transformed to a non-alkaloidal molecule in the latex itself.

Copies of the paper "Distribution of Latex in the Plant Kingdom" on which Dr. Metcalfe's talk was based can be obtained from Dr. Metcalfe at the Jodrell Laboratory, Royal Botanic Gardens, Kew. J. FRIEND

DELAYED CYCLOTRON PULSE GENERATION IN THE TOPSIDE IONOSPHERE DEDUCED FROM *Alouette* I DATA

By D. B. MULDREW

Radio Physics Laboratory, Defence Research Telecommunications Establishment, Ottawa

THIS article describes a physical process in which the passage of an electromagnetic pulse through the Earth's ionosphere can result in the delayed generation of a second pulse. The initial pulse must have right-hand polarization. The delayed pulse is generated in a height region where the angular frequency ω of the pulse is approximately equal to twice the angular electron gyrofrequency $2\omega_H$. The computed delay time of the delayed pulse is found to be consistent with a 'remote resonance' trace[1] observed on *Alouette* I and *Alouette* II ionograms.

A well-defined remote resonance trace is shown in Fig. 1. From the characteristics associated with such traces it may be inferred that the energy responsible for producing the remote resonance propagates along an ionospheric field-aligned wave guide[2]. In such a guide there would be a gradient in the electric field of the wave in a direction normal to the direction of the Earth's magnetic field. The production of a remote resonance trace is made possible by this gradient.

Owing to the gradient in the electric field there can be a net energy transfer per cycle between the electromag-

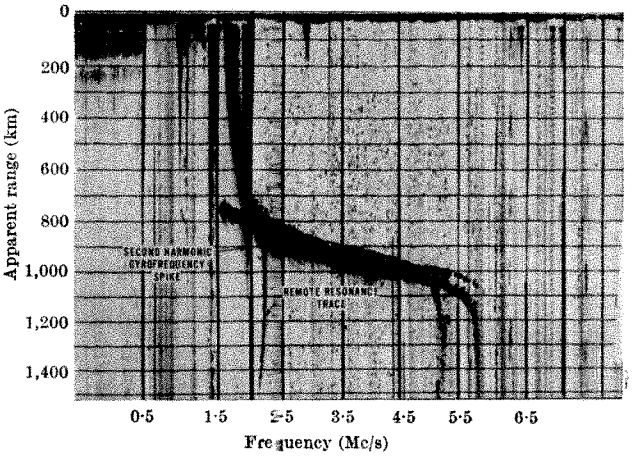

Fig. 1. *Alouette* I ionogram, showing remote resonance trace, recorded September 16, 1963, 1715 U.T. Satellite location 43° N., 65° W., at a height of 1,025 km

netic pulse and the gyrating electrons and it can be shown that this transfer is maximum when $\omega = 2\omega_H$. The position of each electron in its gyrating orbit may be specified in terms of a phase angle, measured from a fixed direction in the plane normal to the direction of the Earth's magnetic field. Before the passage of the pulse, the phases of the electrons are randomly distributed with respect to the thermal energy of the electrons. Energy transfer between the pulse and the electrons is a function of phase and results in a non-random distribution of phase with electron energy that persists for a considerable time after the passage of the pulse. This non-random distribution of electron energies with respect to phase is referred to here as 'energy bunching'. It is convenient to consider the behaviour of all the electrons which, immediately following the passage of the pulse, have a particular phase shift relative to those electrons which gain the maximum amount of energy from the pulse; the phase of these electrons is a function of height, r, measured from the centre of the Earth, and time t measured from the passage of a downward propagating pulse through the height r_0 at which $\omega = 2\omega_H$. These specific electrons will be called 'tagged' electrons. The duration of the initial pulse is assumed to be negligible. The phase of a tagged electron at time t and height r may be written in the form $\varphi(t, r)$; $\varphi^-(t, r)$ will be used to represent the phase distribution with respect to t and r resulting from a right-hand polarized downward propagating pulse at $t = 0$ and $\varphi^+(\tau, r)$ will be used to represent the phase distribution with respect to r at some time τ, resulting from a right-hand polarized upward propagating pulse at $t = \tau$.

For $\omega = 2\omega_H$ the pulse completes two cycles by the time the electron completes one at the gyrofrequency. Electrons which are separated by π radians in phase thus experience the same variation of the field of the pulse and hence there are two possible phase groups for the tagged electrons. It follows that if the phase of one of these groups is considered at a particular time, as a function of height, it will go through one cycle in a height equal to two mean wave-lengths of the pulse. Thus if the mean wave number of the pulse is k, the phase of the tagged electrons at $t = 0$ for a downward propagating wave is

$$\varphi^-(0, r) = \varphi(0, r_0) + \frac{k}{2}(r - r_0) \quad (1)$$

Similarly, in the height region where $\omega \simeq 2\omega_H$, the phase of the tagged electrons at time τ when a pulse propagates upward through the region is

$$\varphi^+(\tau, r) = \varphi(\tau, r_0) - \frac{k}{2}(r - r_0) \quad (2)$$

If it is assumed that there is no component of thermal motion of the electrons parallel to the Earth's magnetic field, then from (1)

$$\varphi^-(t, r) = \varphi(0, r_0) + \frac{k}{2}(r - r_0) + \omega_H t \quad (3)$$

where ω_H, the gyrofrequency at height r, is a function of r. The strength of the Earth's magnetic field (and hence the magnitude of the gyrofrequency) varies as the inverse cube of the distance from the centre of the Earth. Using a Taylor expansion for the gyrofrequency, and retaining the first two terms, we get

$$\omega_H = \omega_{H0} - \frac{3\omega_{H0}}{r_0}(r - r_0) \quad (4)$$

where ω_{H0} is the gyrofrequency at r_0. Substituting (4) into (3) yields

$$\varphi^-(t, r) = \varphi(0, r_0) + \omega_{H0} t + \left(\frac{k}{2} - \frac{3\omega_{H0}}{r_0} t\right)(r - r_0) \quad (5)$$

Since it has been assumed that there is no thermal electron motion along the field, the phase of the tagged electrons at r_0 at time τ, $\varphi(\tau, r_0) = \varphi(0, r_0) + \omega_{H0}\tau$. Hence from (2) and (5) the variation of the phase of the tagged electrons with height, initiated by a downward propagating pulse at $t = 0$, becomes identical with the phase distribution corresponding to an upward propagating pulse at time τ, where τ is given by

$$-\frac{k}{2} = \frac{k}{2} - \frac{3\omega_{H0}}{r_0}\tau \quad (6)$$

$$\tau = \frac{kr_0}{3\omega_{H0}} = \frac{\omega n}{c}\frac{r_0}{3\omega_{H0}} \quad (7)$$

where c is the velocity of light and n is the index of refraction of the pulse of angular frequency ω at the height r_0. At r_0, $\omega = 2\omega_{H0}$; hence from (7)

$$\tau = \frac{2}{3}\frac{r_0}{c} n \quad (8)$$

Any particular phase could have been chosen for the tagged electrons so that the above expression is applicable for all the electrons affected by the pulse near $r = r_0$. Since an electromagnetic pulse propagating in an ionospheric wave guide can produce energy-bunched electrons it might be expected that the reverse process may also occur; that is, that energy-bunched electrons with the correct phase distribution with height could produce an electromagnetic pulse. The evidence that a pulse is produced having the requisite delay time is given by Muldrew and Hagg[2].

It should be noted that if the pulse propagating through the height r_0 at $t = 0$ were an upward propagating pulse (that is, one propagating toward decreasing magnetic field strength), then τ would turn out to be negative. That is, a remote resonance pulse is only generated if the initial pulse propagates downward into increasing magnetic field strength.

The mode of propagation (that is, the path taken by the radio energy) involved in the generation of resonance traces observed by the *Alouette* satellites is then as illustrated in Fig. 2. A pulse of angular frequency ω transmitted from the satellite propagates downward, along an ionospheric wave guide, through the height A in the ionosphere where $\omega = 2\omega_H$. After a time delay τ, the distribution of the phase with height of the energy-bunched electrons at A becomes identical to the distribution that would be produced by an upward propagating extraordinary wave pulse of angular frequency ω. At this time an upward propagating pulse is apparently generated, and it is this delayed pulse that produces the resonance trace on the ionogram. The total time delay of the generated pulse may be calculated by adding to τ twice the time required by the extraordinary wave to propagate from the satellite to height A.

Energy bunching of the electrons at a given height can be affected by random thermal motion of the electrons

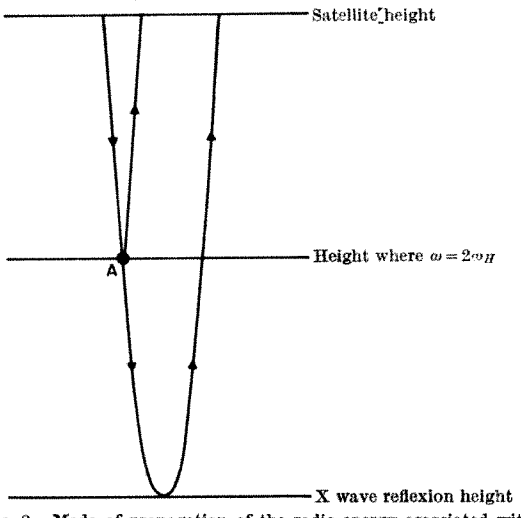

Fig. 2. Mode of propagation of the radio energy associated with the remote resonance trace

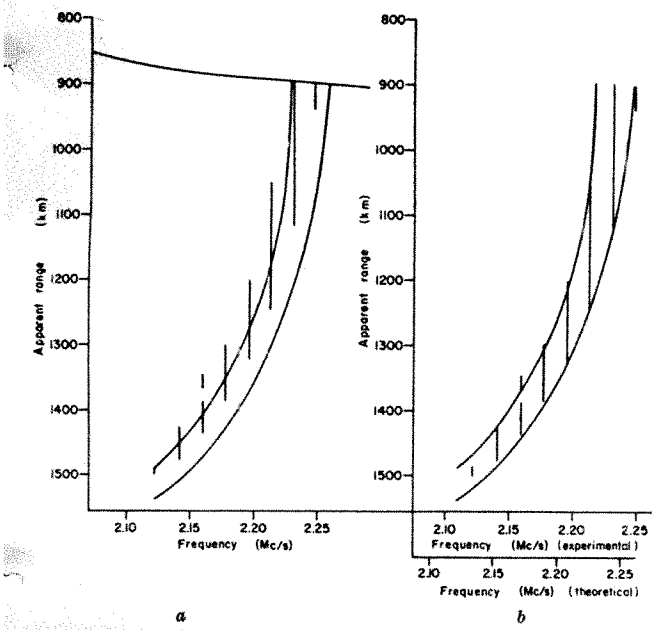

Fig. 3. Comparison of observed (vertical bars) and theoretically computed (solid curves) remote resonance echoes. (*a*) Theoretical curves as computed, (*b*) theoretical curves shifted 12 kc/s for best fit

parallel to the Earth's magnetic field. For a downward propagating pulse initially (at $t=0$) electrons at a given height have two energy bunches; at later times energy bunched electrons arriving at the given height from nearby heights will mix and there will no longer be well-defined energy bunching. However, it can be shown[3] that at the time τ, due to the initial phase distribution of the electrons set up by the pulse and to the gradient in the Earth's magnetic field strength, the electrons at the given height once again become energy bunched and they become bunched in exactly the way that they would have been bunched at τ if there were no thermal electron motion along the field. Thus, neglecting thermal motion along the field does not seriously affect the results of the presentation given above.

The above study does not treat the variation of the index of refraction n with height, electron-ion Coulomb interactions, pulse length, and the finite propagation time of the pulse through the height region near r_0. A consideration of these effects[2] enables the time delay and duration of the remote resonance echoes to be calculated accurately. The results are shown in Fig. 3*a*. The vertical bars show the upper and lower apparent range limits of the observed remote resonance echoes obtained from the ionogram of Fig. 1. The solid curves show the theoretically calculated upper and lower apparent range limits. In Fig. 3*b* the theoretically calculated curves are shifted 12 kc/s to higher frequencies with respect to the experimental data to obtain the best fit. This shift is within the estimated limits of accuracy. The observed and theoretically calculated traces are thus found to be in good agreement.

I thank Dr. R. E. Barrington and Mr. E. L. Hagg for helpful discussions.

RADIATION MEASUREMENTS IN COMMERCIAL AIRCRAFT USING A SINGLE COUNTER

By PROF. V. D. HOPPER and W. R. RAWLINSON
Department of Physics (R.A.A.F. Academy), University of Melbourne

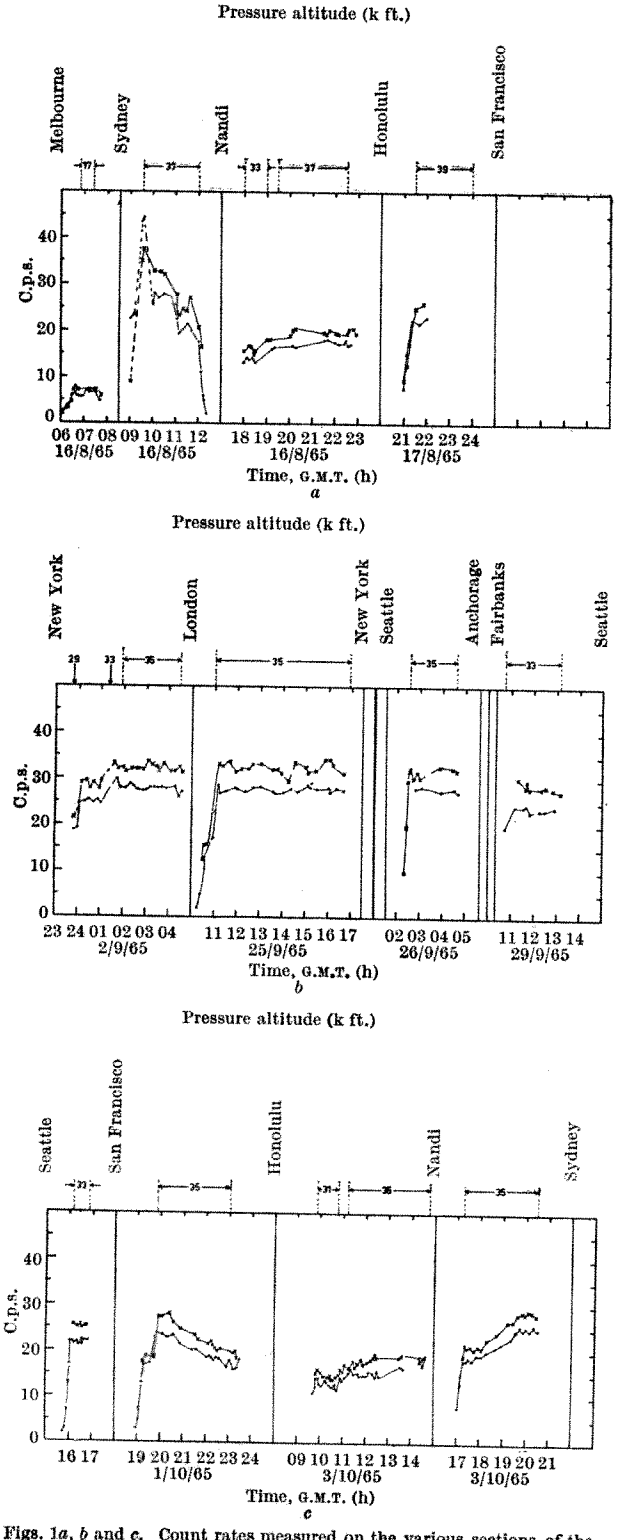
THE opportunity was taken to make cosmic-ray measurements in aircraft during a recent visit by one of us to the United States and the United Kingdom.

Three types of readings were taken using a single Geiger–Müller counter: first, the count rate due to cosmic-rays with the unshielded Geiger tube, secondly the cosmic-ray count rate with the tube shielded by 2·12 g cm^{-2} of lead, and finally measurements of radioactive sources in the aircraft themselves.

The equipment consisted of a single *MX* 120/01 thick-walled halogen-quenched Geiger tube connected to a ratemeter unit giving a direct reading in counts per second (c.p.s.). The lead shield consisted of a cylinder of lead that could be slid on and off the Geiger tube.

The results obtained on each section of the trip are plotted against time (G.M.T.) in Figs. 1*a*, *b* and *c*, together with the altitude record of each flight. Each point in the level parts of the flights consists of the average of between ten and thirty-two spot readings of count rate taken at 10-sec intervals. Few readings were taken on short flights across the United States due to the short times at constant altitudes.

There are two contributions to the experimental error of the results obtained. The first is the statistical fluctuations depending on the smoothing time constant of the ratemeter circuit, the number of readings averaged for each point (usually about twenty), and the count rate concerned. The second source of error is the accuracy of the readings of pressure altitude supplied by the crews of the aircraft. These were generally quoted in thousands of feet, and so an error of ± 500 ft. must be assumed. There may occasionally have been a deviation larger than this. For example, the dip in the results from Sydney to Nandi on August 16, 1965, between 1100 and 1130 h G.M.T. could possibly be due to an altitude drop of 1,000–2,000 ft. The overall accuracy of the results obtained is of the order of ± 1 c.p.s.



There is a general decrease in count rate as the aircraft approached the equator. The sections Nandi to Honolulu and vice versa include the crossing of the equator and have the lowest overall count rates of the whole trip. This effect is caused by the deflexion of low-energy particles by the magnetic field of the Earth, the intensity reaching a minimum at the geomagnetic latitude[1] with all readings corrected to an altitude of 35,000 ft. using profiles of count rate against altitude at various latitudes obtained in previous work. The points plotted in the region 50° S.–70° S. are taken from the southerly flight on June 3, 1965, already described[2].

From this plot it is seen that the minimum count rate occurred at the geomagnetic equator with a slow increase to 10°, and a steep increase between 25° and 40°. Between 40° and 50° there is a sudden drop in the slope of the curve, giving the so-called 'knee', and from 55° upwards the increase is very slow. Both curves are also symmetrical about the geomagnetic equator within the statistical limits of the points obtained.

At all times (with one exception—see later) on the level parts of the flights the apparatus gave a higher count rate with the lead shielding covering the tube. This is due to the production of secondary particles as the cosmic-ray particles pass through the lead. Also, due to their

energy spectrum, only a small proportion of the cosmic-ray particles are stopped by this thickness of lead (2·12 g cm^{-2}).

Two processes are involved in the increase in count rate with shielding. The first is cascade production where the increase is proportional to Z^2 (Z is the atomic number of the shielding material), and the second is star production where the increase is proportional to Z. Thus for high atomic numbers (for lead, Z is 82) the first process, cascade production, will dominate. From Fig. 2 it is seen that the fractional increase in count rate with 2·12 g cm^{-2} of lead

Figs. 1*a*, *b* and *c*. Count rates measured on the various sections of the trip, plotted against time (G.M.T.). ×, With lead; ●, unshielded

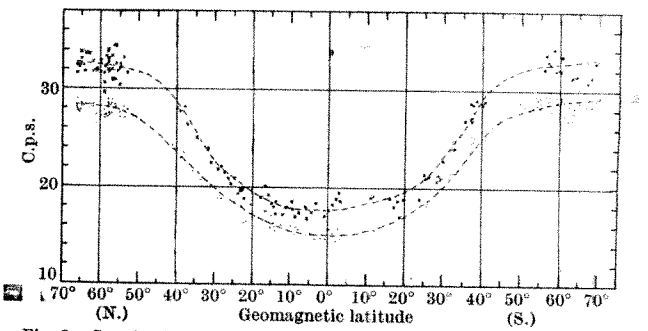


Fig. 2. Count rates corrected to 35,000 ft. plotted against geomagnetic latitude. ×, With lead; ●, unshielded

over the value without shielding at 35,000 ft. is 15 ± 1 per cent for all latitudes covered.

At various times during the trip, measurements were made of radioactive sources in the aircraft. It was found that on two occasions radioactive sources were being carried, and that the 'Exit' notices were also radioactive. In the first part of the trip from Melbourne to Sydney, measurements were made of the radioactivity of the instrument panel in the pilot's compartment. The various readings obtained are listed in Table 1.

Table 1

Date and flight	Position in aircraft	Count rate
August 16; TAA 418	6 in. from instrument panel	40 c.p.s.
	Pilot's seat	12
August 16; Qantas 530	Seat 16*E*: at seat-level	22
		8 (with lead shield)
	at floor-level	60

	6·5 ft. away	0·5
August 25; BOAC 501	Maximum read in 'economy class' compartment	10
October 1; Qantas 597	6 in. from 'Exit' notice	60
October 3; Qantas 587	6 in. from 'Exit' notice	60

Table 2. FLIGHTS ON WHICH MEASUREMENTS WERE TAKEN

Date	Trip	Flight No.	Airline
16.8.65	Melbourne to Sydney	418	TAA
16.8.65	Sydney to Nandi	530	Qantas
16.8.65	Nandi to Honolulu	530	Qantas
17.8.65	Honolulu to San Francisco	586	Qantas
2.9.65	New York to London	2002	Pan American
25.9.65	London to New York	501	BOAC
26.9.65	Seattle to Anchorage	007	North-Western Airlines
29.9.65	Fairbanks to Seattle	902	Pan American
	Seattle to San Francisco	631	Western Airlines
1.10.65	San Francisco to Honolulu	597	Qantas
3.10.65	Honolulu to Nandi	587	Qantas
3.10.65	Nandi to Sydney	587	Qantas

The readings on Qantas Flight 530 and BOAC Flight 501 are due to radioactive isotopes being carried in the aircraft. This is the reason for the count rate with shielding being lower than the count rate without shielding during the first hour of the trip from Sydney to Nandi on August 16. The lead shield reduced the count number of particles from the radioactive sources carried in the aircraft. It was necessary to change seats during this flight so that cosmic-ray readings could be made without measurable interference. It was also necessary to avoid sitting too near to an 'Exit' notice which was radioactive.

A check calibration showed a reading of 10 c.p.s. could be produced by a radium source giving a dosage in the counter of 0·1 mr./h. Thus the maximum dosage observable during the trip of 60 c.p.m. is equivalent to 0·6 mr./h and so for 24 h a dosage of 14 mr. is possible. This may be compared with the acceptable rate of 60 mr./day. The total equivalent γ-ray dosage on a flight from the North to South Pole with a modern jet aircraft is estimated to be less than 5 mr. The cosmic radiation is not the same as γ-radiation from radium in that it penetrates to a greater extent, but the dosage at any part of the body would be well within acceptable limits. A new feature will arise in studying effects above 70,000 ft. where the heavy primary radiation exists, but the simple technique used has produced a valuable record of the cosmic and other radiation levels in the present-day jet airliner.

We thank the crews of the Qantas, Pan American, BOAC, TAA, Western Airlines and North-Western Airlines for allowing these measurements to be made and providing the flight records. The assistance of the Department of Civil Aviation in providing the letter of introduction to these airlines is acknowledged, and also in providing some funds towards the cost of an air fare. The help of the technicians at Naval Observatory at China Lake and at the University of Minnesota in repairing and testing the equipment is appreciated. This work is supported by an Air Force and a Radio Research Board grant.

CHROMIUM TRIOXIDE AEROSOL FROM HEATED 80:20 NICKEL–CHROMIUM WIRE

By P. GOLDSMITH, F. G. MAY and R. D. WIFFEN

Health Physics and Medical Division, Atomic Energy Research Establishment, Harwell, Didcot, Berkshire

WHEN wires are heated to temperatures of about 1,000° C they give off a considerable number of very small particles. In laboratory experiments on the behaviour of sub-micron particles it is often convenient to produce the test aerosol by passing air over an electrically heated wire of such metal as 80 : 20 nickel–chromium alloy, platinum or silver. Since most laboratory work has been concerned with the physical characteristics of the sub-micron particles such as their diffusion, deposition and coagulation properties, very little work has been done on the chemical nature of the particles produced from hot wires. The only direct investigation on the chemical composition of the particles was done by Megaw and Wiffen[1] using neutron activation techniques. They concluded that the particles from heated nickel–chromium wires consisted mainly of chromium with about 2 per cent copper from impurities in the metal wire. There was no evidence of the presence of nickel in the particles. The aerosol production from a heated nickel–chromium wire is also dependent on the presence of oxygen in the surrounding gas, and this makes it reasonable to assume that the particles are composed of the stable oxide of chromium, chromium sesquioxide, Cr_2O_3. However, during recent work on the behaviour of sub-micron particles in gradients of temperature and in the presence of diffusing water vapour[2], it was concluded that the particles produced from a heated nickel–chromium wire were deliquescent. To account for this property it was speculated that some chromium trioxide, CrO_3, must be present in the particles. This has since been substantiated by direct chemical tests.

In these experiments the aerosol was produced by passing air over a nickel–chromium wire (electrical resistance 190 ohms/m) 30 cm in length and 0·0083 cm in diameter. The wire was mounted vertically down the centre of a 'Pyrex' glass tube 5 cm in diameter, the walls of which were water cooled. Air was passed through the tube at flow rates of between 4 and 10 l./min. The wire was maintained at a temperature of about 1,000° C by means of a stabilized mains a.c. supply. The aerosol, produced in this way, was stored in either a bag made of aluminized 'Milar', or a water-sealed steel gas holder of about 500 l. capacity. Under these conditions, a very high concentration ($> 10^6$/cm^3) of small particles ($< 0{\cdot}003$ μm radius) was produced, which initially coagulated very rapidly. After storage for about 18 h the concentration was about 5,000/cm^3 with a mean size of 0·05–0·1 μm radius as deduced from their diffusion characteristics.

The particles were found to have the following properties: (*a*) When the gas was supersaturated with water vapour the particles increased in size at a supersaturation lower than that expected from their physical size, assuming them to be insoluble. This increase in size was detected by measurements of their gravitational settling velocity. (*b*) When allowed to coagulate at low humidities in the 'Milar' bag (~10 per cent relative humidity), they formed chain-like aggregates; Megaw and Wiffen had also observed this[1]. Fig. 1 shows an electron microphotograph of such particles. Coagulation at high humidities (> 85 per cent) in the gas holder resulted in the formation of near-spherical particles. Fig. 2 shows the appropriate electron microphotograph. (*c*) After coagulation in the dry state to form chains, the particle shape could be modified to become more spherical by increasing the

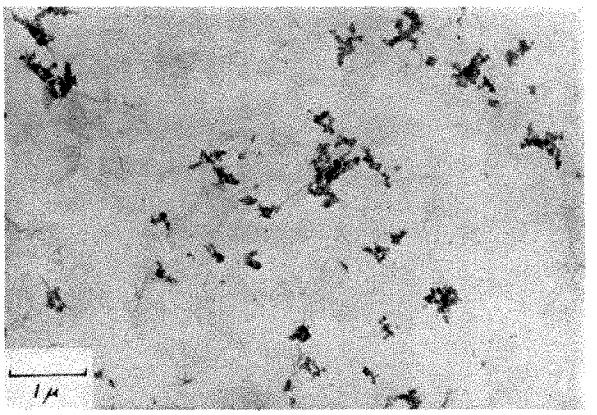

Fig. 1. An electron microphotograph of the particles produced by a hot nickel–chromium wire and allowed to coagulate for 18 h under dry conditions to form chain-like aggregates

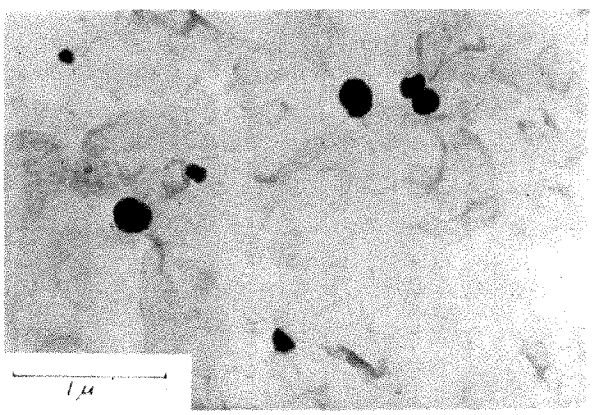

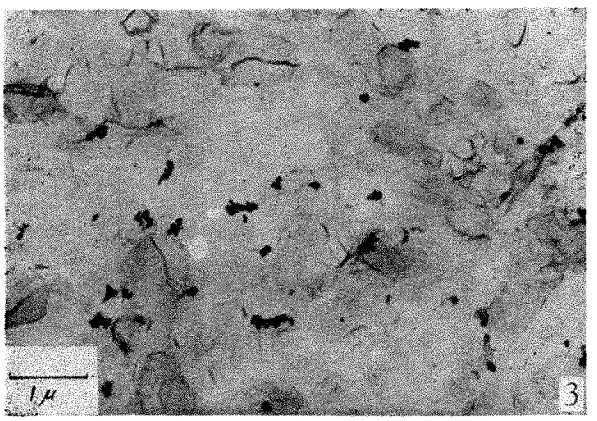

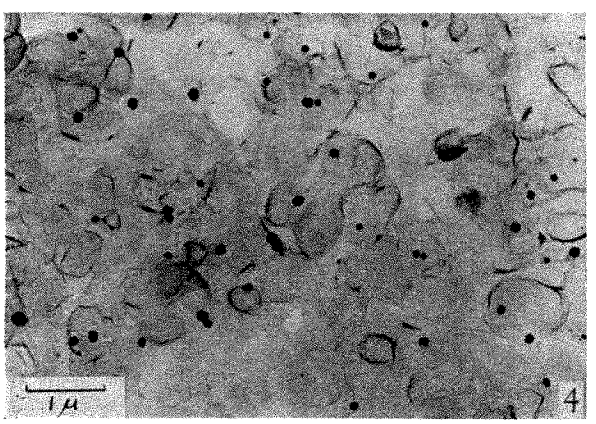

Fig. 2. An electron microphotograph of particles produced under similar conditions to those shown in Fig. 1, but allowed to coagulate under humid conditions. The deliquescent nature of the particles results in droplet-like coagulation to form spherical aggregates

humidity. The aerosol particles before and after humidifying are shown in Figs. 3 and 4. These three properties are all explained if the particles were deliquescent. That these properties are peculiar to particles from nickel–chromium was demonstrated by similar tests with an aerosol produced by a heated platinum wire. These particles coagulated to form chains even in a saturated atmosphere (Fig. 5). The stable oxide, Cr_2O_3, is, however, insoluble and so could not give rise to the deliquescent character of the particles. The presence of some chromium trioxide (CrO_3) on the particles would satisfactorily account for the deliquescence since the relative humidity over a saturated solution of chromium trioxide is 35 per cent. The presence of chromium trioxide in the aerosol deposited on the glass walls of the production chamber was confirmed by spot tests for the chromate ion using barium chloride and silver nitrate, and a blue colour was obtained with hydrogen peroxide which extracted into ether.

The production of chromium trioxide from heated nickel–chromium wires is at first sight surprising, if only because of the fact that this oxide of chromium decomposes at high temperature and the wire is at about 1,000° C. However, it may be that its production is an important step in the liberation and formation of the aerosol. Preliminary results on the relative proportions of the aerosol consisting of chromium VI and chromium III indicate that as much as half the aerosol may be in the form of chromium trioxide shortly after production from a wire at 1,250° C. It is not certain whether all the chromium leaves the surface as chromium trioxide vapour, some of which afterwards breaks down to chromium sesquioxide before leaving the hot zone around the wire, or whether some of the sesquioxide is released by quite a different process.

Figs. 3 and 4. Particles of the nickel–chromium aerosol before (Fig. 3) and after (Fig. 4) being passed into a humid atmosphere after initial coagulation in the dry state. The modification in shape is due to the surface tension of the water film on the deliquescent particles in the humid atmosphere

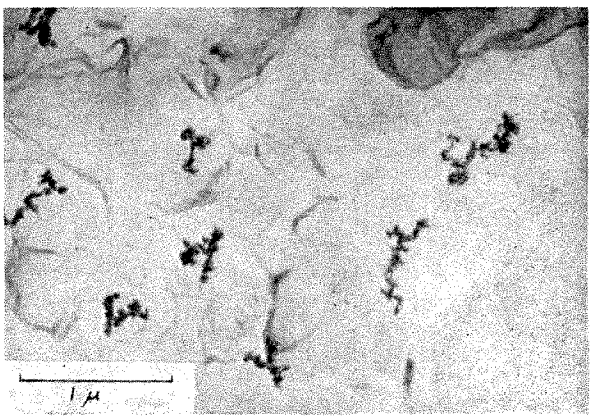

Fig. 5. An electron microphotograph of particles from a hot platinum wire which were allowed to coagulate under humid conditions. The insolubility of these particles results in a chain structure even at high humidities

The results of studies of the corrosion of heated nickel–chromium alloys are not at variance with the formation of chromium trioxide. In tests on the failure of 80 nickel–20 chromium alloy wires, Holler[3] found that the percentage of chromium in the metal fell from 20 per cent to 6·4 per cent when the wire was heated in air at a temperature of 1,100° C for 172 h. Holler suggested that the failure of electrical heaters was due to non-uniformity in the loss of chromium producing local changes in the electrical resistance which gives rise to 'hot-spots' in which loss of chromium is accelerated. Failure of the wire then occurs in these regions.

Work on the oxidation rate of nickel–chromium alloys at temperatures between 500° and 900° C by Gulbransen and Andrews[4] demonstrated the formation of a protective oxide coating which was predominantly chromium sesquioxide. The oxidation rate was dependent on minor constituents such as manganese and silicon as well as the temperature. Oxidation at temperatures between 1,000° and 1,300° C (ref. 5) showed three regions in the neighbourhood of the alloy surface. The innermost layer consisted of granules of chromium sesquioxide dispersed in pure nickel. The intermediate region consisted of granules of nickel chromite, $NiCr_2O_4$, dispersed in nickel oxide, NiO. The layer immediately in contact with the air was composed of pure nickel oxide.

The threshold temperature at which particles are produced by electrically heated nichrome wires is about 850° C. This suggests that the chromium leaves the surface at temperatures above 850° C to produce the sub-micron particles and that this temperature coincides with that at which the oxidation process changes from one type to the other. A study of the aerosol particles emitted by hot surfaces may be a neglected source of information on oxidation–corrosion mechanisms.

The identification of chromium trioxide as a constituent of the particles emitted by hot nickel–chromium wires has led to a consideration of the possibility of an associated hazard to health, as chromium trioxide, unlike chromium sesquioxide, is toxic[6]. It is possible from our results to make some rather crude estimates of the concentration of chromium trioxide in a room heated by a radiant electric fire.

The concentration of particles containing chromium trioxide in a room is a balance between the rate of production and the various loss processes. These processes are the deposition of the particles on the walls and other surfaces of the room, destruction of the chromium trioxide by chemical interactions with minor constituents in the air, and the ventilation rate of the air from the room. For sub-micron particles of chromium trioxide, the ventilation rate will be the controlling loss mechanism. Preliminary results so far obtained on the production of chromium

aerosol from 80 : 20 nickel–chromium wire as a function of temperature show that the production rate in dry air varies from 28 μg/h/cm² of wire surface at a temperature of 1,200° C to 0·14 μg/h/cm² at 950° C. These results were obtained by collecting the particles emitted from a short length (9 cm) of neutron activated nickel–chromium ribbon (0·063 cm × 0·015 cm cross-section) over periods of from 10 to 200 min and assaying the total amount of chromium in the particles from the radioactivity due to the neutron induced chromium-51.

If the rate of production of chromium is only dependent on the surface area of the wire and its temperature, then the production rate of chromium trioxide from a 1-kW electric fire element made of 26 s.w.g. nickel–chromium wire can be calculated, assuming in accordance with our findings that chromium trioxide makes up about half the chromium in the particles. Considering a room of 30 m³ in volume and allowing a ventilation rate of three air changes per hour, it can be shown, for a typical fire temperature of 950° C, that the average chromium trioxide concentration of the air in the room is about 10^{-3} of the 'maximum allowable concentration' of 0·1 mg/m³ given by the Ministry of Labour's *Safety, Health and Welfare Booklet* No. 8 (ref. 7).

This conclusion relates strictly to the particular batch of commercial wire (Nichrome V) used in these experiments, but it is of the type used in many domestic heating appliances. However, it may be expected that the chromium trioxide production rate will also vary with the minor constituents of the alloy, the length of time heated and the type of wire mounting used.

VARIATION IN SOLAR INSOLATION TO THE SOUTH POLAR REGION AS A TRIGGER WHICH INDUCES INSTABILITY IN THE ANTARCTIC ICE SHEET

By PROF. A. T. WILSON

Victoria University of Wellington, Wellington, New Zealand

WHEN considering the physics of past glacial advances it is necessary to divide glacial or potential glacial areas of the Earth into two regions: (*a*) regions where glacial ice now melts producing water which flows away from the snout of the glacier; (*b*) regions such as the polar regions where there is very little melting and where the ultimate fate of the glacial ice is either to sublime or to flow as ice on to the sea and be calved as icebergs

In the former case, for example, the Swiss Alps, Scandinavia and the temperate Alpine regions, a lowering of the mean annual temperature will lower the 0° C isotherm so that precipitation which flowed away as water will remain as ice and snow. If the cooling should be sufficient for the ice to spread on to the flat lowlands, the glacial advance will produce ice sheets. The effect is to some extent self-perpetuating in that large areas of ice and snow will cause local cooling.

In the second case, for example, Antarctica, where, because of the low temperatures, glacial melting is already negligible, further lowering of the mean annual temperature does not lead to a glacial advance. In fact, in these regions a lowering of temperature would lead to more extensive cover of the surrounding oceans by sea ice which would decrease the precipitation to the land. This would lead, in turn, to a retreat of the glaciers.

There is considerable evidence[1–3] that Antarctica was more extensively glaciated at times in the past than it is at present. It is frequently assumed (for example, refs. 3, 4 and 5) that the last of these glaciations occurred during the last northern glaciation. From the arguments already stated it can be seen that this is physically unlikely, and that it is more reasonable to expect Antarctica to have been more glaciated during the northern interglacial periods. Thus, it would be expected that periods of growth and recession in the Antarctic ice cap would be out of phase with the glacial phases of the more temperate regions.

Recent work[6–8] on heat transfer between northern and southern hemispheres makes it appear unlikely that temperate regions of one hemisphere could be in a glacial period while those of the other were in an interglacial period. This means that the Milankovitch theory[9], which is based on variations in solar insolation at 65° N. causing glaciations in the northern hemisphere, needs some drastic revision. As Zeuner[10] and others have pointed out, the variations in solar insolation calculated by Milankovitch are in themselves inadequate to produce large-scale glaciation. It has generally been felt that some additional mechanism was required. I suggested[11] that this mechanism was the inherent instability of the Antarctic ice sheet and that the instability might be triggered

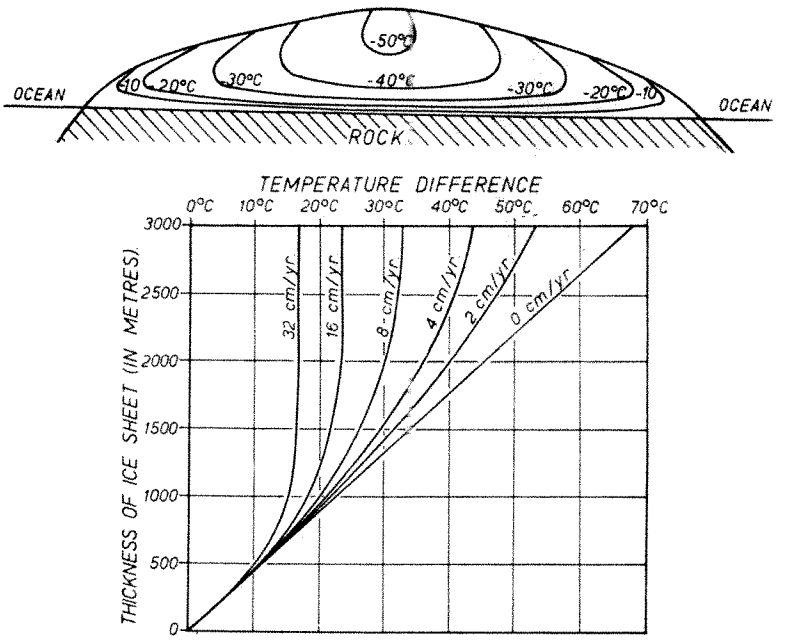

Fig. 1. Schematic diagram of the temperature distribution in a simplified ice sheet and a plot of the temperature difference between the base and other levels near the centre of such an ice sheet (after ref. 14)

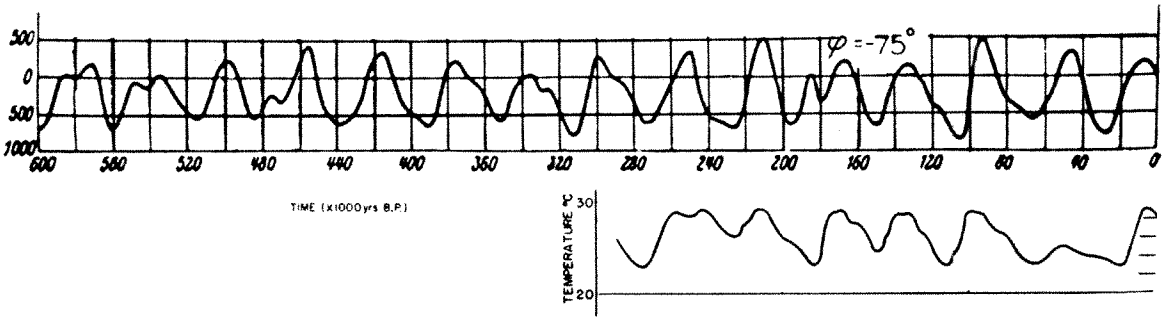

Fig. 2. Top curve: plot of the solar insolation for latitude 75° S. (after ref. 9) compared on the same time scale with the bottom curve, which is a plot of the generalized temperature curve for tropical surface waters (after ref. 13). Note correlation of curve minima

by a minimum in the solar insolation curve. E. P. J. Van den Heuval has, quite rightly, pointed out[12] that it is the variation in insolation to the polar regions that is of particular importance. I would like to enlarge further on this aspect of the theory.

As Emiliani[13] has pointed out, the palaeotemperature record of deep-sea cores seems best interpreted in terms of the periodicity of about 40,000 years. It is interesting that this corresponds to the period of oscillations of the obliquity of the Earth's ecliptic (usually indicated by ε), that is, variations in the angle of inclination of the Earth's axis to a line perpendicular to the plane of the Earth's orbit. This angle is at present 23·5°, but varies periodically between 24·5° and 21·5°. Minima in this value appear to correspond to minima in the temperature curve for tropical surface waters (as measured by the variations in the oxygen-16 : oxygen-18 ratio in the carbonate of foram shells in deep sea cores[13]).

Maxima in ε would correspond to the polar regions being more inclined towards the Sun in summer giving warmer summers in polar regions. Conversely, minima in ε would correspond to cooler summers in the polar regions. During the period of minimum ε the sea ice, which now forms a belt about 300–1,000 miles wide around the Antarctic continent in winter, would be more extensive and would persist farther north for a greater fraction of the summer. Since this would have the effect of moving the Antarctic ice cap farther from the ocean, the precipitation on the surface of the Antarctic sheet would decrease.

It can be seen, therefore, that the obliquity of the Earth's axis affects the insolation to the South Polar regions, which in turn determines the extent and persistence of the sea ice. This controls the effective distance of the ice cap to the open ocean and thus the precipitation on the ice cap. If the precipitation falls below a certain critical value (see Fig. 1) the temperature at the bottom of the ice cap rises above the pressure melting-point. This leads to a catastrophic instability which generates an ice shelf around Antarctica, as I have already proposed[11]. This ice shelf acts as a giant reflector which lowers the heat input to the Earth and drives the temperate regions of the Earth into an ice age.

The net accumulation of snow at the South Pole is 7·4 g/cm², and our recent work[15] has shown that this represents half the total precipitation. The total precipitation at the South Pole is therefore 15 g/cm². If, for example, precipitation were to be reduced by 30 per cent to 10 g/cm² and if the sublimation were to remain constant, the net accumulation would be only 2·5 g/cm²; the ice sheet in the model shown in Fig. 1 would become unstable. If the polar plateau were higher in the past than at present, as is suggested by glaciated nunataks[1–3], the percentage reduction in precipitation required to induce instability would be even less (see Fig. 1).

Thus it can be seen that a decrease of solar insolation in the South Polar regions due to cyclic reductions in ε would offer an attractive mechanism for explaining how the Antarctic ice sheet becomes unstable and thus triggers a catastrophic advance. Fig. 2 shows a comparison of the solar insolation curve in the South Polar regions calculated by Milankovitch[9] as compared with that for Emiliani's oxygen-16/oxygen-18 temperature curves for the surface ocean waters at low latitude[13]. As can be seen, the agreement is remarkably good.

'DATING' GROUND WATERS OF AGES YOUNGER THAN 1,000–1,500 YEARS USING NATURAL SILICON-32

By V. N. NIJAMPURKAR, B. S. AMIN, D. P. KHARKAR and PROF. D. LAL

Tata Institute of Fundamental Research, Colaba, Bombay-5

FOR the determination of the characteristics of ground waters with respect to their rate of recharge from the surface by percolation of rain/river waters, two techniques based on natural radioactivities have so far been explored. These are based[1–3] on two radioisotopes produced by cosmic rays; namely, tritium (half-life, 12·3 yr.) and carbon-14 (half-life, 5,730 yr.); in recent waters appreciable amounts of these activities arise owing to their injections into the atmosphere during the testing of nuclear weapons. The principle involved in the application of these activities to investigations of ground water characteristics lies in the estimation of fractional decrease due to radioactive decay and thus obtaining the apparent 'age': corrections have to be made for any loss of activity

by other means, for example, chemical losses. The corrections are minimal for tritium, which closely follows the motion of bulk water molecules except for a small isotopic fractionation. In the case of carbon-14, an appreciable and variable loss occurs in its specific activity in the ground waters due to chemical exchange between the bicarbonate in solution and carbonate in limestone minerals present in soil or the water-bearing rocks[2,3]. The errors in the apparent carbon-14 'ages' due to this are estimated to be ± 1,000 yr., thus making the method useful only for dating waters older than 2,000 yr. The tritium method, on the other hand, is limited to determination of ages of water younger than 50 yr.—due to its short half-life.

There is thus a need for a suitable method of dating waters which are 50–2,000 yr. old. This article presents the results of our exploratory analyses carried out to study the possibility of using silicon-32, a radioactive isotope with a half-life of about 500 yr., which is continuously produced in the atmosphere by spallation of argon by the primary and secondary particles of cosmic rays[4]. Its activity has been determined in wet precipitations (rain/snow) and ocean water[5–7] and adequate information also exists on its production by cosmic rays[8]. It also seems certain that all silicon-32 on Earth has originated from cosmic ray action and that so far no measurable amounts have been added by nuclear weapon trials[6].

Silicon-32 decays by β-emission to phosphorus-32, the half-life of which is 14·3 days. The activity of silicon-32 is thus conveniently determined by 'milking' phosphorus-32 activity. We extracted silica from several surface and sub-surface waters by scavenging it with ferric-hydroxide. The extract was chemically purified and allowed to equilibrate with its daughter nuclide, phosphorus-32. The activity of phosphorus-32 was counted using highly sensitive β-counters (background 2–3 counts per hour, with a counting efficiency of about 40 per cent). The radiochemical and counting procedures have already been described in detail[6].

The results of determinations of silicon-32 activity in several surface and sub-surface waters are presented in Table 1. The sampling sites are marked in Fig. 1.

Using a few thousand litres of water, the net phosphorus-32 activities obtained are in the region of a few counts per hour. These small signals can nevertheless be measured with a high precision, because the decay of

* This represents the equivalent volume of water from which silicon-32 was extracted: the actual volume taken was 15–30 per cent larger.

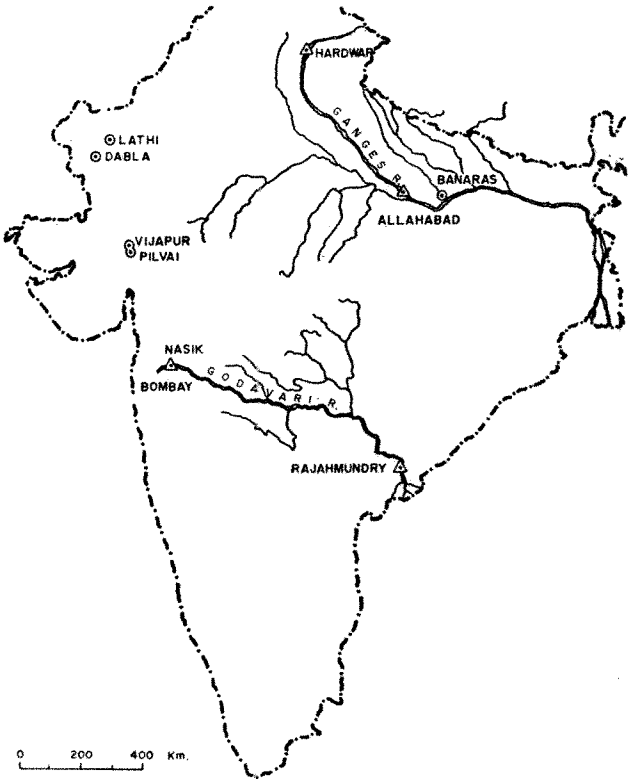

Fig. 1. Sampling sites of surface and sub-surface waters. △, River water samples; ○, tube-well samples

phosphorus-32 activities is followed over periods of 2–3 months. Fig. 2 shows some typical decay curves. Experience based on 'remilking' phosphorus-32-activities from weak silicon-32 activities has shown that we can detect a net counting rate due to phosphorus-32 if it exceeds 0·5 c.p.h., and a high precision in measurement is possible for signals exceeding 5 c.p.h.

The concentrations of silicon-32 in river samples (*T.F.* 51, 50, 53, 49) are in the range of about 0·1 d.p.m./10^3 l. The concentrations in tap water and Lake Tansa, which supplies water to the city of Bombay, are higher by about a factor of two. The tube-well samples from the semi-arid and arid regions of Gujarat and Rajasthan, respectively, have activities which are lower than those in rivers. The results for the Banaras tube-well, which is situated in the Gangetic plains, are not precise enough, as the volume of water processed was small.

The concentrations[6] of silicon-32 in wet precipitations in India average out at about 0·45 d.p.m./10^3 l.—a value which is considerably higher than that even observed for river water samples. In order to understand the geochemical behaviour of dissolved silica in rock/soil environments we carried out several tests, the results of which will now be summarized.

(1) The content of dissolved silica in rain water is small —of the order of 0·2–1·5 p.p.m. Water flowing over rock terrains, or in contact with soil, quickly attains large concentration values, 5–30 p.p.m., as are usually found in surface and sub-surface waters, depending on the rock/soil types. The chemical form of silicon in solution at *p*H less than 9, which, in the case for waters under question, is believed to be monomeric silicic acid[9], and the amorphous species of silica present in soil are supposed to undergo dissolution.

(2) If, to a sample of water containing 20 p.p.m. silica in solution, some soil is added for which the equilibrium silica solubility value is in the region of about 5 p.p.m., the concentration of dissolved silica rapidly drops to 5 p.p.m.

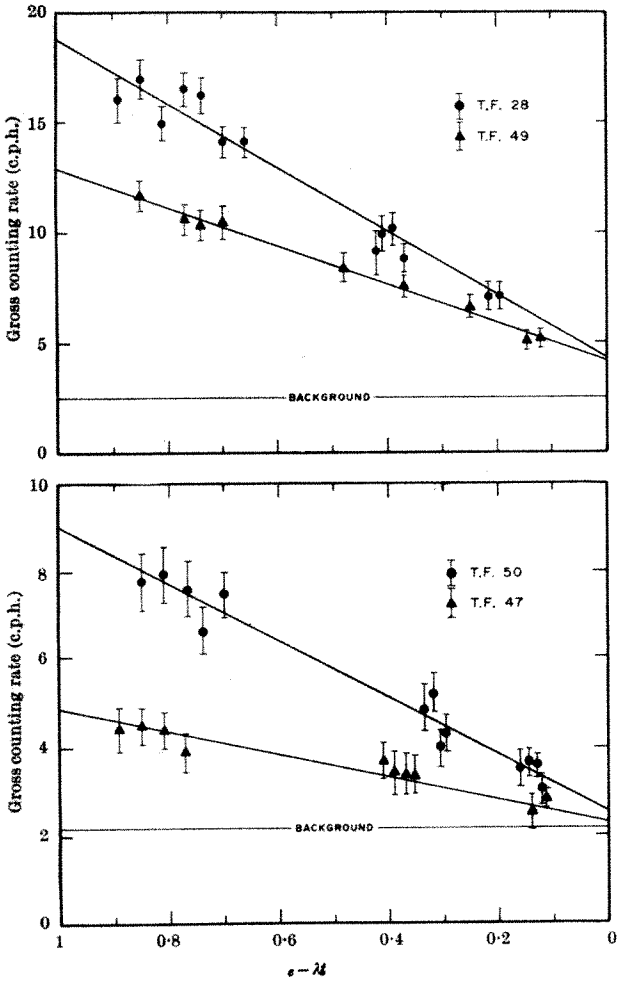

Fig. 2. Observed decay of phosphorus-32 activities 'milked' from silicon-32

(3) The total amount of silica which can be dissolved out of soil by contact with water is quite large—typical values are of the order of 1 per cent.

(4) If the concentration of dissolved silica is increased in a sample of water containing silicon-32 from nearly zero concentrations (0·5 p.p.m.) to about 10 p.p.m., no measurable decrease in silicon-32 activity occurs. (This result is based on an experiment carried out on a sample of rain water (5×10^3 l.). Half the water was processed directly for its silicon-32 concentration. 80 kg of red soil were added to the other half. The soil was stirred occasionally over a period of a month, and silicon-32 activity was then determined in the water.)

From the results already discussed here, and also from the fact that detectable amounts of silicon-32 are found in ground waters, it seems clear that the loss of silicon-32 by chemical exchange in a particular environment is unimportant. Appreciable losses would occur only when the environments alter so that an inorganic precipitation may occur. We ignore in our present discussions the role of biological processes for the removal of dissolved silicon, which seems important only in the case of marine environments or special cases of 'closed' water bodies.

Thus, depletions by chemical exchange between the dissolved silicon and silicon minerals of the water-bearing rocks seem to be unimportant. However, as the rock/soil types may change considerably along the migratory routes of water, significant losses may occur. The magnitude of losses can possibly be ascertained by measuring the concentrations of dissolved silicon at different regions. Analysis of water samples collected from several regions of Gujarat and Rajasthan area showed that these waters have similar silicon concentrations in the two regions (within ±5 per cent) and there was little variability in the sub-surface soil-gravel type. In these cases, it is probable that inorganic precipitation is unimportant.

The present results do not offer any simple explanation of why the Ganges and Godavari river waters near the points of their origin (Hardwar and Nasik, respectively) are already depleted in their silicon-32 concentrations by a factor of about four, whereas subsequent traversals of a thousand kilometres or more do not appreciably change the concentration. The concentration values for Lake Tansa lie between those of river and rain water; about half its total water is annually charged by wet precipitations.

At present, even crude 'age' estimates are not available from the hydrological data for the various tube-well samples. We could not detect any tritium activity in the Rajasthan or Gujarat wells (less than 0·5 T.U.). Detectable amounts of tritium were only found in the Gujarat region, close to the expected recharge zone. Extrapolation of these results indicates that the Gujarat waters may be older than 100 yr. The water supply in this region is rapidly depleting and deeper aquifer-beds have to be tapped. The aquifer in the Rajasthan area is believed to be confined, with a possible recharge from the south. The lack of sufficient rainfall in this area makes it likely that these deep-seated waters are of considerable age.

If a value of 0·08 d.p.m./10^3 l. is assumed for the waters feeding the ground, based on river water data, it is possible to estimate the apparent ages for the water in these tube-wells. Vijapur water would then be estimated to be the youngest of the four tube-wells sampled, *T.F.* 60, 61, 47 and 46, which is in good agreement with expectations considering the recharge direction. It can also be stated with some certainty that none of these waters is older than about 1,000 yr., which is quite significant in considering the hydrological problems encountered in the two areas.

There is a distinct advantage in measuring both tritium and silicon-32 for any study of the characteristics of ground waters. Usually it is not known whether or not the water tapped from an aquifer is isolated from an input system. If a small continuous input occurs, measurable amounts of tritium can be detected, as surface waters are now very rich in 'artificial' tritium. In such cases this will result in wrong apparent 'ages'. A small recent recharge, however, will not alter by any appreciable amount the silicon-32 ages.

Experiments are now being planned to evaluate the feasibility of using silicon-32 for precise 'dating' of ground waters; its validity in determining upper limits in the region of a few hundred years, for which no other method is at present available, seems to be established.

We thank the Exploratory Tube Well Organization of the Indian Government and the Deputy Engineer, Tube Well Maintenance Department, Government of Gujarat, for their help in collecting sub-surface waters for this work. We also thank Mr. P. G. Adyalkar and Mr. R. N. Athavale for several helpful discussions.

AMINO-ACID COMPONENTS IN FOSSIL CALCIFIED TISSUES

By DR. W. G. ARMSTRONG

Department of Biochemistry, Royal Dental School of London, W.C.2

AND

DR. L. B. HALSTEAD TARLO

Department of Geology, University of Reading, and Royal Dental School of London, W.C.2

ABELSON[1] has shown qualitatively, using paper chromatography, the presence of aspartic acid, glutamic acid, glycine, proline, alanine, valine and isoleucine in fossil bone of Devonian age (380 million years old). Later, Wyckoff *et al.*[2], in similar investigations on more recent bone from the Pleistocene period (1 million years), found most of the amino-acids demonstrated by Abelson, and also hydroxyproline, the latter being virtually specific to the collagen group of proteins. In 1962, Little *et al.*[3], using electron microscopical methods, found collagen-like fibrillar fragments present in bone of Miocene age (25 million years old), and in the following year Isaacs *et al.*[4] also gave evidence for the presence of collagen in bone of Devonian and Triassic (200 million years) age, based on X-ray and electron diffraction investigations. Shackleford and Wyckoff[5] investigated bone of Miocene (and Pleistocene[2]) age by means of the electron microscope, and not only observed a fibrillar pattern, but also bandings similar to that characteristically associated with collagen fibrils. More recently Ho[6] has published quantitative data on the amino-acid residues in Late Pleistocene bone, the recovery pattern of which, while showing similarities to collagen composition, also indicated that differential rates of breakdown had occurred through geological time, some amino-acids, such as hydroxyproline, being very rapidly lost or destroyed.

In similar quantitative studies at the Royal Dental School, London, on considerably older specimens ranging in age from Jurassic (150 million years) to Devonian, the following were selected for preliminary analyses: (1) conodonts from the Genesee Group of the Upper Devonian from Erie County, New York; (2) a pliosaur tooth from the Kimeridge Clay of the Upper Jurassic of Ely; (3) a pliosaur ischium of the same age. The separation and assay of the amino-acids present in hydrolysates of the fossil specimens were made by means of a 'Technicon' automatic amino-acid analyser, and the results are shown in Table 1 and Fig. 1.

The results clearly confirm that micro quantities of many amino-acid components are to be found in fossil calcified tissues of considerable antiquity, but a comparison of them with a typical analysis of modern collagen provides only little evidence of affinity on compositional grounds. The amino-acids hydroxylysine and hydroxyproline, which are almost unique to the collagen group, are noticeably absent from the fossil material, though it does contain relatively large amounts of glycine, alanine and glutamic acid as in collagen. These two fossil tissues do show compositional similarities to each other and, from the work of Ho[6], it is conceivable that the amino-acid compositional profiles of the fossil material represent extrapolations of differential rates of loss and destruction,

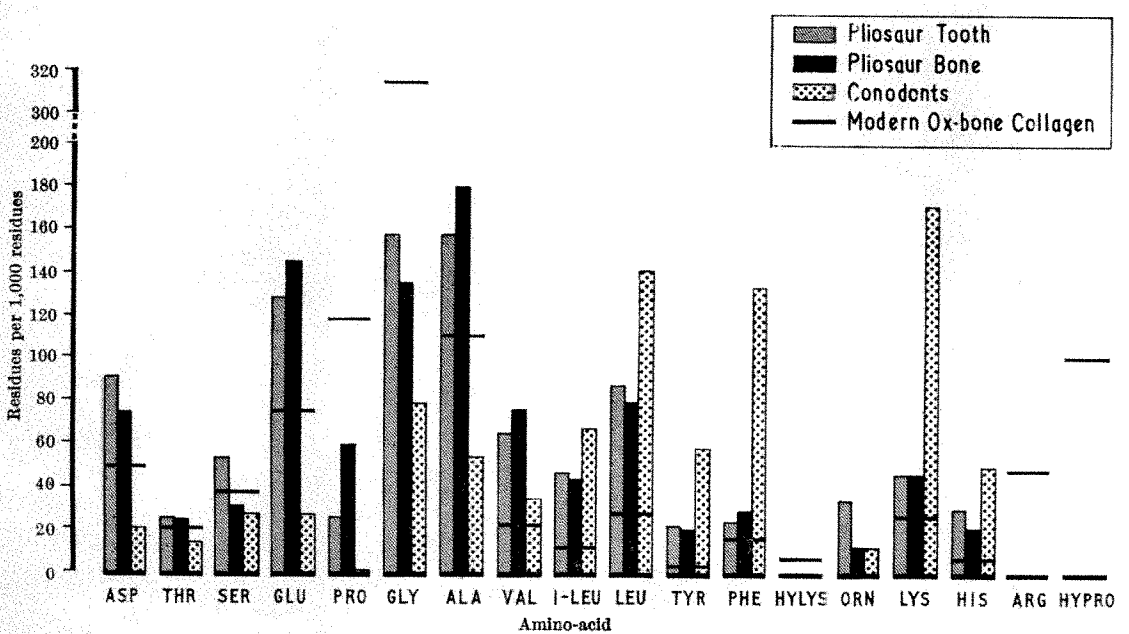

Fig. 1. Amino-acids in fossil calcified tissues expressed as residues per 1,000 residues

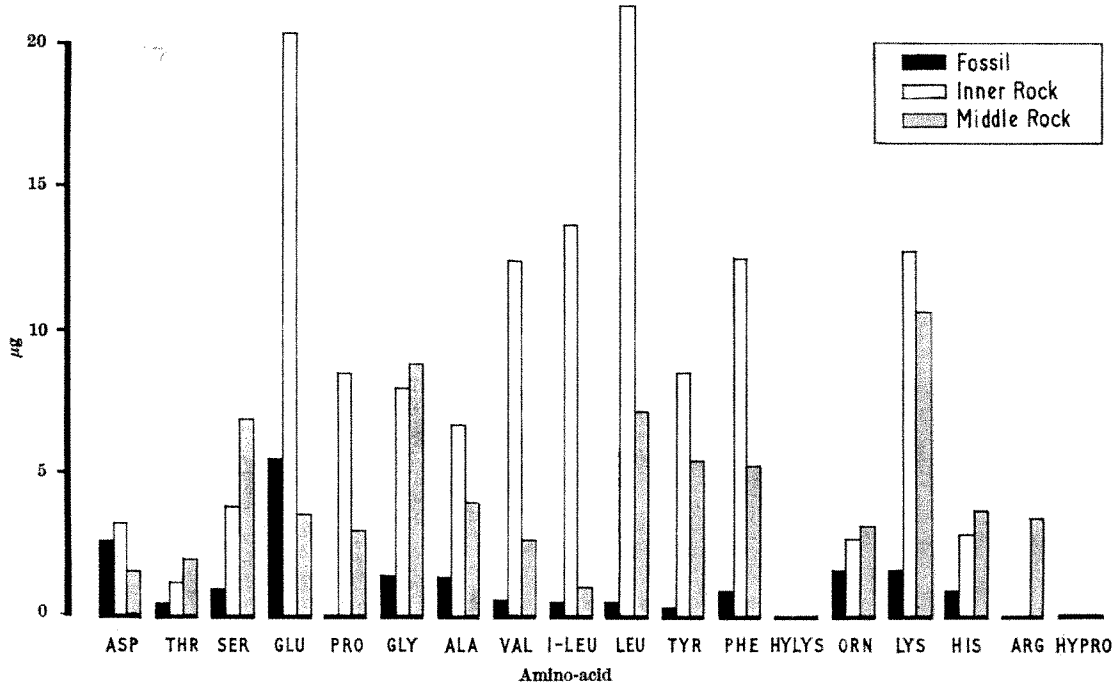

Fig. 2. Amino-acid per 5 g fossil or rock sample

although confirmation of this hypothesis requires further investigation. A comparison of the amino-acid pattern obtained from the conodonts with those of the two pliosaur fossil calcified tissues reveals little evidence of any affinity, the conodont hydrolysate showing only a trace of proline, relatively low concentrations of glycine, alanine and glutamic acid, and significantly large amounts of leucine, phenylalanine and lysine. Such a result could lead to the suggestion that the organic material in conodonts showed little similarity to fossil vertebrate calcified tissues, thus denying a possible vertebrate affinity for the conodonts as previously postulated by Tarlo[7].

However, arguments such as the foregoing can only be valid if, as some workers have suggested, the amino-acid components found in fossil material are derived solely from the remains of the organic matrices of the original animal tissues. With the observations of Erdman, Marlett and Hanson[8] that the same amino-acids found by Abelson in fossil bone are also present in both recent and ancient sediments, it was considered important that quantitative amino-acid analyses of the sedimentary rocks surrounding fossil specimens be carried out simultaneously with analyses of the fossil material itself. In consequence, a preliminary analysis has been made of ichthyosaur bone of Oxfordian (Upper Jurassic) age, together with sediments both immediately surrounding the fossil (inner rock) and sediments from a zone between 0·5 cm and 2 cm away from the fossil (middle rock). The quantitative results of these investigations are shown in Fig. 2.

Table 1. MICROGRAMS AMINO-ACID PER 5 g FOSSIL SPECIMEN

Amino-acid		Pliosaur tooth	Pliosaur bone	Conodonts
Aspartic acid	(ASP)	13·84	10·12	2·00
Threonine	(THR)	3·38	2·98	1·19
Serine	(SER)	6·54	3·36	2·21
Glutamic acid	(GLU)	21·54	21·92	3·09
Proline	(PRO)	3·28	7·14	trace
Glycine	(GLY)	13·62	10·43	4·50
Alanine	(ALA)	16·12	16·57	3·65
Valine	(VAL)	8·58	9·02	3·05
Iso-leucine	(I-LEU)	7·34	5·90	6·82
Leucine	(LEU)	13·10	10·89	14·00
Tyrosine	(TYR)	4·66	3·80	8·15
Phenylalanine	(PHE)	4·50	4·97	16·68
Hydroxylysine	(HYLYS)	0	0	0
Ornithine	(ORN)	5·08	1·19	3·44
Lysine	(LYS)	7·52	7·16	19·00
Histidine	(HIS)	5·12	3·26	5·90
Arginine	(ARG)	0	0	0
Hydroxyproline	(HYPRO)	0	0	0
Unknowns*		1·24	4·07	0

* Calculated as *nor*-leucine equivalents.

These results show that all the amino-acids detected in the actual fossil are to be found in considerably greater concentration in the surrounding rock. Certain amino-acids (glutamic acid, valine, isoleucine, tyrosine, phenylalanine and lysine) are found in the highest concentration in the inner rock zone, and this could infer that these amino-acid components had been leached from the bone at some stage, to become concentrated in the region immediately surrounding the fossil, with a subsequent slow diffusion into the surrounding sediment (middle rock). In contrast, the amino-acids threonine, serine, ornithine and histidine, which are found in higher concentration in the middle rock region, would have diffused from the surrounding sediment into the fossil, having originated from other organic debris.

Whether or not the foregoing hypotheses and explanations prove valid, it is apparent that the processes of differential breakdown and diffusion of organic substances involved in fossilization are far more complex than has previously been realized. For the present, caution must be exercised in drawing too obvious conclusions from the mere demonstration of organic components in fossil material without prior reference to the surrounding sediment. Further work is in progress on this topic in an attempt to clarify some of the many problems raised by these results.

We thank Prof. F. H. T. Rhodes for the gift of conodonts and the Medical Research Council for financial assistance enabling one of us (W. G. A.) to purchase apparatus.

EVIDENCE FOR DEPOLARIZATION OF THE INTERNAL MEMBRANE SYSTEM IN ACTIVATION OF FROG SEMITENDINOSUS MUSCLE

By DR. L. L. COSTANTIN and DR. R. J. PODOLSKY
National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Maryland

THE first direct evidence that the internal membrane system of skeletal muscle is involved in transverse activation was the demonstration by Huxley and Taylor[1] that application of current to certain sites of the frog muscle membrane produced reversible contractions which spread towards the centre of the muscle fibre without an equivalent longitudinal spread. Sensitive sites were confined to the level of the *Z* line, and, since a characteristic triad arrangement of internal membranes was found at this level of the sarcomere, they suggested that a component of these triads was associated with inward conduction of the 'influence' of surface depolarization. Since this report, the internal membrane system of skeletal muscle has been extensively investigated[2,3], and in most instances has been shown to consist of two discrete membrane-limited spaces, transversely oriented tubules (the *T* system), and longitudinally oriented sacs which envelop the myofibrils (the sarcoplasmic reticulum or SR). In frog twitch fibres, the membranes of the SR fuse to form cisterns (terminal sacs) at each end of the sarcomere which, together with a central transverse tubular element, constitute the triads. The *T* system appears to be directly continuous with the surface membrane[4,5] and also in close apposition to the terminal sacs of the SR[4,6,7]. Since these sacs appear to be specific regions for calcium accumulation[8], and since much evidence exists that the final step in activation is an elevation of the intracellular calcium ion concentration[9–12], it seems possible that depolarization beginning at the surface membrane could spread into the depth of the fibre by way of the *T* system to influence the release of calcium from the SR, and thus initiate contraction. As yet, however, there is no direct evidence for potential changes within either the *T* system or the SR as a step in the activation process.

Electrical activation. Both Csapo[13] and Natori[14] have reported that muscle fibres in which the sarcolemma had been removed could be activated electrically. This phenomenon was reinvestigated to see whether it could be attributed to current flow across the internal membrane system. A photomicrograph of the experimental preparation is shown in Fig. 1. A bundle of six to ten fibres was removed from a frog semitendinosus muscle in a sucrose Ringer's[15] or a normal Ringer's solution, blotted lightly, and covered with paraffin oil on a microscope slide. A short segment of one fibre was dissected free and the sarcolemma removed manually from about half its length. The procedure involved dissecting the sarcolemma and a superficial layer of myofibrils from the bulk of the fibre in one region and teasing this along the fibre until a length of about 1 mm had been skinned[16]; the sarcolemma can be removed in this way much as a sleeve is rolled up. Following dissection, the preparation was placed on a microscope stage, permitting simultaneous visual observation and cinephotographic recording. The preparation was illuminated by ordinary light with the condenser aperture stopped down until striations were readily visible.

To study the effects of current flow, silver–silver chloride wire electrodes were positioned in the two bundles of muscle tissue at the ends of the single fibre (Fig. 1*A*). This arrangement provided a large surface area of electrode contact relatively far from the skinned portion of the fibre, so that the irreversible and presumably unphysiological contractures seen at the site of contact between electrode and preparation[14] could be avoided in the skinned portion.

Passage of direct current pulses (200–1,000 msec in duration) between the electrodes resulted in reversible contractions in the skinned portion of the fibre; typical responses are seen in Figs. 1*C* and 1*E*, 2*B* and 3*B*. The contractions were confined to discrete regions, usually less than 50μ in longitudinal extent, and a contractile region as extensive as that seen in Fig. 2*B* was encountered only rarely. In all cases, only a small portion of the sarcomeres in a responsive region contracted, usually in groups of two to five adjacent sarcomeres with apparently relaxed sarcomeres between.

If the direction of current flow was reversed, variable results were obtained. In many instances, no response was elicited until the current was increased, while in others, a more vigorous response resulted from reversal of electrode polarity. Although the same general region of fibre usually contracted with reversed current flow, the distribution of contracting sarcomeres within this region was quite different and bore no apparent relation to the initial distribution. The lowest current that elicited contraction was 1·5 μamp in a fibre of 100μ diameter, a mean longitudinal current density of about 20 m.amp/cm². Thresholds were variable, however, and a current of 4–5 μamp was usually needed to elicit visible contraction.

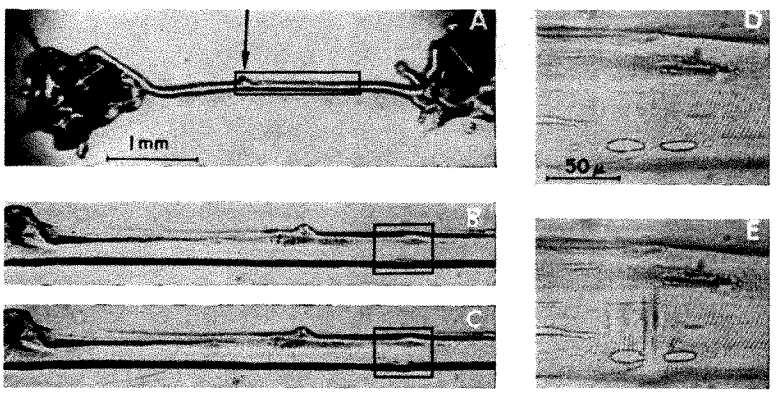

Fig. 1. Electrical activation of skinned muscle fibre. (*A*) Low-power photomicrograph of experimental preparation. Single fibre segment isolated between two multifibre bundles; the sarcolemma has been removed from the junction with the muscle bundle on the right to the point in the centre of the preparation indicated by the black arrow. The silver–silver chloride wire electrodes in the two bundles of muscle tissue at the ends of the single fibre are indicated by white arrows. The electrode in the muscle bundle on the right is not clearly seen. (*B*) and (*C*) Higher magnification of the region outlined in panel *A*. *B*, Before stimulation; *C*, peak of contraction during a 1-sec direct current pulse of 5 μamp. (*D*) and (*E*) Higher magnification of the region outlined in panels *B* and *C*. *D*, Before stimulation; *E*, peak of contraction during 500 msec direct current pulse of 10 μamp. The magnitude of the contraction to 5 μamp had decreased between *C* and *E*

Somewhat larger currents were required with pulse durations less than 100 msec; the threshold for brief pulses was not examined extensively, but, in one instance, a 1 msec pulse of 10 μamp elicited contraction. A few preparations were totally unresponsive, a finding more frequent when the dissection was hindered by the presence of large amounts of connective tissue within the muscle. Although the response disappeared with repeated stimulation, it was sometimes possible to stimulate at a rate of 1/sec for up to 5 min. Following disappearance of the response at one site, an increase in stimulating current usually produced contractions in different regions of the skinned fibre, but it was never possible, even with currents one hundred times threshold, to contract the entire skinned region. Similar responses were not seen in the unskinned portion of the fibre. 'Break' responses, brief localized contractions which followed the cessation of direct current pulses of 200 msec or longer, were readily obtained in both the skinned and unskinned portions, but were not investigated in detail. Large-tipped micropipettes (25–100μ in diameter) filled with 140 mM potassium methyl sulphate agar were occasionally used as electrodes with similar results.

Chloride activation. To test the possibility that longitudinal current acts by producing voltage changes across part of the internal membrane system, an attempt was made to mimic its effect by changing the ionic environment of the membranes. Since the surface membrane of the fibres had been removed under paraffin oil, the composition of the medium bathing the intracellular membrane system in these preparations was essentially that of the normal sarcoplasm and would be expected to have a relatively low concentration of diffusible anions[17]. An increase in the intracellular concentration of a diffusible anion would tend to drive the potential of the myofibrillar space positive with respect to the spaces within the internal membrane system; the magnitude of this potential change would depend on the anionic permeability of the internal membranes. Accordingly, the effect of elevation of the 'intracellular' chloride and methylsulphate ion concentration was compared by application to the surface of the skinned fibre of 0·2–1·2-mμl. droplets of 140 mM sodium chloride, potassium chloride, *tris* hydrochloride (*tris*(hydroxymethyl)aminomethane titrated to *p*H 7 with hydrochloric acid), or potassium methyl sulphate. Alternate droplets containing Cl^- or $CH_3SO_4^-$ were applied every 250μ along the skinned portion. Reversible contractions lasting 1–2 sec were seen in about half the trials the first time a region was tested with the chloride solutions; if a second chloride droplet was applied to the same region, the response was either markedly reduced or absent. The distribution of the chloride-induced contraction appeared to be determined by the inherent responsiveness of the fibre itself. In the experiment shown in Fig. 2, for example, the applied droplet remained well circumscribed, and, presumably, diffusion into the bulk of the fibre produced a symmetrical elevation of the chloride ion concentration about the site of application; nevertheless, a markedly asymmetrical contraction resulted. Sodium chloride, potassium chloride and *tris* hydrochloride were apparently equally effective in eliciting contractions, while the fibre was not responsive to similar droplets of potassium methyl sulphate; the contractions thus seemed to result from the elevation of intracellular chloride.

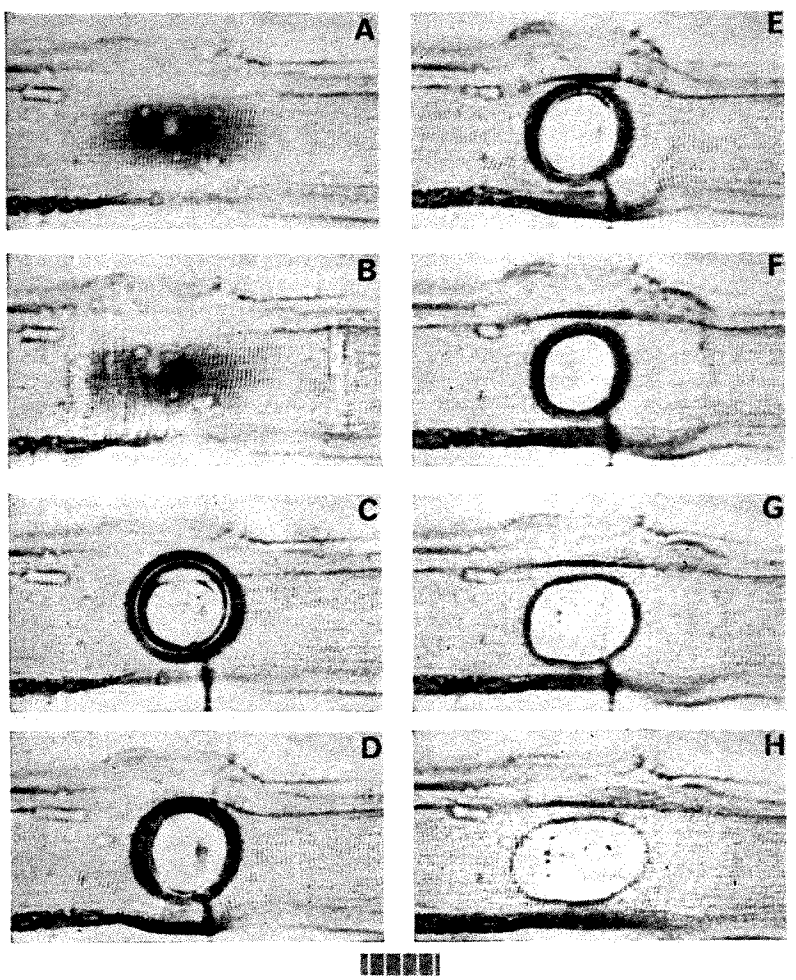

Fig. 2. Response of skinned muscle fibre to current flow and potassium chloride droplet. (*A*) Segment of skinned fibre. (*B*) Same region at peak of contraction during 1 sec direct current pulse of 8·3 μamp. The shadow in the centre of panels *A* and *B* is a potassium chloride droplet out of focus above the preparation. (*C*) Same region at moment of contact of 0·3 mμl. droplet of 140 mM potassium chloride with surface of skinned fibre. (*D*)–(*H*) 0·5, 1, 2, 3 and 4 sec following droplet contact. Note the asymmetrical distribution of the contraction about the region of application of the chloride solution. Grid spacing, 10μ

Over the range of droplet sizes from 0·2 to 1·2 mμl., the extent of the chloride-induced response was not correlated with droplet size. With much smaller droplets (less than 0·01 mμl.), however, chloride did not elicit contractions, presumably because the probability of producing an appreciable increase in chloride ion concentration in a responsive region was much less with the smaller droplets.

The results of chloride application differ markedly from the response of the skinned fibre to calcium application[18]. The calcium-activated contractions are invariably confined to the immediate site of application, and, when the fibre surface is explored, all regions are found to be responsive. In further contrast to chloride-induced contractions, the calcium-activated response can be elicited repeatedly at the same site, and the magnitude and duration of the contraction depend on the amount of added calcium. It is apparent that the mode of action of added chloride is quite different from that of added calcium.

Electrical and chloride activation. If the mechanism of activation by electric stimulation and chloride application were the same, it should be possible to activate the same regions of the skinned fibre with either stimulus. Since chloride application markedly reduced the response of a region to subsequent electrical stimulation, it was necessary to locate an active region first by electrical stimulation and then to

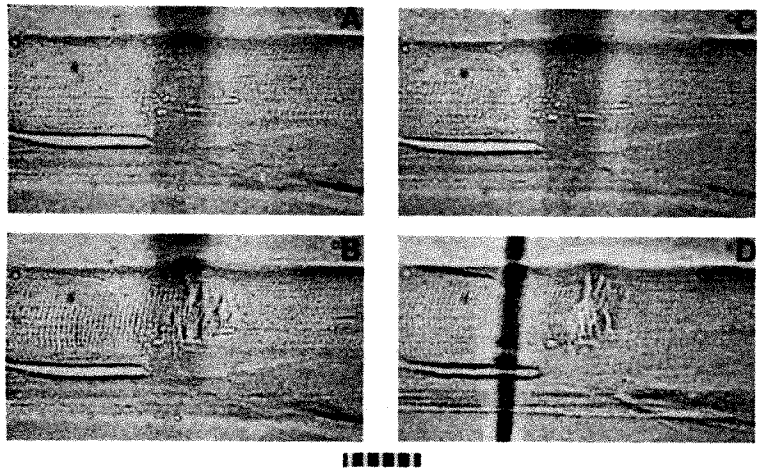

Fig. 3. Experiment showing similar response of skinned muscle fibre to electrical and chloride activation. (*A*) Segment of skinned fibre. (*B*) Same region at peak of contraction during 1 sec direct current pulse of 6·7 μamp. (*C*) Same region following cessation of electric stimulation. The shadow in the centre of the records *A*–*C* is a micro-pipette which is out of focus above the preparation. (*D*) Same region at the peak of contraction about 1 sec after application of 1·2 mμl. of 0·14 M potassium chloride to the preparation. The pipette had been lowered to apply the solution and is more clearly seen. Grid spacing, 10μ

test its response to chloride application; such an experiment is shown in Fig. 3. Fig. 3*B* was taken at the peak of a contraction induced by a 1-sec pulse of 6·7 μamp. A 1·2 mμl. droplet of 0·14 M potassium chloride was then applied to the slide immediately adjacent to the electrically responsive region of the fibre. The applied volume spread rapidly over the fibre surface and elicited the contraction seen in Fig. 3*D*. The distribution of this response is similar to the distribution of the electrical response (Fig. 3*B*), which suggests that both contractions were due to stimulation of the same specialized structure within the fibre. In other experiments chloride application and electric current usually stimulated the same general regions, but the chloride-induced contraction was often more extensive (Fig. 2) and currents many times threshold were able to stimulate only a part of the chloride-responsive regions.

These experiments strongly suggest that chloride application and electrical stimulation activate the skinned muscle fibre by a common mechanism. The spotty distribution of responsive regions indicates that these stimuli do not act on the contractile mechanism itself which, as demonstrated by calcium application, is uniformly responsive in the skinned fibre. It is, of course, possible that the dissection procedure damages the internal membrane system in some fashion so that the contractions induced by chloride application and current flow occur by a totally unphysiological process. Electron microscopic investigations, however, show an apparently intact sarcotubular system through the bulk of the preparation[8], and the finding that those fibres which were dissected with difficulty were less responsive to both current flow and chloride application also argues against this view. Since both stimuli can produce potential changes in the surface membrane, the most direct explanation for the present findings is that they produce similar changes in elements of the internal membrane system and that this leads to activation of the contractile mechanism.

The absence of response of the unskinned portion to current flow is not surprising; electrical activation in intact muscle is abolished when the membrane potential falls below 20–30 mV (ref. 19), and this is presumably the situation in the unskinned portion of the fibre. The responsiveness of the skinned portion to current flow implies that the dissection procedure serves to re-establish excitability in some way. One possibility is that, when the sarcolemma is dissected away, a potential difference can be maintained between the myofibrillar space and the interior of the internal membrane system. This could occur, for example, if the transverse tubules were to seal following disruption of continuity with the surface membrane. Although we have no direct evidence for such a mechanism, it is consistent with the finding that seemingly intact triadic structures are found even in isolated vesicle preparations[20].

If we accept the hypothesis that a potential change across the internal membranes is the mechanism for activation in the present experiments, the question then arises as to whether the primary change occurs across membranes of the *T* system or the SR. Since elements of both membrane systems course continuously in a transverse direction for long distances and seem to be confined longitudinally to one or two sarcomeres[3,5], the predominantly transverse distribution of most of the contractions as seen in Figs. 1, 2*B*, and 3 favours neither alternative. The current strength required to elicit contraction does, however, provide some evidence for excluding the *T* system from a primary role in this phenomenon. Using Sten-Knudsen's analysis[21] of the effect of a longitudinal electric field on the *T* system, the potential across the tubular membrane would change by only a fraction of a millivolt with the current strengths employed in the present experiments. In this case, it would seem more likely that a displacement of the potential across the membranes of the SR itself is the mechanism for activation by externally applied current. (The following values were used in the calculation: the specific resistivity of the SR and *T*-tubule membrane was taken to be that of the surface membrane: 3,000 Ω-cm² (ref. 22). The specific resistivity of the interior of the SR and *T*-tubule was taken to be that of normal Ringer's fluid: 80 Ω-cm. The specific resistivity of the sarcoplasm was taken as 200 Ω-cm[22]. The diameter of the *T*-tubule was taken as 350 Å (ref. 5). The longitudinal stimulating current was taken as 50 m.amp/cm² (4 μamp in a fibre 100μ in diameter), and the current density was assumed to be uniform through the cross-section of the fibre. It should be noted that the calculated potential change across the *T*-tubule is essentially the same for values of tubular membrane and tubular lumen resistance which are an order of magnitude different from those used here.)

Any estimate of voltage changes across the SR membranes involves considerable uncertainty because of the complex geometry of the SR, but, taking a space constant of 60μ and considering the SR as composed of discrete cylinders 400 Å in diameter and 3μ long, the present currents would produce a 1·5-mV displacement of membrane potential at each end of the sarcomere (see earlier). If specialized junctions with a low electrical resistance exist between adjacent terminal sacs by way of the *T* system[7], the effective length of the SR would be increased and the change of membrane potential in a longitudinal field would be greater. In this situation, current could enter or leave the sacs over more than one sarcomere and this might account for the observation that the electrical responses usually involved a few adjacent sarcomeres even when chloride application produced a rather extensive response (Fig. 2).

The present experiments demonstrate that the contractile mechanism of the skinned muscle fibre can be activated by stimuli which are known to depolarize the surface membrane. The possibility that these stimuli act directly on the SR, considered with the localization of calcium to the terminal sacs of the SR[8], suggests that translocation of calcium from the terminal sacs to the myofilament space can be produced by appropriate potential changes across the SR membranes. If this is the case, the normal sequence of excitation-contraction

coupling could involve a sequential depolarization of the surface membrane, T system and, by a mechanism which is still unclear, subsequent depolarization of the terminal sacs of the SR.

A PHYSIOLOGICAL METHOD FOR DETERMINING THE DEGREE OF METEOROLOGICAL COOLING

By SOLCO W. TROMP

Biometeorological Research Centre, c/o University Medical Centre, Department of Internal Diseases, Leiden, The Netherlands

THE great importance of cooling, both for general physiological and clinical studies, explains the many research studies carried out in the past to develop a simple method for determining this cooling factor. However, it is generally known that it is very difficult to determine accurately the degree of atmospheric cooling with a meteorological instrument. Hill's katathermometer[1], the Frigorimeters of Dorno[2], Thilenius[3], Wierzejewski[4], Henneberger and Mörikofer[5] and other similar instruments give only an approximate picture of the physiological influences due to the combined effect of temperature, air movement and humidity known as the 'cooling index'.

Bedford[6], Siple[7], Court[8] and Thomas and Boyd[9] suggested an empirical formula for calculating the cooling index: $h = \Delta t\ (9{\cdot}0 + 10{\cdot}9\ \sqrt{v} - v)$ in which h is the heat loss or wind chill in kcal/m²/h; Δt is the difference in temperature between the surface of the human body and the environment in °C; v is the speed of the wind in m/sec.

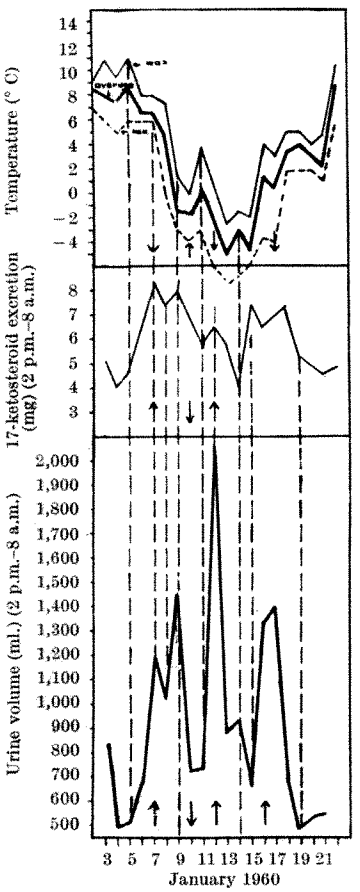

Fig. 1. Urine volume, 17-ketosteroid excretion and air temperature (——, maximum; - - -, minimum; ——, average) during the period January 3–22, 1960

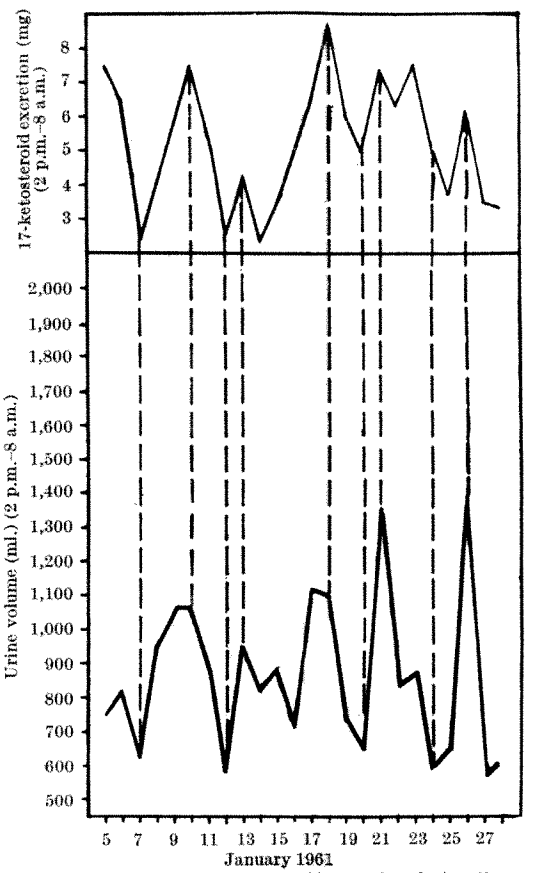

Fig. 2. Urine volume and 17-ketosteroid excretion during the period January 5–28, 1961

A very useful formula was also suggested by Thom[10] at the U.S. Weather Bureau:

The discomfort or temperature–humidity index (THI) = $Td - (0{\cdot}55\text{–}0{\cdot}55\ R) \times (Td - 58)$

in which Td is the dry bulb air temperature in °F, R is the percentage of relative humidity (65 per cent, indicated as 0·65). However, in this latter formula the effect of air movement was neglected, which restricts the field of application to indoor conditions.

In some earlier investigations I found[11] that in subjects with an efficient thermoregulation mechanism[12,13] a num-

ber of characteristic physiological changes occur, as a result of cooling, which seem to give a better picture of the degree of atmospheric cooling from a biological point of view. The changes observed can be summarized as follows: (1) During periods of strong atmospheric cooling a sharp increase of the daily urinary volume occurs within 12 h after a subject has been exposed to the open air for an hour (or even less). With a slight delay in time, the 17-ketosteroid excretion in the urine and the alkalinity increased. These processes are also accompanied by a decreased excretion of hexosamines, of chlorides, sodium and urea. Potassium usually decreased, but due to dietary conditions an increase was sometimes noted. Examples are given in Figs. 1–4. (2) Depending on the degree of cooling, the daily changes of these different physiological parameters may fluctuate as follows: Urinary volume between 500 and 2,000 c.c. (in the adult male subjects studied during our experiments), 17-ketosteroids may fluctuate up to 300 per cent (for example, 9–3 mg/24 h), hexosamines between 20 and > 70 μg/100 c.c., chlorides between 60 and 190 m.equiv./l., sodium between 110 and 170 m.equiv./l., urea between 600 and 2,200 mg/100 ml., the *p*H of urine (at 6 p.m. before dinner) between 4·9 and 6·9 (or more).

In subjects with an efficient thermoregulation mechanism this group of 7 curves (partly parallel, partly inverse) is

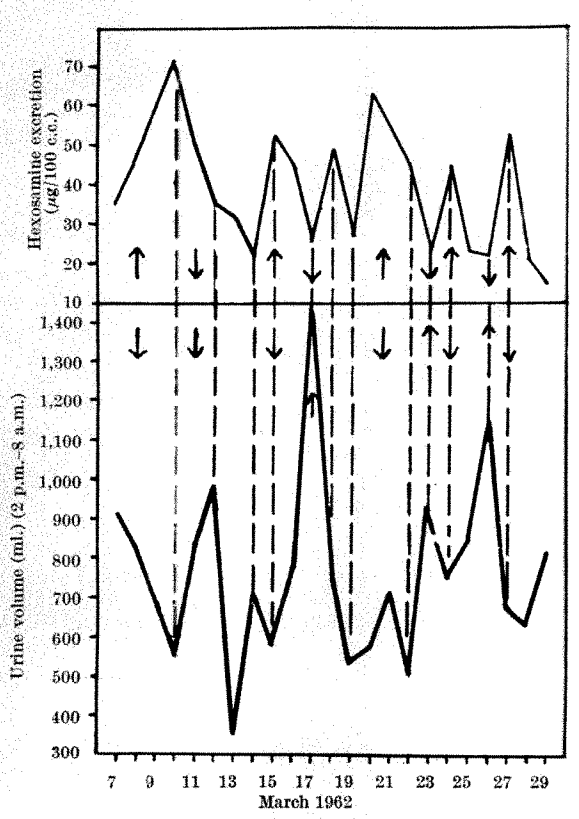

Fig. 3. Urine volume and excretion of hexosamines during the period March 7–29, 1962

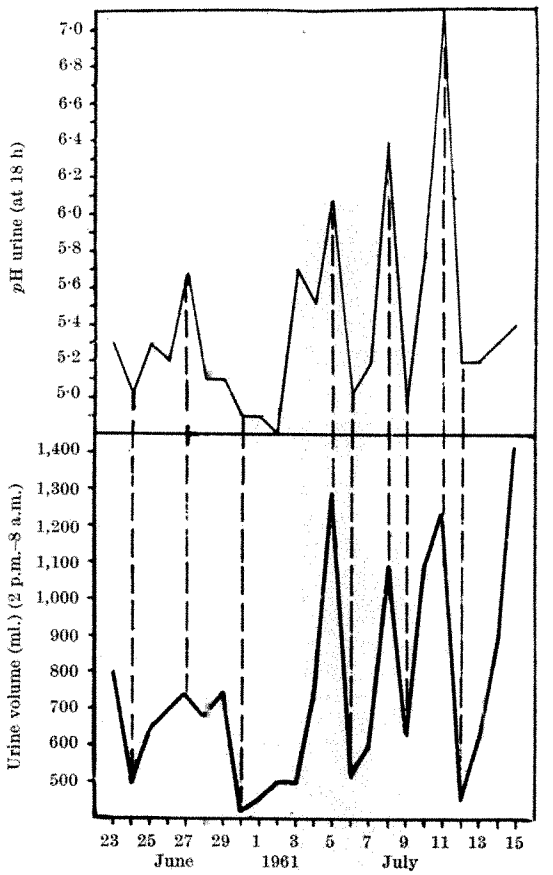

Fig. 4. Urine volume and *p*H during the period June 23–July 15, 1961

so characteristic and indicates so clearly the degree of atmospheric cooling that both for biological and clinical studies it is strongly recommended that this physiological method be used in conjunction with the existing meteorological instruments already mentioned.

As cooling is primarily a biological concept, based on certain human experiences as a result of changes in the thermal environment, it also seems logical to express the cooling index mainly in biological units.

ERYTHROCYTE PHOSPHOGLUCONATE DEHYDROGENASE POLYMORPHISM

By C. W. PARR
Department of Biochemistry, The London Hospital Medical College, London

VARIOUS autosomally inherited differences in electrophoretic character[1–4] and quantitative enzymatic activity[3,5–7] of human red cell phosphogluconate dehydrogenase are known. Fig. 1 is a composite photograph showing eight different phenotypes, after starch-gel electrophoresis of haemolysates and specific staining for this enzyme. Each of the types has been encountered at least once during an electrophoretic survey of 4,558

unrelated individuals from among the patients, students and staff at the London Hospital and Medical College, and during family studies.

About 95 per cent of unrelated subjects were found to possess the single sharply defined electrophoretic band *A* shown in Fig. 1*a*. This 'normal' phenotype is a homozygous state for the enzyme, for which the genotype $PGD^{\alpha}PGD^{\alpha}$ has been proposed[2,4]. Two faint 'satellite' bands (not illustrated), which run ahead of the *A* band, are sometimes seen when the gels are overstained.

Haemolysates from certain related individuals were found to give a single *A* band with substantially reduced intensity of staining (Fig. 1*b*). When assayed, these haemolysates showed only 50–60 per cent of the normal activity. This 'half activity' trait is inherited autosomally and is a heterozygous condition[3,5–7] with one usual gene, PGD^{α}, and one almost completely inactive gene, PGD^{0}. It is not at present certain whether the gene determining this quantitative variant is an allele of the genes determining variations in electrophoretic character but, for reasons given below, it is provisionally regarded as such, and given the symbol PGD^{0}.

Half activity phenotypes can easily be missed during routine electrophoretic investigations and are best discovered by enzymatic assay and checked by family studies. We have recently begun to examine our local population by spectrophotometric assay, for this trait, and as yet do not have a good estimate of its occurrence, but would agree with Brewer and Dern[5], who are studying this condition in the United States, that the frequency is low, and probably less than 1 per cent.

Fig. 1*c* shows a haemolysate electrophoretic pattern with three bands which has been found in 188 individuals (an incidence of 1 in 24). The fastest of these bands is an *A* band; the middle band, *B*, is about as intense as the *A* band; and slowest and faintest of all is the *C* band, sited slightly closer to the middle band than is the *A* band. This triplet pattern was first reported as two bands[1], but as the electrophoretic technique improved it was realized that the third faint *C* band was always present[2]. This phenotype, described as the 'Common Variant', has been shown by family investigations[1,4] to be autosomally inherited and to be a heterozygous condition: it has one usual gene, PGD^{α}, and a structurally modified allele, PGD^{β}. When subjected to mild stress in various ways (by incubation of haemolysate with 0·2 M *tris* buffer at *p*H 8·0 and 37° C for 15 min, or by incubation at 25° C with 1·5 M urea or 0·01 M iodoacetate for similar short periods), common variant haemolysates lose significantly more activity than do normals[8].

Electrophoretic examinations of blood collected in Brazil (35 samples), Nigeria (100 samples) and Uganda (109 samples) revealed three, twelve and twelve instances respectively of the common variant, suggesting that the incidence of the PGD^{β} gene may be greater in these parts of the world than in London.

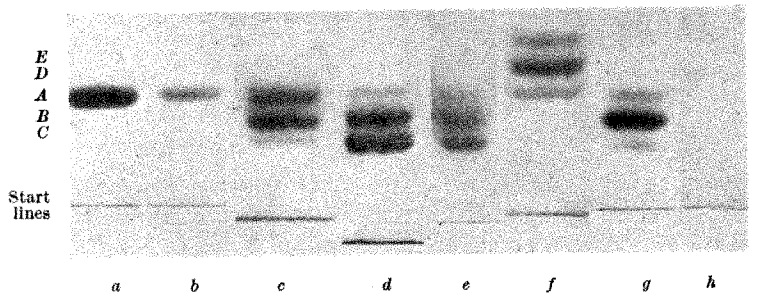

Fig. 1. Composite photograph showing eight different electrophoretic patterns found for human red cell phosphogluconate dehydrogenase after starch-gel electrophoresis of haemolysates. The *A* bands have been placed in line. Since the conditions varied somewhat from experiment to experiment, the start lines do not always coincide. Haemoglobin moves towards the cathode, on the other side of the start line, and does not show. Electrophoretic conditions and staining procedure for the enzyme were essentially as previously described (ref. 1), but potential gradients of 12–24 V/cm were used for periods of 4–6 h

The opportunity occasionally arose to examine extracts of human white cells and other body tissues in addition to red cell haemolysates. Individuals with a normal type of phosphogluconate dehydrogenase in their red cells were always found to have a normal type in other body tissues, whereas when the common variant phenotype was found in the erythrocytes, this was reflected by the presence of the common variant triplet in the extracts from other body tissues, although the relative intensities of the bands sometimes varied. Thus it appears that for this enzyme an inherited variation detected in the red cells is indicative of the presence of that same variation in all other body tissues.

The electrophoretic pattern shown in Fig. 1*d* was given by haemolysates from two subjects in the survey. The same three bands are present as in the common variant, but they have different intensities: the *C* band is the most intense, the *B* band is intermediate in intensity and the *A* band is faint. Normal or near normal activity (70–90 per cent) is found on assay. This phenotype is described as the 'Canning' variant, after the Canning Town district of London where the first subject discovered with this phenotype resides. White cell extracts from these individuals showed a strong *C* band only. Family studies[4] indicated that the Canning variant is the homozygous state for the atypical allele PGD^{β}. If the greater lability to mild physical and chemical stresses of the common variant (genotype $PGD^{\alpha}PGD^{\beta}$) when compared with the normal (genotype $PGD^{\alpha}PGD^{\alpha}$) is to be attributed to the PGD^{β} gene, then the $PGD^{\beta}PGD^{\beta}$ genotype of the Canning variant would be expected to be even more labile, and this was found to be so experimentally[8].

Two brothers gave the electrophoretic pattern of the Canning variant, but the bands stained only weakly (Fig. 1*e*) and the haemolysates showed something less than half activity (40–50 per cent of normal)[3,7]. The seven children of these two brothers segregated into either half activity variants (5 children) or into common variants (two children). The wife of one of the brothers was demonstrated to be of normal phenotype and it is likely that the wife of the other brother was also. Thus it seems that these 'half activity Canning' variants must be of genotype $PGD^{\beta}PGD^{0}$. The segregation of the children into either half activity or common variant phenotypes is noteworthy, and indicated that in this family the genes for quantitative variation and for variation in electrophoretic character are separate from one another. It thus appears likely that these two abnormal genes are alleles of one another (and of a single normal gene).

Fig. 1*f* shows a 'Richmond' triplet, which has occurred twice at random in our survey. The slowest band of this triplet is an *A* band, and the middle band, *D*, is symmetrically placed and has substantially greater intensity than the bands on either side of it[3,4]. Like the other phosphogluconate dehydrogenase variants, the Richmond phenotype has been shown by a family study to be a heterozygous condition, autosomally inherited, and it has been given the genotype $PGD^{\alpha}PGD^{\gamma}$.

Another rare triplet pattern, the 'Hackney' variant, is illustrated in Fig. 1*g*. The slower two bands, although in approximately the same positions as the *B* and *C* bands of the common variant, do not appear to coincide exactly with them, and for this reason are referred to as the *B′* and *C′* bands. The *A* and *C′* bands have approximately similar activities while the symmetrically placed middle *B′* band is substantially more intense. Genetic studies have indicated that this triplet is also a heterozygous condition, autosomally inherited, and the genotype $PGD^{\alpha}PGD^{\delta}$ has been proposed[4].

A brother and sister were discovered who gave no staining reaction at all for erythrocyte phosphogluconate dehydrogen-

Table 1. HUMAN RED CELL PHOSPHOGLUCONATE DEHYDROGENASE PHENOTYPES

Position in Fig. 1	Phenotype No.	Description of phenotype	Approximate activity (as a percentage of normal)	Proposed genotype	Incidence in non-related individuals in London (percentage)
a	I	Normal	100	$PGD^{\alpha}PGD^{\alpha}$	95
b	VI	Half activity	50–60	$PGD^{\alpha}PGD^{\varepsilon}$	(say) 1
c	II	Common variant	80–100	$PGD^{\alpha}PGD^{\beta}$	4

ase after electrophoresis (Fig. 1*h*), and haemolysates showed about 5 per cent of the activity of normals when assayed spectrophotometrically[7].

The properties of the eight known phosphogluconate dehydrogenase phenotypes in the human are summarized in Table 1. Seven of them can be regarded as resulting from combination of the gene products of identical or non-identical gene pairs selected from five alleles at a single autosomal structural locus.

Three different autosomally inherited phenotypes of phosphogluconate dehydrogenase have also been shown to be present in the red cells of the rat, and starch-gel patterns for these are shown in Fig. 2. The single 'slow' band (Fig. 2*a*) is given by haemolysates from laboratory rats (it is considerably faster than the *A* band of the human). However, this type, plus two additional phenotypes, one with a single 'fast' band (Fig. 2*c*) and one with a triplet of bands comprising both fast and slow bands and also an intermediate band of substantially greater intensity, were obtained when a number of wild rats trapped in the London area were examined. These observations suggested that rats with the slow band are homozygous for a gene PGD^{s}, that rats with the fast band are homozygous for a gene PGD*f*, and that animals with the triplet bands are heterozygous with the genotype $PGD^{s}PGDf$. A possible genetic mechanism is set out in Table 2. These

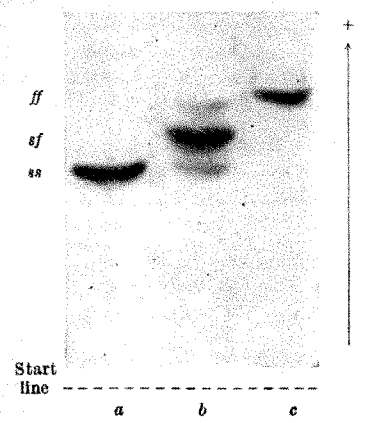

Fig. 2. Three starch-gel electrophoretic patterns given by rat red cell haemolysates when developed for phosphogluconate dehydrogenase activity

Table 2. FORMATION OF PHOSPHOGLUCONATE DEHYDROGENASE ISOENZYMES BY ALLELIC GENES PGD^{s} AND PGD*f*

Genotype	Enzyme sub-units (gene products) Type	Amount (per cent)	Isoenzymes (formed by random association of sub-units in pairs) Structure	Rate of migration	Amount (per cent)

PGD*f*/PGD*f*	*f*	100	*ff*	Fast	100

suggestions are supported by examination of the progeny in a breeding programme using rats of known phosphogluconate dehydrogenase phenotypes[9]. Workers in Baltimore[10] have recently found similar slow, fast and triplet bands of phosphogluconate dehydrogenase to be present in pigeons, and they have also concluded that the enzyme is autosomally inherited and that the triplet phenotype is a heterozygous state.

I thank Dr. G. B. West and Dr. K. B. Roberts for blood samples from both wild and laboratory rats, Prof. I. Doniach and Mr. C. V. Mann for human autopsy and biopsy specimens respectively, Mr. A. R. Njogu, Dr. F. M. Salzano and Mr. A. Sheiham for blood collections made in Uganda, Brazil and Nigeria, and Dr. A. E. Mourant for advice. This work was supported in part by a grant from the Ministry of Overseas Development.

STRUCTURAL STUDIES OF PIG HEART MALATE DEHYDROGENASE

By DR. TIBOR DÉVÉNYI*, DR. S. J. ROGERS and PROF. R. G. WOLFE
Department of Chemistry, University of Oregon, Eugene, Oregon

COMPARATIVE structural studies of pig heart malate dehydrogenases (*E.C.* 1.1.1.37) have been initiated in this laboratory. The mitochondrial enzyme (*m*-MDH), obtained from Seravac Laboratories (Pty.), Ltd., was submitted to final purification by *CG*-50 column chromatography using a modification of the method of Thorne[1]. Supernatant malate dehydrogenase (*s*-MDH) from the same source was used without further purification.

Comparative Fingerprint Analysis of *m*-MDH and *s*-MDH

Both enzymes were labelled with ^{14}C-iodoacetate after denaturation in 8 M urea, and tryptic hydrolysates were prepared. Two-dimensional 'fingerprints' were made using a double buffer system[2] with pyridine acetate buffer, *p*H 6·5, between the origin and the cathode, and pyridine acetate, *p*H 5·0, between the origin and the anode in one dimension. Formic acid–acetic acid buffer, *p*H 1·9, was used in the second dimension. The fingerprints of *s*-MDH and *m*-MDH are shown in Fig. 1.

Approximately 36–38 peptide spots appeared on fingerprints made from the tryptic digest of *m*-MDH. Six of these peptide spots were positive when tested with the Pauli reagent and five of the spots reacted with the Sakaguchi reagent. Initially five peptides (one neutral and four acidic) containing ^{14}C-*S*-carboxymethyl cysteine (CMC) were located by autoradiography. Later two additional radioactive CMC-peptides were resolved. The first of these was recognized when, during purification, the neutral peptide (*T*-*N*) was separated into two components by paper chromatography. The second 'addi-

* From the Institute of Biochemistry, Hungarian Academy of Sciences, Budapest.

tional' peptide was found when the most acidic peptide (*T*-6) was resolved into two components (*T*-6*a* and *T*-6*b*) by paper electrophoresis. Ultimately these two neutral peptides were found to be overlapping homologous fragments. There appear to be, therefore, six different SH-peptides which can be isolated from tryptic hydrolysates of *m*-MDH.

The probable presence in *m*-MDH of identical, or very similar, sub-units with a molecular weight of about 35,000 is consistent with the following observations: the number of tryptic peptides observed in the *m*-MDH fingerprint is approximately half that expected on the basis of basic amino-acid composition[3]. Moreover, Pauli-positive and Sakaguchi-positive spots number somewhat less than half that predicted on the basis of the amino-acid composition of the protein, assuming a molecular weight of 65,000–70,000. Finally, the number of SH-peptides identified is half the number of cysteine residues present in the (mol. wt. ~ 65,000) molecule.

The number of peptide spots on *s*-MDH fingerprints is considerably more than half that expected on the basis of the amino-acid composition. Moreover, detailed comparison of the fingerprints of *s*-MDH and *m*-MDH reveals apparent similarity only to the extent of several basic peptide spots. The radioactive CMC-peptides in particular were entirely dissimilar by this criterion. It is tentatively concluded, therefore, that any similarity in the two enzymes must be restricted to structural features which remain obscure under these experimental conditions, and that duplicity in the sub-unit structure of *s*-MDH seems to be contra-indicated.

The Structure of Mitochondrial MDH SH-peptides

The radioactive peptides from a tryptic hydrolysate were purified using 'Biogel' filtration and paper electrophoresis. One neutral (T-N_2) and five acidic peptides (T-2, T-3, T-4, T-6*a* and T-6*b*) so obtained were further purified by electrophoresis at *p*H 1·9 and by descending paper chromatography using butanol–acetic acid–water (120 : 30 : 50). The peptide T-N_2 was resolved into two components, T-N_2a and T-N_2b in this solvent system. The amino-acid composition of these six peptides is given in Table 1.

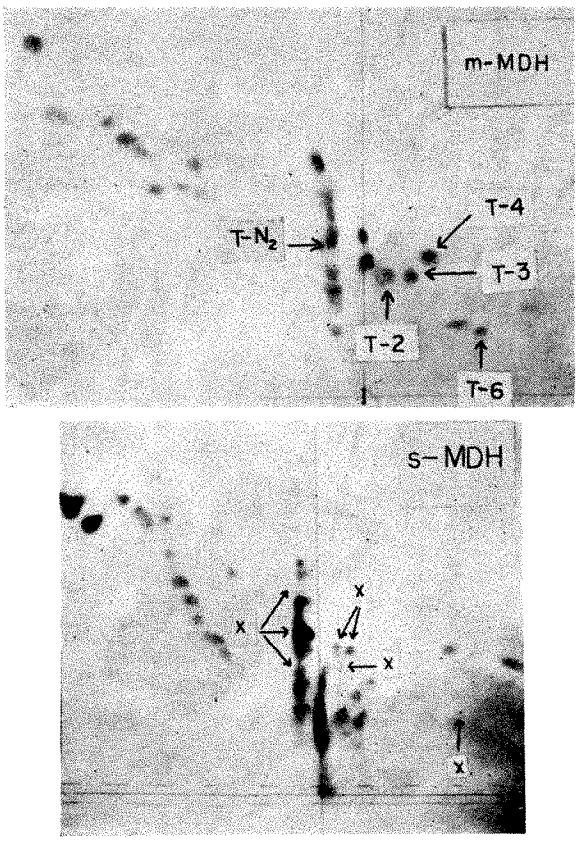

Fig. 1. Ninhydrin-sprayed 'fingerprints' of tryptic hydrolysates from malate dehydrogenases. *m*-MDH, mitochondrial; *s*-MDH, supernatant enzyme. The labelled peptides were detected through autoradiography and are indicated by T-N_2, T-2, . . . in *m*-MDH and by (*x*) in *s*-MDH. See text for experimental conditions

* Amino-acid analysis with a Beckman model 120 *B* analyser according to Spackman, Stein, and Moore (ref. 4).

Peptides T-N_2a and T-N_2b. Treatment of each of these peptides with subtilisin (in 0·1 M ammonium carbonate at *p*H 8·2 for 4 h at 35° C) gave hydrolysates which afterwards were subjected to paper electrophoresis at *p*H 1·9. Autoradiography of the electropherogram revealed that each peptide produced two electrophoretically similar radioactive peptides, which indicates that two were overlapping peptides. The composition of the two radioactive peptides was determined to be:

S-N_2-1^x H_2N-Ile*(Glu,CMC)

S-N_2-2^x (CMC,Ala,Pro)Lys-OH

Ile.Glu.CMC.Ala.Pro.Lys-OH

The *N*-terminal isoleucine (*) was determined using the dansyl method[5]. The sequence - - - - Ala.Pro - - - - was assumed because of the known resistance of prolyl peptide bonds to subtilisin.

Peptide T-N_2b produced two radioactive peptides on treatment with chymotrypsin (4 h at 37° C in 0·1 M ammonium carbonate, *p*H 8·2). One of these (C-N_2b-1) was identical with the original peptide in amino-acid content. The second peptide (C-N_2b-2) was a nonapeptide with the following amino-acid composition: (Asp,Thr,Ser, Glu,Pro-Ala-CMC,Ile)Lys.

From these data the remainder of the peptide T-N_2b consists of the following fragments:

(Ile,Glu,Pro)Lys-OH (T-$N_2b - T$-N_2a)

(His,Thr,Glu,Pro,Gly,Ala,Val,Ile,Leu) (T-$N_2a - C$-N_2b-2)

(Asp,Thr,Ser) (C-N_2b-2) − (S-N_2-1 + S-N_2-2)

Peptide T-2. Three radioactive (*x*) peptides as well as one unlabelled peptide were obtained by electrophoresis after subtilisin (see here) treatment of the peptide T-2. The composition of these peptides was as follows:

S-2-1^x NH_2-Ile*(Glu_2,Ala,CMC)

S-2-2^x (CMC,Thr,Glu,Gly)

S-2-3^x CMC

S-2*a* (Glu,Gly,Val_2)Lys-OH

Ile*(Glu_2,Ala(CMC.Thr)Glu,Gly,Val_2)Lys-OH

The N-terminal isoleucine (*) was determined using the dansyl method[5].

Peptide T-4. Treatment of peptide T-4 with chymotrypsin produced one radioactive peptide with the amino-acid composition (Glu_2,CMC,Gly,Val_2)Phe-OH. Treat-

ment of peptide *T*-4 with subtilisin resulted in three radioactive peptides as follows:

S-4-a^x	(Gly,CMC,Gly,Val,Phe)
S-4-b^x	(Glu,CMC,Gly,Val)
S-4-e^x	CMC

The partial structure of this peptide is: (Glu_2,CMC,Gly, Val_2)-Phe.Val.Lys-OH with valine as a probable *N*-terminal residue.

Peptides T-6a and T-6b. A probable explanation for the lack of basic amino-acids in these peptides is that they represent the C-terminal fragment of the enzyme. Attempts to obtain chemical evidence in support of this explanation have, however, been unsuccessful. The carboxypeptidase and hydrazinolysis[6,7] procedures were both ineffective when applied to native and acetone denatured *m*-MDH. Both these procedures gave completely satisfactory results on insulin, β-lactoglobulin and the synthetic tripeptide Gly.Phe.Ala. The purified peptides have not been tested directly for the C-terminal residue structure. If indeed peptides *T*-6*a* and *T*-6*b* represent the C-terminal peptides of *m*-MDH, the possibility of minor structural differences between the two polypeptide chains (or between components resolved by gel-electrophoresis) is suggested.

Comparison of the amino-acid compositions and the partial sequences of the isolated SH-peptides from *m*-MDH with the published structures of SH-peptides from glyceraldehyde-3-phosphate dehydrogenase[8], two alcohol dehydrogenases[9], and lactate dehydrogenase[10] indicates that there are no similarities in the primary structure. Because particular SH-peptides were determined in the last-mentioned four enzymes, it is not possible to compare all the SH-peptides in these enzymes with those from *m*-MDH.

EFFECT OF NITROUS ACID ON POLYOMA VIRUS

By SOFIA LEVENTON-KRISS and DR. TAMAR GOTLIEB-STEMATSKY
Ministry of Health, Public Health Laboratories, Virus Laboratories, Tel-Aviv-Jaffa, Israel

RECENT reports have indicated that nitrous acid has a mutagenic effect on animal viruses[1,2]. We have previously reported the isolation from *SE* polyoma virus of two variants which differed in their biological and oncogenic properties[3]. Similar polyoma virus variants were isolated by other investigators[4–6].

It was thought of interest to investigate the mutagenic effect of nitrous acid on these variants, especially to discover whether chemical mutagenesis would be effective in raising the rate of spontaneous mutation and/or inducing changes in the properties of these variants. Special attention was given to the effect of nitrous acid on the oncogenic properties of the variants. In addition to the action of nitrous acid on the intact viruses, its effect on their DNA extracts was also studied. The media, cell cultures, virus assay and animal tests which were used in this investigation were as previously described[3].

The procedure for DNA preparation used was that of Gierer and Schramm[7], with the modification that the virus suspension was shaken twice with 80 per cent phenol for 20 min at 60° C. To determine the infectivity of the extracted material, mouse embryo cell monolayers (MECC) in Petri dishes and tubes were inoculated with 0·2 ml. of the sample material diluted in 0·03 M *tris* ('Sigma 7–9') buffered saline. After 1 h of adsorption the fluid was removed and 5 ml. of Eagle's medium supplemented with 5 per cent horse serum were added to each plate and 2 ml. to each tube. The supernatant from the infected tubes and plates was collected and examined for virus content.

Treatment of intact virus with nitrous acid was carried out at 26° C. The reaction mixture contained 2·0 M sodium nitrite; 0·25 M acetate buffer, 0·6 sodium chloride; 0·02 M sodium orthophosphate at *p*H 4·2 or *p*H 5·2. Samples were removed after 1 and 2 h and immediately assayed for surviving virus. After 7–10 days incubation of the inoculated mouse embryo cell monolayer tubes the supernatant was transferred to new mouse embryo cell monolayers and only then could a cytopathological effect (CPE) caused by virus be observed. Every positive sample was identified for the type of virus by *in vitro* markers: haemagglutinating antibody (HA), CPE and plaque size. Virus samples isolated from the individual tubes which differed from the parent strain were also tested for their oncogenic properties by inoculation of 1-day-old mice or 1–3-day-old hamsters. Treatment of the phenol extracted material by nitrous acid was carried out at *p*H 5·2 at 4° C by the method described previously for intact virus. The controls of untreated virus or DNA extract were carried out in acetate buffer saline without sodium nitrite at the same hydrogen ion concentrations.

Experiments on the inactivation of polyoma virus strains treated with nitrous acid carried out at *p*H 4·2 and *p*H 5·2 showed a decrease of infectivity of both strains. No difference in the kinetics of inactivation of the two *SE* polyoma strain variants was noted. Treatment of DNA extracts with nitrous acid at *p*H 4·2 caused rapid inactivation and subsequent experiments were therefore carried out at *p*H 5·2. No inactivation whatsoever was observed in the controls when virus was exposed to acetate buffer at the same *p*H without nitrous acid.

Infectious DNA was extracted from the two polyoma variants and examined for the type of their viral progeny. The yield of infectious nucleic acid was low, and infectious virus was usually obtained from undiluted material. It can be seen from Table 1 that the virus progeny isolated from C^+H^- small plaque and C^-H^+ large plaque variant extracts showed no change from the parent strain in their HA titres, CPE, plaque size and tumour induction in mice.

When 5 mg/ml. DNase were added to the extracts and allowed to act for 10 min, the extracts completely lost their infectivity. Even three consecutive subcultures of the DNase-treated material in mouse embryo cell monolayers remained non-infective.

The two polyoma virus strains were treated with nitrous acid by the technique described previously. Each sample was inoculated into ten to thirty mouse embryo cell monolayer tubes. A control of untreated virus in acetate buffer saline without nitrous acid was inoculated in the same way at limiting dilutions. Uninoculated mouse embryo cell culture tubes were also set up. After 10–14 days of incubation, the tubes were examined for the development of CPE or HA, and 0·2 ml. of the supernatant from each negative tube was passed to freshly

prepared mouse embryo cell monolayer and the procedure was repeated three times for inoculated and control uninoculated tubes.

The data summarized in Table 2 show that the C^+H^- variant treated with nitrous acid yielded the parent-type virus only. Of 77 positive tubes obtained out of 380 inoculated all showed the C^+H^- type markers. In the control untreated titration of the same virus inoculated at limiting dilution, 74 positive tubes were obtained out of 300 inoculated, and none showed conversion to another virus type. On the other hand, when the C^-H^+ virus variant was treated with nitrous acid and inoculated into 299 mouse embryo cell monolayer tubes immediately after treatment, two out of 103 positive tubes resembled the C^+H^- type variant. One of these two viruses was isolated in the first passage and the other in the second subculture. At the same time, in control untreated titrations of C^-H^+ virus at limiting dilution, no C^+H^- virus type could be detected in 72 positive tubes out of 287 tubes inoculated and examined. Eighty-four uninoculated mouse embryo fibroblast cell culture tubes which were included in the test and passaged three times did not show any contamination by latent virus particles.

The DNA extracts of the two virus variants were also treated with nitrous acid. It can be seen from Table 3 that the virus isolated from the C^+H^- variant extract had the same properties as the parent strain. However, treatment of the DNA extract of C^-H^+ variant yielded viruses which were similar to the C^+H^- strain; these showed changes in their haemagglutinin, cytopathogenic, plaque size and oncogenic properties. The HA titre was not more than 1 : 20. The cytopathogenic effect as measured in mouse embryo cell monolayers was very strong, and when they were plated out small distinct plaques appeared. The tumour-inducing capacity in mice decreased significantly. About 10 per cent of baby mice inoculated with undiluted virus with a titre of $10^{6.9}$ in a concentration of 0·2 ml. developed tumours. The few tumours which appeared after inoculation with this strain were subcutaneous sarcomata and mammary gland tumours. Paralysis was also sometimes observed. No parotid gland tumours were seen. When these newly isolated strains were inoculated in baby hamsters (Table 4) a decrease in tumour-producing capacity was noted as compared to the parent C^-H^+ or even C^+H^- strains[8]. These strains were also passaged six times in tissue culture and no change in their properties was observed.

The control virus and DNA samples treated with acetate buffer saline without nitrous acid did not cause changes in the virus type as tested by CPE. HA, plaque size and tumour induction.

The C^+H^- virus or its DNA extract which were treated with nitrous acid did not yield virus different from the parent strain. On the other hand, the C^-H^+ intact virus or its DNA extract which were treated with nitrous acid yielded virus which was not identical with the parent strain but resembled the C^+H^- virus type.

It was shown that cells persistently infected by *SE* polyoma virus yielded virus which has characteristics in common with the small plaque type variant[8–10]. It seems that the small plaque variant becomes predominant whenever conditions for selection or mutation exist. In our case the biological examination of the newly isolated virus strains after treatment of the C^-H^+ variant with nitrous acid shows that they are similar to but not identical with the C^+H^- strain type. They were less variable in the H character; they did not give or only occasionally gave HA titres of 1 : 20. They produced strong cytopathic effect and small plaques, and were less tumorigenic for baby mice and baby hamsters. They yielded tumours in about 10 per cent of mice and hamsters inoculated with virus diluted 1 : 100. These strains were assayed for susceptibility to nitrous acid. The inactivation curves were compared with curves obtained with the parent strains. All the curves were found to fall within the same range of variation.

From our preliminary experiments it became evident that the first inoculation of mouse embryo cell monolayers was not sufficient for isolation of polyoma virus from single particles or from residual virus after partial inactivation[11]. Similar results were reported by Rowe *et al.*[12]. Therefore, three successive passages were carried out from each

tube inoculated. For elimination of the possibility of use of virus-contaminated tissue cultures as a result of latent viral infection, examination of mouse embryo cell monolayer control tubes was carried out in the same manner. Also the control virus titration of C^-H^+ virus type at limiting dilutions showed no appearance of C^+H^- variants. From the results of our experiments it seems that we are dealing with mutations induced by the nitrous acid treatment. However, no final conclusion on whether selection or mutation has taken place can be reached.

We thank Dr. N. Goldblum and Dr. E. Heller for their help.

A MOLECULAR MECHANISM FOR ENZYMATIC TRANSAMINATION

By DR. M. Ya. KARPEISKY and DR. V. I. IVANOV
Institute of Molecular Biology, Academy of Sciences of the U.S.S.R., Moscow

IT is well known that many reactions catalysed by coenzyme-dependent enzymes can be reproduced in model systems containing only the coenzyme or an analogue of it. However, under these conditions the strict substrate specificity and reaction specificity that are characteristic features of the enzymatic process are, to a large extent, lost. The role of the protein moiety of the enzyme molecule in providing substrate specificity is evidently determined by the presence, in the active centre, of a 'binding site' that is complementary to the substrate. The questions that arise as to the means by which the action of an enzyme causes the selective cleavage of only some of the available covalent bonds in the substrate molecule are more complicated.

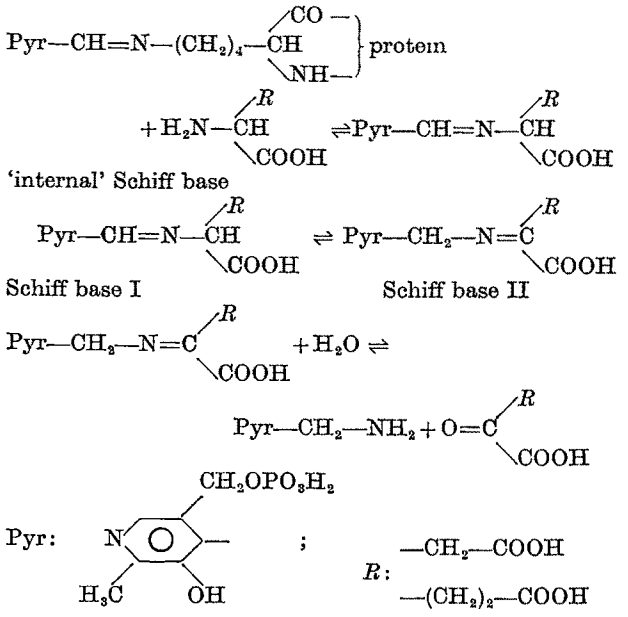
Elucidation of the absolute functions, in the catalytic process, of the specific protein of the enzyme (in particular, of an enzyme containing a bound coenzyme) is essential for any understanding of the principal features of enzymatic catalysis, namely, substrate specificity and specificity for a definite type of reaction. In fact, these are the features which, in the final reckoning, make possible the high velocities of enzymatic reactions.

In this article, which relates to the mode of action of pyridoxal phosphate-dependent enzymes (PALP-enzymes)*, we examine possible mechanisms determining the spatial interrelationships of coenzyme, apoenzyme and substrates during the course of the enzymatic reaction.

A general scheme for reactions catalysed by PALP-enzymes was proposed by A. E. Braunstein and M. M. Shemyakin[1] and by D. Metzler, M. Ikawa and E. E. Snell[2]. It was shown by Snell *et al.* that practically all the types of enzymatic reactions of amino-acids that are effected by this group of enzymes may be observed also in model systems containing pyridoxal or pyridoxal phosphate. In the case of such non-enzymatic catalysis, there is no necessity for the entire coenzyme molecule, and only its 4-formyl-3-hydroxypyridine part is needed.

Aspartate transaminase (AS-transaminase, aspartate : 2-oxoglutarate aminotransferase, *E.C.* 2.6.1.1) catalyses the reversible reaction:

$$\underset{\text{L-aspartic acid}}{HOOCCH_2CHNH_2COOH} + \underset{\alpha\text{-ketoglutaric acid}}{HOOC(CH_2)_2COCOOH} \rightleftharpoons$$



$$\underset{\text{oxaloacetic acid}}{HOOCCH_2CCOOH} + \underset{\text{L-glutamic acid}}{HOOC(CH_2)_2CHNH_2COOH}$$

It should be noted that other PALP-enzymes exist which specifically catalyse the α-and β-decarboxylation

* Abbreviations in the text: PALP, pyridoxal-5-phosphate; AS-transaminase, L-aspartate : 2-oxoglutarate aminotransferase (*E.C.* 2.6.1.1).

of aspartic acid and the α-decarboxylation of glutamic acid. Therefore, a detailed examination of the mechanism of the transamination reaction should contribute also to our understanding of the selectivity of enzyme catalysis.

Since pyridoxal phosphate exists in AS-transaminase in the form of an aldimine (Schiff base) with the ε-amino group of a lysine residue[3], the first step of the reaction appears to be a transaldimination, that is, a reaction of an amine with an imine, resulting in conversion of the 'internal' Schiff base of PALP with the lysine of the apoenzyme into a Schiff base with the substrate amino-acid. This is followed by tautomeric conversion of the so-called Schiff base I (aldimine) into the Schiff base II (ketimine); in the next stage the double bond of the latter intermediate is hydrolysed to yield a keto acid and protein-bound pyridoxamine phosphate:

Scheme 1

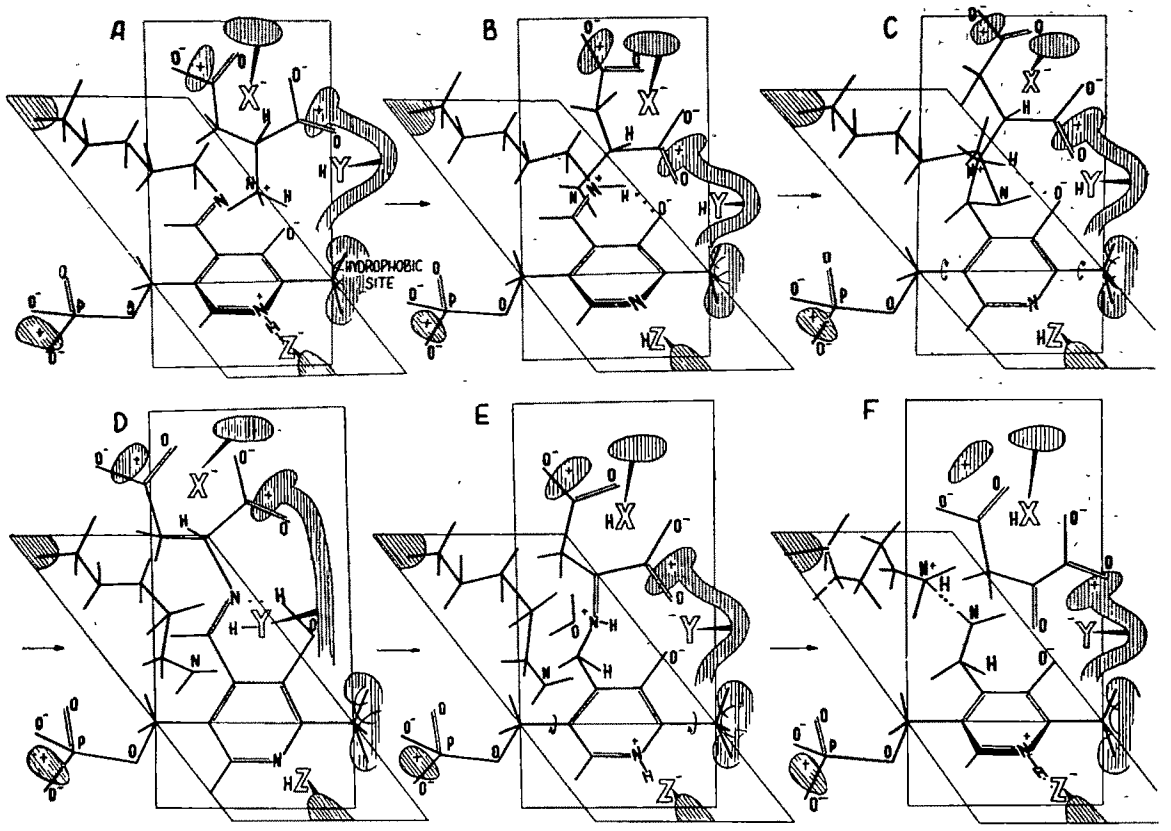
Extremely important to this sequence of reactions is the following circumstance. Each of the aforementioned steps has alternating requirements in regard to the ionization state of the 3-hydroxy group of the coenzyme.

The enzyme possesses maximum activity at *p*H 8–8·5; investigation of the spectral properties of the enzyme showed that in this range of hydrogen-ion concentrations, the phenolic group of the coenzyme exists in the ionized state[4].

In scheme 2*A* is shown the initial state of the protein-bound coenzyme, prior to interaction with the substrate. The existence of a non-covalent bond between the phosphate group of the coenzyme and the protein was established several years ago[5]. The presence of a bond between the apoenzyme and the nitrogen atom of the pyridine nucleus was postulated by Sizer and Jenkins[4] in order to account for the shift in the *pK* associated with the '*p*H-indicator' spectral change of the cofactor in AS-transaminase. This *pK* is shifted to the acid side (to 6·3) relative to the *pK* of the analogous transition, in the free imines of pyridoxal in aqueous solution (*pK* 10·8)[7]. Thus, protonation of the nitrogen atom in the pyridine nucleus by some proton-donating group of the protein leads to ionization of the 3-hydroxy group at lower values of *p*H. As a consequence, the dipolar ionic species of the PALP aldimine exists in the active centre of the enzyme at its *p*H-optimum, although this species is thermodynamically unstable in solution. Comparative studies of the fluorescence of the imine of pyridoxal phosphate with valine, and of AS-transaminase, confirmed the existence of such a state of ionization of the groups of the coenzyme[6]. Velick and Vavra[7] showed that the binding of aspartate to the enzyme is controlled by the dissociation of a proton with a *pK* of 6·3 which coincides with the *pK* of decolorization of AS-transaminase. Thus, the presence of an ionized phenolic group would seem to be an essential condition for the occurrence of the first step of the enzymatic reaction.

However, in this state the electron density in the pyridine ring of the coenzyme is significantly increased, and its properties as an electron-accepting group that provides for polarization of the carbonyl group in position '4' are, to a significant degree, lost. The subsequent reaction stages necessitate the presence of an un-ionized phenolic hydroxyl, in so far as the intramolecular hydrogen bond involving this group provides planarity in the conjugated system and returns to the pyridine nucleus the capacity to act as an electron acceptor.

While the aforementioned ionization state is also realized in the 'internal' Schiff base at *p*H < 6·3, this is not accompanied by transamination between the coenzyme and the ε-amino group of the lysine residue.



It is evident that any plausible mechanism describing enzymatic transamination must, on one hand, explain what is meant by the change in the state of ionization of the phenolic group which occurs in the course of this reaction, and, on the other hand, account for the absence of transamination in the 'internal' Schiff base over the whole range of *p*H from 5 (or less) to 10.

The results of our investigations of the mechanism of reaction of AS-transaminase with *cyclo*serine and its analogues provide evidence suggesting that the tautomeric interconversion of Schiff bases I and II in the transaminase-substrate complex is catalysed by functional groups of the active centre[8]. The recent investigations of Bruice and Topping[9] on non-enzymatic transamination reactions with the participation of pyridoxal also showed that the rate of the step involving the prototropic shift was substantially increased in the presence of imidazole, which apparently acts as an acid-base catalyst. Investigations of the parameters of luminescence and circular dichroism of the enzyme, and of its complexes with inhibitors, have provided evidence indicating that the coenzyme, under certain conditions, may acquire a definite degree of mobility. Thus, exposure of AS-transaminase at *p*H 8–9, where the enzyme exists in the active form, to light of wave-length 365 mμ (at this *p*H the absorption maximum of the protein-bound coenzyme is situated at 360–370 mμ) evokes a definite drop in the degree of polarization of fluorescence of AS-transaminase which is reversible in the dark. At the same time, the polarization of fluorescence in the absorption band of a dye, fluorescein isothiocyanate, with which the enzyme had been pre-treated, remained constant. It follows that the phenomenon that we observed was related to an increase in the degree of mobility of the enzyme-bound coenzyme, and not of the protein[10].

An examination of published data on AS-transaminase, in the light of our newly obtained results, enables us to propose a dynamic model for the functioning of the active centre of this enzyme (scheme 2).

A molecule of substrate amino-acid, the dissociable groups of which, at physiological values of *p*H, are ionized, is bound to a cationic site of the active centre above the plane of the pyridine ring of the coenzyme; under this condition, geometric interrelations are achieved that favour nucleophilic addition. Since maleic acid acts as a competitive inhibitor of AS-transaminase, but fumaric acid does not[12], the structure of this site must be such that it provides for binding of the aminodicarboxylic acid in a conformation with adjacent carboxylic groups.

Interaction between the negatively charged phenolic group of the coenzyme and the positively charged amino group of the substrate favours attainment of the correct

Scheme 2 Four-proton mechanism for enzymatic transamination

orientation of the reacting parts of the molecules. It is well known that nucleophilic addition to a C=N double bond depends on the degree of polarization of this bond and the nucleophilicity of the attacking reagent. However, the nitrogen atom of the substrate is positively charged, and in the unprotonated Schiff base the double bond is not significantly polarized (scheme 2*A* and 2*B*). In the model under consideration, the apparent contradiction is removed by the suggestion that the ionized hydroxyl group of the coenzyme accepts a proton from the amino group of the substrate, whereby this amino group acquires nucleophilic properties; at the same time, a positive charge appears on the formyl carbon atom, owing to formation of an intramolecular hydrogen bond. Protonation of the hydroxy group has a further important consequence, namely, a decrease in the basicity of the pyridine nucleus of the coenzyme, leading to breaking of the hydrogen bond between the pyridine nitrogen atom and the protein (scheme 2*B*).

The addition of the amino group of the substrate to the C=N bond of the enzyme results in the formation of a tetrahedral intermediate (*C*) that is further converted, with liberation of the ε-NH_2 group of lysine, into the enzyme-substrate Schiff base (scheme 2*C*→2*D*).

In so far as planarity of the coenzyme-substrate complex is a necessary condition for the subsequent tautomeric transition, formation of the 'Schiff base I' must inevitably be associated with a change in spatial position of the coenzyme.

In our opinion, this change is produced by way of rotation of the coenzyme around an axis passing through its 5-methylene and 2-methyl groups. The position of the axis remains fixed, owing to the fact that its end-points, the phosphate group on one hand, and the methyl group on the other, are bound to the protein. We have thus postulated, in this model mechanism, the existence of an additional site of attachment between the coenzyme and the protein, namely, a hydrophobic interaction between the methyl group of PALP and the side-chains of aliphatic amino-acid residues of the apoenzyme. The coenzyme turns around single C—C bonds which allow free rotation. Such rotation is made possible by cleavage of the covalent bond between the formyl group of the coenzyme and the ε-NH_2 group of lysine, and breaking of the hydrogen bond that links the pyridine nitrogen to a proton-donating group of the apoenzyme. The coenzyme, now fixed only at two points situated at the ends of the axis, rotates relative to the protein into a plane perpendicular to the original one, at the expense of transition of the tetrahedral carbon atom in position '4' into the trigonal form (scheme 2*D*). This results in the necessary orientation of the functional groups, *X* and *YH*, of the active centre, which catalyse the prototropic shift, in relation to the >C=N—CH-group of the enzyme-substrate complex. Translational displacement of the carboxyl groups of the substrate molecule, caused by rotation of the coenzyme, may contribute to bringing the catalytic groups of the protein, *X* and *YH*, into closer proximity with the coenzyme-substrate complex ('induced fit').

The tautomeric conversion of 'Schiff base I' into 'Schiff base II' probably proceeds by means of concerted general acid–general base catalysis[9]. Owing to this, the trigonal carbon atom in position '4' of the coenzyme-substrate complex is changed to a tetrahedral form, and the plane of the ring of the coenzyme reverts to its initial position with reconstitution of the hydrogen bond between the pyridine nitrogen and the apoenzyme (scheme 2*D*→2*E*). Formation of this bond leads to a lowering of the electron density on the oxygen atom of the phenolic group; the proton of the intramolecular hydrogen bond dissociates and catalyses hydrolysis of the C=N bond, to yield an α-keto acid and pyridoxamine phosphate. It is plausible that, in the amino-form of the enzyme, an additional hydrogen bond exists between the pyridoxamine phosphate and the protein, wherein the ε-NH_2 group of the lysine residue may act as the proton acceptor. This would

impart to the amino group of pyridoxamine phosphate the nucleophilic properties required for reaction with keto-substrates.

The foregoing dynamic model for the functioning of the active centre in AS-transaminase enables us to explain the role of each group of the coenzyme molecule in the process of enzymatic transamination and to define concrete functions of the apoenzyme. The protein moiety of the enzyme molecule not only catalyses the step of prototropic transition, but also provides for the appropriate mobile orientation of the coenzyme and substrate molecules that makes possible the realization of alternating electronic structures of the coenzyme, required at different stages of the transamination reaction.

From this dynamic model, it becomes clear that AS-transaminase cannot possess either α- or β-decarboxylating activity. In fact, for an α-decarboxylation reaction to occur, the necessary pre-conditions are complete protonation of 'Schiff base I'[13] and the absence of functional group catalysing prototropic transition. Less evident are the causes of the absence of β-decarboxylase activity in AS-transaminase, as β-decarboxylation involves the formation of 'Schiff base II'. Here the decisive factor is, apparently, the 'maleinoid' conformation of the substrate molecule, which hinders the formation of a cyclic transition complex that is characteristic for decarboxylation reactions of β-keto acids and their imines[13].

The proposed model is in good agreement with available experimental data concerning the mechanism of transamination; it gives a unified interpretation to a large number of seemingly contradictory facts, for example, the reactivity of the 'colourless' form of AS-transaminase, stability of the 'internal' Schiff base involving the ε-NH_2 group of lysine, the optical properties of complexes formed by the enzyme with quasi-substrates such as α-methyl-aspartate or β-hydroxyaspartate, etc.[14].

One of the essential features of the reaction scheme discussed here is the postulation of two spatially and functionally distinct sites in the active centre, between which a connexion is established by means of rotation of the coenzyme around an axis passing through the methylene and methyl groups of PALP; localized in one of these sites are the catalytic groups of the protein that are responsible, to a considerable extent, for the reaction type specificity of the enzyme; the other site serves to keep the coenzyme bound in the absence of substrate.

We believe that the conceptions expounded here may also provide a useful basis for the explanation of the molecular mechanisms of action of other types of PALP-enzymes.

We thank Prof. A. E. Braunstein and Prof. D. E. Metzler for stimulating discussions on this work.

NUMBER OF MOLECULES OF ANTIBODY REQUIRED TO PROMOTE PHAGOCYTOSIS OF ONE BACTERIUM

By PROF. DERRICK ROWLEY and KEVEN J. TURNER
Department of Microbiology, University of Adelaide, South Australia

IT was established many years ago by Almroth Wright and Douglas that opsonic factors from serum were desirable components in a mammalian phagocytic system. In the absence of such factors the white cells of mammals were often unable to engulf foreign material such as bacteria, but the addition of specific antibody directed against the bacteria ensured efficient phagocytosis. The mechanism whereby the attachment of the protein antibody molecules to bacteria renders them amenable to the functions of the phagocytic cell is not really known, but it has been tacitly accepted that this must in part be due to a change in the surface charge on the bacteria consequent on the adsorption of a layer of antibody molecules. In recent years there has been a growing body of evidence that complement might be necessary for phagocytosis, and this adds complications to the foregoing easy explanation, involving surface charge alone. In order to begin to understand the process we have chosen to measure the minimum quantity of antibody which will permit the phagocytosis of one bacterial cell. The results in this article indicate that the number of molecules of antibody per bacterial cell seem far too small to alter the total charge on the bacterial surface and that other explanations must be sought.

Previous work has established that the normal mouse peritoneum contains several million phagocytic cells including a high percentage of macrophages which are capable in the presence of antibody of engulfing and killing Gram-negative bacteria with great rapidity. The essence of our method has been to inject 10^6 *Salmonella adelaide* into the peritonea of mice, together with varying amounts of antibody. In this way we have determined the minimum quantity of antibody which would permit the destruction of 99 per cent of the ingested bacteria within the space of 90 min. With no antibody all the bacteria remained viable over this period of time.

The *S. adelaide* antiserum was prepared by injecting rabbits with a boiled suspension of the organism grown for 24 h on nutrient agar plates. The inoculations were at 4-day intervals for 1 month.

S. adelaide lipopolysaccharide was prepared from organisms grown in the same manner by the phenol/water method of Westphal, Luderitz and Bister[1]. For haemagglutination tests we used sheep red blood cells coated with alkaline sensitized lipopolysaccharide as described by Crumpton, Davies and Hutchison[2]. Quantitative precipitin tests were carried out on the antisera following the method of Kabat and Mayer[3]. The precipitates were analysed for protein by the Folin–Ciocalteau method using bovine serum albumin as a standard protein.

The amount of antibody required for phagocytosis was determined by a number of steps as follows:

(1) *The opsonic activity of the whole antiserum.* For this purpose ten mice were injected intraperitoneally with 0·1 ml. containing approximately 10^6 *S. adelaide* with or without previous treatment with a dilution of the rabbit antiserum at 20° C for half an hour, At intervals during 90 min after injection one mouse was killed and the peritoneal cavity washed out with 1·5 ml. of Hanks's solution. Dilutions of the washout were made and plated out to enumerate the numbers of the injected bacteria which were still viable[4]. In this way it was shown that suspensions of the bacteria in as little as 0·1 ml. of a 1/500,000 dilution of antiserum gave 99 per cent kill (see Fig. 1).

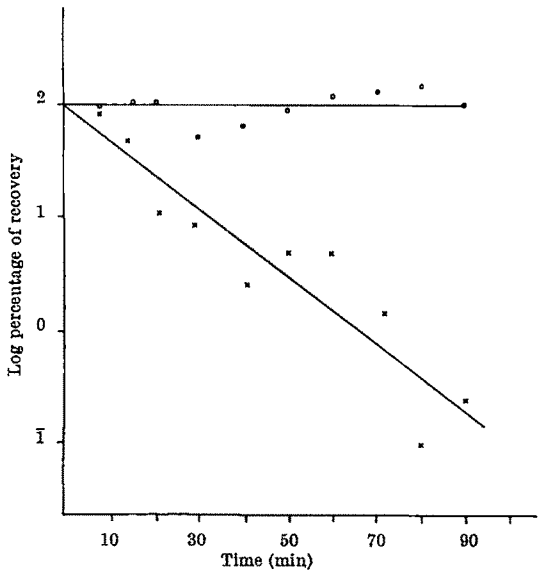

Fig. 1. Recovery of viable organisms after injecting *S. adelaide* intraperitoneally into mice together with dilutions of rabbit *S. adelaide* antiserum. O, Dilutions > 1/2,000,000; ×, dilutions < 1/500,000

(2) *The effect of 0·1 M mercaptoethanol on the opsonic activity.* The *S. adelaide* antiserum (1 ml.) was incubated for 1 h at 37° C with 0·1 M mercaptoethanol, neutralized with iodoacetamide and examined for its opsonic activity as above. The limit of activity was reached at a dilution of 1/50,000, indicating perhaps that a large percentage of the original activity was due to macroglobulin.

(3) *Determination of precipitating antibody against S. adelaide lipopolysaccharide.* When 2 ml. volumes of the antiserum were mixed with varying amounts of the purified lipopolysaccharide prepared from *S. adelaide*, protein analyses showed that 250 μg/ml. of antibody protein was the maximum amount precipitable. After removing the precipitates, the supernatant solutions, even from tubes containing considerable excess antigen, still produced intraperitoneal killing of *S. adelaide* up to a dilution of 1 in 2,000.

(4) *Estimation of γ G and γ M antibody content in the S. adelaide serum.* 2 ml. of the rabbit antiserum were equilibrated with 0·1 M phosphate buffer at *p*H 6·3 and passed through a 26 × 12 cm column of DEAE-cellulose at this molarity. This was exhaustively eluted with 0·1 M buffer before another batch elution was done using 1 M buffer. The two solutions were concentrated to the original serum volume and dialysed against 0·15 M sodium chloride. To each of these solutions was added 1 mg of *S. adelaide* lipopolysaccharide in a total volume of 5 ml. and the content of protein in the precipitate was determined by the Folin–Ciocalteau method. The 1 mg of lipopolysaccharide was known from the previous precipitin determinations to provide excess antigen, but the lipopolysaccharide–antibody systems do not form soluble complexes in antigen excess, so this is a valid method of finding the total antibody.

Total protein precipitated in the 0·1 M fraction = 205 μg/ml. original serum.

Total protein precipitated in the 1·0 M fraction = 66 μg/ml. original serum.

This totals 271 μg/ml. which is reasonably close to the figure of 250 μg/ml. for total antibody precipitated.
